Principles of Critical Care

First Edition: 1999
Second Edition: 2005
Third Edition: **2014**

ISBN 978-93-5152-235-5

Printed at

Dedicated to

Vera and my children, for the love and happiness we share; my parents,
for showing me the way; my house-staff and nursing staff,
for their unstinted support; my patients for teaching me all I know.

Preface to the Third Edition

It is gratifying that this book titled *Principles of Critical Care* continues to be the standard text for critical care in India, and that it is now also read in countries outside India. The Third Edition of this book has been overdue. The task has been onerous, difficult and very demanding, but is at last completed. I felt it would be unwise to attempt at being encyclopedic in both reach and content (as observed in many Western texts) and have therefore elaborated particularly on problems often and commonly observed in intensive care units in our country. It is indeed difficult to strike a balance on what to include, what to elaborate upon and emphasize, what to exclude and yet give a reasonably coherent account of the subject. I do hope this balance has been achieved.

Almost all the chapters have been revised and many of them have been extensively rewritten. These include the section on Cardiopulmonary Resuscitation and Cerebral Preservation in Adults, Clinical Shock Syndromes, Critical Care of the Transplant Patient, Nosocomial Infections, Neurological Problems, Organ System Dysfunction Requiring Critical Care, in particular, Acute Pancreatitis and Critical Care in Acute Hepatic Failure. Besides, a new chapter titled End of Life Care in the Intensive Care Unit has also been included in this book.

The present edition has an excellent format, far better than the earlier two editions. The quality of paper, the quality of illustrations, line drawings, algorithms, tables, boxes and, above all, the quality of numerous images that illustrate the text leave nothing to be desired.

I am very confident that this book will continue to be beneficial to intensivists, anesthesiologists, physicians, surgeons, colleagues practising other specialties, as also to trainees in critical care, to residents, students and nursing staff.

I very sincerely acknowledge my thanks to my distinguished contributors who have once again collaborated in an honorary capacity to this edition, thereby enhancing its prestige. I would like to express my deep gratitude to Dr Khyati Shah, my research assistant, without whose help this work would not have been possible and to Mr Neeraj Chavan for his dedication, unstinted help and support. I thank Dr Aruna Poojari for her suggestions and help with the chapter on Nosocomial Infections and Dr Shilpa Bhojraj for her assistance with the chapter on Control of Pain and Anxiety and the Use of Muscle Relaxants in the Critically Ill Patient. I am grateful to AV Graphic Designs Pvt Ltd (Mumbai) for creating excellent illustrations and tables and also to Jaypee Brothers Medical Publishers (P) Ltd for reproducing them. Their cooperation and punctuality during the course of this work has been outstanding. I thank the publishers and authors who have granted me permission to publish some figures from their books/journals. Although every effort has been made to trace copyright holders of material printed in the book, in some cases the copyright holders are yet to respond. The publishers will be glad to hear from them.

My gratitude above all to my wife, Mrs Vera Udwadia, for correcting page proofs and for her forbearance and care during the many days and nights spent on this work.

Finally, my sincere thanks to Mr Jitendar P Vij (Group Chairman), Mr Ankit Vij (Managing Director) and Mr Tarun Duneja (Director-Publishing) of M/s Jaypee Brothers Medical Publishers (P) Ltd, New Delhi, India and Mumbai Branch for their support in publishing this book.

Farokh Erach Udwadia

Preface to the First Edition

Critical care in India and other developing countries is nascent and needs to strike deeper roots if it is to flourish and prosper. The history of critical care in this country started in the late sixties and early seventies with the establishment of coronary care units in Mumbai and in a few other big cities of India. These units, though centralized, were designed and equipped chiefly to offer intensive care to patients with acute myocardial infarction. They had a poor concept of overall critical care, or of intensive respiratory care. Mechanical ventilator support was primitive, its use being mostly restricted to a token gesture of grace offered to a patient about to depart from this world. In the mid and late sixties, my medical unit at the Breach Candy Hospital, Mumbai, started offering overall critical care, intensive respiratory care and successful ventilator support in critical illnesses due to a wide spectrum of disease. Intensive care in my unit, to start with, lacked good monitoring facilities and was initially offered in a few separate rooms within a general ward of the hospital. These were perhaps the first stirrings of critical care as we know it today in the city of Mumbai, and perhaps in this country. However, the real impetus to organized, centralized, overall critical care arose when, in early 1970, a 34-year-old, 6-month pregnant lady was hospitalized in my unit at the Breach Candy Hospital for increasing breathlessness. She was dubbed as functional by the duty officer, when, in fact, she had acute poliomyelitis presenting with intercostal muscle weakness. She evolved over 24 hours because of bulbar and spinal involvement into an acutely ill, totally paralytic state which needed intensive care of multiple organ systems, together with prolonged ventilator support. We used a pressure-cycled Bird's ventilator, and with the able assistance of an anesthetist colleague, Dr Bhatia, struggled and succeeded against great odds in keeping her alive. Successful ventilator support was continued for many months, and she was delivered by caesarean section of a healthy baby at full term, whilst on ventilator support. About 6 weeks after initiating ventilator support, we fortuitously acquired a Radiometer through the patient's brother who was a pediatric cardiac surgeon in Los Angeles, enabling us thereby for the first time to monitor arterial pH and blood gases by the Astrup technique. This was indeed the first blood gas analysis machine used for intensive patient care in this country. Unwittingly, the illness of this dear lady (who is still well) became an important landmark in the history of critical care both in this city and in this country. Starting in 1971, from a two-bedded, centralized, reasonably well-equipped, multidisciplinary all-purpose intensive care unit, we graduated to a newly constructed eight-bedded well-designed and fully equipped unit which admitted critical problems in all branches of medicine and surgery. This unit over many years continues to have a medical audit as good as any unit in the West. It has also served to train numerous house physicians and registrars who have carried the message of critical care to other hospitals of this city and to many hospitals in other parts of the country. The concept of critical care has now been increasingly accepted and followed in most large hospitals of the big cities of this country.

Some of my colleagues, particularly those engaged in community medicine, preventive and social medicine, are of the opinion that in a poor large country like India, the encouragement of critical care is a misdirected effort. It is indeed true that increasing the number of critical care units in the country will not inflict even a small dent in the overwhelming health problems this country has to cope with. Should then the speciality of critical care be fostered and encouraged? The answer on principle is unquestionably yes. It is the physician's duty to care for the ill, and the more critically ill a patient, the more intensive the care a patient needs for survival. We however need to do this in all poor countries with a logical perspective. It would be unrealistic, futile and morally wrong to dot this huge country with numerous critical care units when even basic primary health care is lacking, and when ordinary hospital facilities in most parts of the country are hopelessly inadequate. Reason demands that well-equipped critical care units should in the foreseeable future be confined to medium and large hospitals which have the infrastructure to support such units. It would also be wiser and profitable to organize general all-purpose intensive

care units rather than copy the West and establish critical care units in different specialities and subspecialities. A multidisciplinary intensive care unit permits concentration of meager resources with regard to staffing, equipment and technical expertise. Above all, it encourages a more holistic approach, so that problems in the critically ill are considered in an overall perspective rather than in terms of disease afflicting isolated organ systems. There is also a crying need to formulate laws and regulations (non-existent at the present time) that govern the establishment and functioning of critical care units in the developing countries. Financial lucre will otherwise continue to allow the mushrooming of so-called intensive care units which are veritable death traps for unwary, unsuspecting patients.

Efficiently functioning critical care units in the foreseeable future will be largely confined to the big cities of this country. Should we not promote a modicum of better care for critical illnesses in the huge population of over 650,000,000 that resides outside these cities? This can for the present only be achieved by providing a better staffed and better equipped high-dependency ward in every district hospital of this subcontinent. These wards would not qualify by Western standards as critical care units, but in our experience, could offer better care, with improved results, at a smaller cost.

This book is largely based on my numerous jottings and notes embodying my experience of problems in the diagnosis and management of critically ill patients over the last 30 years. A book of this magnitude, authored in the main by a single individual helped by just a few distinguished contributors, may seem audacious, but has the intrinsic advantage of presenting the uniform view of one who for many years has had to grapple with a wide spectrum of critical illnesses. It in no way detracts from the fact that for a successful outcome, critical care often needs team effort involving many specialities in medicine, surgery and their allied branches. The emphasis in this book is on fundamentals that form the basis of care and on important problems that find their way to a busy unit. The book also includes in most chapters an insight into the nature of derangement of altered functions in a critical illness. Good management can then be better understood and need not be ritualized or didactic.

Critical care in developing countries encompasses both diseases prevalent in the West, as also special problems chiefly encountered in poor countries such as India. These problems particularly in relation to important fulminant tropical infections have been given due emphasis in this book. We also have to necessarily contend with the lack of sophisticated gadgetry and equipment in many of our units. The successful management of many life-threatening problems under these circumstances and restraints is difficult but still possible, and has been discussed in relevant chapters.

It is essential to stress that the principles of good critical care are the principles of good medicine and surgery. Improvement in critical care can, therefore, only flow from improved standards in general medicine and surgery. A careful history, a good physical examination, and the evaluation of relevant laboratory and imaging data will always form the bedrock for correct diagnosis and management of life-threatening problems. Improved technology and invasive gadgetry can be of help, but they can never be a substitute for sound clinical acumen and experience gathered over years of trials and tribulations. The use of machines and, in particular, of invasive technique, should never be an end in itself, but always a means to the solution of difficult problems. To feed a machine in a critical care unit just because it is there, is to court medical nemesis.

The speciality of critical care by its very nature often incites the caring physician to prompt or hurried action. Admittedly, there are a few emergencies which do demand immediate measures if life is to be salvaged. But in most critical situations, there will be time to stand and wait, to think and deliberate—

"And time for all the works and days of hands
That lift and drop a question on your plate."

The physician must take time to muster the clinical discipline that allows a focused view on an emergent threatening problem, yet not lose an overall perspective of the patient. The initiate in critical care medicine should first and foremost be reminded ever so often of the Hippocratic dictum, *Primum Non Nocere*—first of all, do no harm. He should, therefore, be encouraged to think (without falling asleep) over a problem before jumping into action, else he may well become the prime iatrogenic hazard in the unit.

In the final analysis, critical care is the care that aids and improves patient survival. It is doctors and nurses who care for the patients and not machines. We should take comfort in the fact that there is no substitute for human ingenuity, endeavor and resources. Motivation and dedication toward providing better patient care can indeed compensate significantly in our part of the world for the lack of sophisticated technology and technical expertise.

I very sincerely acknowledge my thanks to all my extremely distinguished contributors who are all well-known specialists in their own fields, and who have so kindly and willingly contributed in an honorary capacity to this book. They have immeasurably enhanced the prestige of this book by their valuable contributors. I would like to acknowledge my immense gratitude most of all to Dr Ruby Jal Kharas, my research assistant, who has made this book her special baby. She has been of immense help in every single aspect of this book, and this book would have had to wait for many more months to see the light of the day, if it had not been for her dedication and perseverance. I also owe an immense debt of gratitude to Mr Oatta, Chairman of Hindustan Lever Ltd, India, who on behalf of his company has been kind enough to give a very generous subsidy toward the publication of this magnum opus. The price of this work has thereby been substantially reduced so that the book is now within the reach of all students and all my medical colleagues. Dr Ramnik Parikh and Dr Rajgopal were instrumental in arranging for this munificent subsidy, and to them I express my sincere gratitude. I would also like to thank the publishers and authors who have granted me permission to reproduce some figures and tables from their books/journals. Although every effort has been made to trace copyright holders of material printed in this book, in some cases, this has not proved possible. In a few cases, the copyright holders are yet to respond. The publishers will be glad to hear from them.

I would also like to thank Dr Shilpa Bhojraj for her assistance with the chapter on Control of Pain and Anxiety and the Use of Muscle Relaxants in the Critically Ill. My special thanks are due to Mrs Lavanya Ray and Ms Rivka Israel for their excellent editorial advice and assistance. I am grateful to Mr Abe Aboody and Mr Balagangadharan of Alliance Phototypesetters for their kind cooperation and excellent work. I am also grateful to Mr V Pradhan and Mr Prabhu for the good art work and X-ray plates. I also offer my thanks to Ms Katy Irani who has helped with the typing of this manuscript and with the Index. My gratitude to my wife, Vera, for having helped to correct the page proofs and for her extra forbearance and care during the many days and nights spent on this work. Finally, my sincere thanks to the Oxford University Press in Mumbai and Delhi for their unstinted help and cooperation in publishing this work.

An Introduction to Critical Care

- Overview
- Principles, Philosophy and Ethics of Critical Care
- Critical Care Scoring

CHAPTER 1

Overview

Critical care is the care of seriously ill patients with life-threatening illnesses or trauma, as also of patients who have the potential to develop life-threatening complications from their disease. Critical care should, correctly speaking, be reserved for patients with severe but potentially reversible problems. Patients with chronic terminal illnesses, with the end close at hand should be given every care at home or in the ward of a hospital, but not in critical care units.

The origin of the present day intensive care unit started with the use of the postoperative recovery room for immediate special postoperative care. This concept was given a further impetus during the poliomyelitis epidemic in the early 1950s when the use of mechanical ventilation salvaged many paralyzed patients. Present day intensive care is however far more meaningful than mere postoperative care and ventilatory support. It incorporates the knowledge and experience of numerous specialties that have blossomed over nearly four decades from 1960 onward. Pulmonary medicine with the concept of respiratory care, cardiology with the concept of the coronary care unit and advances in anesthesiology have all contributed greatly to the evolution of the modern day critical care unit. While specialties in medicine or surgery are sharply focused on a single organ system within the body, a general medical or surgical critical care unit is devoted to the patient as a whole, recognizing the overwhelming fact that there is a tremendous interdependence and interrelationship between various organ systems, so that a serious involvement of one strongly jeopardizes the function of others. The approach to critical care medicine is thus simultaneously holistic, viewing the patient in an overall perspective, and yet focused on one or more problems that constitute an immediate threat to life.

It was obvious from the 1960s onward that critically ill patients are best and ideally cared for in special units which centralize equipment, staff and facilities, so necessary for the care of life-threatening problems. Intensive or critical care has blossomed into a specialty with special training and certification in the West, and also in many developed or quickly developing Southeast Asian countries.

In India the seed of critical care planted in the mid and late sixties has now grown into a strong tree trunk with spreading branches and deepening roots. The Indian Society of Critical Care Medicine holds an examination that accredits trained doctors qualified to practice this specialty. These accredited intensivists will in future train junior colleagues, so that the future of this specialty is assured. However, in large cities of the country there are still many privately owned so-called critical care units, which are poorly equipped and poorly staffed. These are death traps for unwary patients. It would be ideal if all units claiming to be intensive (critical) care units have a certificate of accreditation from a responsible professional body.

Many practitioners of critical care medicine are specialists in cardiology, pulmonary medicine, anesthesiology or in critical care itself. However, the principles of critical care are the principles of general medicine and general surgery, rather than the principles applicable to any particular specialty. An individual with a wide experience of medicine or surgery coupled with suitable training and exposure to acute medical or surgical problems has perhaps the best aptitude and philosophy for organizing and directing a critical care unit.

It is important, particularly in a poor country like ours, that the few good critical care units we have, admit patients who truly need appropriate care. It is sad to see critical care

units cluttered with patients who are unquestionably better looked after in the wards or at home. A critical care unit has its advantages and disadvantages. The chief advantage is that it provides better and more organized care. The main disadvantage is of a hostile environment contributing to anxiety, emotional stress, loneliness, fear and above all a greater risk of developing nosocomial infections.

The following conditions require intensive or critical care—

1. Acute life-threatening illnesses which are potentially reversible.
2. Acute illnesses with potential and likely to occur life-threatening complications.
3. Monitoring of vital parameters of patients with symptoms and/or signs that suggest the possibility of an evolving life-threatening illness.
4. Acute or immediate life-threatening crisis or complications in a chronic illness, even when the latter by itself is almost certain to cause death within a matter of months. An example of this is a patient with cancer at a stage when his life expectancy is 3–6 months. An acute complicating pneumonia in such a patient is a life-threatening emergency, which is treatable, curable and may well necessitate critical care.

A critical care unit as already mentioned should not be used for terminal cases where the end is close at hand. The tendency to use a critical care unit as the last halt or stopping station before an expected departure from this world should be strongly deprecated.

This section first deals with the principles and philosophy of critical care. This is followed by a short discussion on ethical principles governing critical care, on ethical issues in terminal illness, and on euthanasia. The section ends with a description of current critical care scoring systems.

CHAPTER 2

Principles, Philosophy and Ethics of Critical Care

INTRODUCTION

The principles of critical care are in quintessence the same as those underlying good medicine and surgery. They include the following—

Early Diagnosis and Identification of the Problem

The doctor in the critical care unit often deals with life-threatening illnesses with serious dysfunction involving one or more organ systems. The early diagnosis and identification of the problem is imperative for correct management. This is a basic dictum for all fields of medicine and surgery but is indeed a matter of urgency in critical care medicine.

Anticipation of Possible Events and Complications

I consider this the very essence of good critical care. The treating doctor must have a firm grip on what is happening to a patient and must acutely anticipate possible events and complications in the immediate future. This he can only do, if he has the knowledge, wisdom and experience of judging the possible evolution of a life-threatening illness in a given patient. To be one step ahead in one's mind with reference to an acutely evolving disease is an important tactical advantage that often leads to victory for the patient and his doctor.

Holistic Approach to a Critical Illness

The holistic approach has already been mentioned earlier. It cannot be overstressed that the patient must be viewed in an overall perspective with interrelated functions of interrelated organ systems. This is not to decry team effort involving various specialists in the management of a critical illness. Team effort is indeed crucial for success, as there is no single physician or surgeon who can know everything, there is to know about the multiple facets of medicine and surgery. Yet, team effort must be conducted and carefully orchestrated by a single individual, if it is to prove successful. Too many specialists and superspecialists individually looking after a critically ill patient more often than not hasten his departure from this world. Their overenthusiastic and often overfocused attention on the organ system of their choice needs to be tempered and viewed with reference to the patient as a whole. The many problems in such patients should be considered in their overall perspective, priority being assigned to those needing immediate attention. Yet it must always be asked as to how best one can engage an emergent problem without seriously jeopardizing the function of other organ systems. A management decision in a not so critically ill patient is often easy and straightforward; a similar decision in a critically ill individual is beset with complex difficulties. The hazards involved in implementing a therapeutic procedure should always be balanced against the possible benefits. There are no clear-cut guidelines in many decisions that need to be made in the care of critically ill individuals. It is a question of experience, wisdom, and at times an intuitive feel of what is probably right or wrong in a given situation.

Considered Use of Technology

The patient is to be cared for by the doctor and the nurses and not by machines. Machines and sophisticated gadgets are an adjunct to the doctor's skill and care; they cannot replace them. Merely because machines have been provided is no reason to use them. Invasive procedures and invasive gadgetry have an inherent risk even in the best of hands; they pose grave hazards in inexperienced or poorly trained hands. Invasive diagnostic procedures may help to fine-tune

management in individual patients, but their overall influence on reducing morbidity and improving mortality in critically ill patients is debatable. It is remarkable that how with increasing experience, the use of invasive monitoring is significantly reduced. Again this is not to decry the use of sophisticated technology in the intensive care unit (ICU). It is merely to restress that in the final analysis, good care rests with doctors and nurses, and not with machines.

Primum Non Nocere

First of all, do no harm. This is an ancient Hippocratic tenet. Do not subject the patient to procedures and investigations which add to pain and suffering, when one is certain or almost certain that these can lead to no extra benefit. The risk-benefit ratio should always be kept in mind in all management decisions in the ICU.

Recognition of the Limits of Critical Care

Physicians involved with critical care must recognize the limits of such care. Critical illnesses are necessarily associated with a high morbidity and mortality, and quite often this morbidity and mortality cannot be improved despite all the care available in present times. The discerning physician learns to recognize the limits of care, knows when to draw the line, and recognizes the futility, and often the cruelty of aggressive management in patients who are well past the point of no return. Learning the limits of care is not easy; it is fraught with doubts, difficulties and danger. A working guideline is to struggle unto life or death in a young individual with a potentially reversible life-threatening illness, and to remember not to play God in the ICU. Yet in the old and feeble, in patients who are clearly dying, and in those with serious background illnesses, one must learn through wisdom and experience to temper care with reason.

CRITICAL APPRECIATION OF EVIDENCE-BASED MEDICINE

Evidence-based medicine is the rallying cry of all modern medicine, a shining banner held aloft by the profession for all to view, a promised trail for better health care and for appropriate management of critically ill patients. It is unquestionably important to judge the clinical effectiveness or otherwise of treatment options through scientifically accumulated evidence. It is even more important to gather evidence to ensure that a treatment option is not injurious to patients. However, in critical care medicine, it may be impossibly difficult and even unethical (in some situations) to furnish evidence or proof as to the optimal approach to acutely emergent problems occurring in very ill patients with many variables. In spite of all protocols and guidelines based on evidence, the practice of critical care medicine today remains largely empirical. The student of critical care medicine should be aware of a few more aspects of evidence-based medicine. Double blind randomized controlled trials are the gold standard, which provide evidence for patient management with regard to a particular problem in critical care. Yet, it must be remembered that the evidence provided, though valuable, is based on a statistical study of large population groups. The results of a statistical study of large population groups, however scientific, need not necessarily apply to the individual patient in one's care. On the other hand, observational studies are considered the weakest form of evidence in critical care medicine. Yet, some of the greatest discoveries in medicine have been made by our illustrious ancestors through the sheer excellence of observation—discoveries far greater than some of the best double blind randomized controlled studies of the present era. Witness the discovery of small pox vaccination by Jenner, antirabies vaccination by Pasteur, the observations of Lister that led to advances in surgery and the observation of the importance of handwashing by Thomas Ignas Semmelweis.

The intensivist should also remember that evidence can be imperfect, can change and is not sacrosanct. If it were, medicine would be static, whereas history teaches us that it is ever-changing, dynamic. It is also possible that the conclusions drawn from evidence-based medicine in the Western world will not always apply to the rest.

Therefore, evidence-based medicine should be viewed in its proper perspective—*good but not infallible, important but not all-inclusive; applicable in many, but not in all. Medicine has several other aspects —social, cultural, economic, psychological, philosophical, religious, genetic, and other nebulous aspects that characterize a trusting caring doctor-patient relationship. It is important to take all into consideration when caring for acutely ill patients.*

CLINICAL JUDGMENT

A physician must be a judge. Judgment is difficult, for indeed medicine has been defined as the art of coming to a conclusion on insufficient evidence. It is no surprise that errors in judgment frequently abound. Clinical judgment does not come within the purview of art or science. It is a special quality, a faculty—often inborn and occasionally cultivated. It cannot be equated to intellectual ability for it may be lacking in brilliant minds and be present to a marked degree in those who are in other respects for less clever or knowledgeable. Perhaps a knowledge of and an interest in the humanities—literature, poetry, music, history, philosophy, religion—can improve clinical judgment by providing a more holistic perspective of man and medicine and of health and disease.

To cope with the diagnosis and management of a life-threatening emergency requires more than mere factual knowledge, reason, logic, experience and skill. It requires good clinical judgment—the hallmark of a good physician. Clinical judgment is a rich blend of all the above requisites and adds to these a further intangible, indefinable quality; a quality that encompasses faith, charity, hope and compassion; a quality that has a deep understanding of human nature. It is also the quality that gives the doctor in crisis the wisdom to know what to say and do, and what not to say and do; when to

wait and watch, and when to treat vigorously without delay; when to fight death and when to give in to it; when to press for a cure and when to console with words, or to rest content with palliative relief. Sound clinical judgment includes an extra-special perceptive ability that enables a doctor to sense a clue which his less fortunate colleagues will miss; the ability to process this clue and judge its correct diagnostic, therapeutic and prognostic implications. A physician who combines the sharpness of his perceptive faculties with a wisdom born of reading and experience, with a compassion for and an understanding of human suffering and who also possesses the faculty of good clinical judgment in truly blessed by the Gods. He has an attribute which no medicine can duplicate and no science can invent. He enjoys a ringside seat in the theater of life and has the most intimate insight into many who seek his help.[1]

ART OF MEDICINE

Today, science rules medicine. However, the practice of its science without an equal measure of its art dehumanizes medicine, robs it of its essence. This is unfortunately the trend today, which must be reversed. The art of medicine lies in the artful, appropriate application of its science to the overall holistic care of an individual patient. The art of medicine remains all pervasive even when its science fails or has reached its utmost limits. "For when all the marvels of science are of no avail to unfortunately ward off the fatal end, it is no small portion of a physician's art to rid his patient's path of thorns if he cannot make it bloom with roses."[1]

The art of critical care medicine lies in hearing an unspoken subtle nuance in a patient's history and in the ability to spot and appreciate the significance of one or more subtle physical signs that no gadget or machine could possibly recognize. It lies in his ability to sift the evidence before him and give the right answer (of several possible answers) to the appropriate question. It lies in the intuitive feel for a solution either in diagnosis or management. Above all, it consists of looking at a very ill patient holistically rather than compartmentalizing the patient into different organ systems. The art of medicine is the art of healing, not just treating, not even just curing. Yet it is only when art and science join hands that healing is best accomplished. It is only then that a physician can engage the unique individuality of a particular human being so that a critically ill patient becomes much more than a disease that needs to be treated.[1]

I came across the ancient description of a good physician and I feel that it has a timeless relevance—"it was his path to learn the practice of medicine and the practice of healing, and careless of fame, to exercise the quiet art".

ETHICAL PRINCIPLES GOVERNING CRITICAL CARE

The principles of ethics are rooted in religious, philosophical and sociocultural traditions. These vary in different cultures and countries, but the absolute values of good and evil, right and wrong, and the sanctity of human life are remarkably similar in all civilized societies.

There are three basic ethical principles derived from these absolute values, which govern the art and science of all medicine, and in particular of critical care medicine. The first is beneficence and its companion-in-arms, nonmaleficence. Beneficence is an all-important ethical principle and duty of the physician, which has been emphasized in ancient Ayurvedic texts, as also by Hippocrates. Beneficence directs the physician to do good by relieving suffering and restoring good health. Beneficence does not merely involve technical expertise and medical skill; it equally involves human qualities, particularly in the care of critical illnesses. It is these human qualities, which tend to be unfortunately forgotten or pushed into the background by the frontiers of advancing technology in medicine. The chief of these human qualities expressed in a single word is humanity. Humanity can be defined as the sensibility, which enables a physician to feel for the distress and suffering of a patient, prompting him to relieve them. True humanity in a physician is the fount of sympathy and care for a critically ill patient. A critically ill but conscious patient in my opinion has special antennae (very like what the child has for the mother), which enable him to promptly recognize, reach out and clasp to his heart a physician who truly cares. This often makes the difference between life and death in a critical illness. In a similar manner, a critically ill individual often recognizes the pseudosympathy exhibited by some physicians; however, brilliant and technologically well-equipped they may be. Knowledge and experience when linked to humanity make a great physician and indeed a great man.

Nonmaleficence is the companion-in-arms of beneficence. It reminds the physician that above all, he should do no harm. Beneficence and nonmaleficence may at times in a critical care setting be in apparent conflict. Thus, the use of a narcotic to relieve pain is beneficence in a dying patient, yet this may hasten death by depressing respiration, thus violating the tenet of nonmaleficence. This conflict, as explained later, is apparent and not real.

The second basic ethical principle governing decision-making and management in critical care medicine is patient autonomy. This is the patient's right to self-determination—the right after being properly informed, to accept or refuse medical treatment offered to him including life support measures like mechanical ventilation. It is indeed the proper interpretation of the balance between the principles of beneficence and the principles of patient autonomy, which governs decision-making and management in critical care medicine. This balance is indeed difficult and not easy to strike in a critical care setting. This is because seriously ill patients may be unable to make proper decisions about their own care. In fact, they may often make the wrong decisions under the physical and emotional stress of their illness. In these circumstances, the physician must lean toward the principle of beneficence, and take management decisions, which he

genuinely believes, are in the best interests of the patient. It is important to illustrate this point with true-to-life examples. A patient was brought in nearly dead after a sedative poisoning, with a note informing the physician that it was her express wish not to be resuscitated and treated. The directive was ignored; the patient was resuscitated and discharged in good health. She was forever grateful for being restored to life.

A patient with quickly progressive respiratory muscle weakness, in his extreme fright, agitation, anxiety and distress, refused intubation and mechanical ventilator support. The request was ignored, appropriate management decisions taken, and the patient was again ever grateful to the doctor for having ignored his directive.

There are many factors which distort, prejudice or interfere with autonomous decisions of patients in critical care medicine. These include fear, anxiety, depression, panic, lack of information and abhorrence of invasive modalities of treatment, which prompt them to decide (often wrongly) to die with dignity. The working ethical principle is that in acute medicine, when confronted with a potentially reversible life-threatening illness, beneficence prevails over patient autonomy.

The third and final ethical principle is justice—to distinguish in patient care, the right from the wrong. If at times this is difficult or impossible to determine in absolute terms, one should determine what is more right or less wrong. In developing countries where resources are limited, justice dictates that treatment is administered to patients who are more likely to benefit from them. This often produces an ethical quandary. Witness for example a situation where there are three ventilators in an eight-bedded tetanus ward and all eight patients have severe tetanus requiring mechanical ventilation. Physicians should unquestionably be involved in the ethics of resource distribution that provide equitable medical care to the society in which they live and work. Yet, ethical arguments limiting care because of limited resources should not in my opinion be applicable to an individual patient already under intensive care. Wisdom however dictates that in all situations requiring protracted intensive care, the burden-benefit relationship should be carefully considered, and care be tempered with reason, when judged to be an exercise in futility.

EUTHANASIA

No discussion of ethics in relation to modern day medicine, including critical care medicine, can be complete without a short discussion on euthanasia. Euthanasia includes—

Voluntary euthanasia or intentional killing of patients who express a competent, freely made wish to die, because of the pain or suffering they experience.

Medically assisted suicide, at the patient's insistence and wish.

Homicide following a surrogate decision on a crippled or handicapped patient, or in a patient with a poor or hopeless quality of life. In this case, the patient is not involved in the decision.

Advocates of euthanasia remarkably enough invoke the ethical principles of beneficence, stating that the act is morally justified because it is doing good to the patient and is in his or her best interest. In my opinion, this act is wrong, unjustifiable, and violates the sanctity of life, as it is perpetrated with known intent to kill. Yet, it must be clearly understood that withholding or withdrawing treatment, when it is certain that such treatment will be of no benefit and when death is inevitable, does not constitute euthanasia (even though some prefer to call this passive euthanasia) because the intent is not to kill but to prevent prolongation of the act of dying.

I gather from discussions with my colleagues in the West, that a significant number of acutely ill patients who are about to die, as also patients with chronic but terminal disease, express a desire to be killed or to be medically assisted in suicide. It is amazing that in my long association of over 45 years with so many critically ill patients in their terminal state, there has not been a single individual who has persistently wished for euthanasia. There have been a few who have expressed a fleeting wish, but talking to them and gently explaining measures to relieve their symptoms have led to a resigned and comparatively unanguished acceptance of their destiny. Why is there this difference between the East and the West? I think it is basically related to sociocultural and religious differences. A patient's, and for that matter a physician's attitude to suffering, pain, impending death, and death itself, is conditioned by these sociocultural and religious factors. Most people in our part of the world and in the Far East believe that life cannot be divorced from pain and suffering, that we live in the midst of pain and suffering, and that each one in this world is apportioned one's share of pain and suffering. This is the law of Karma—a belief that one reaps in the present life what one has sown in previous lives, and that one will reap in future existences what one sows in the present.

In our experience, suffering in a terminal illness (whether this is a sequel to an acute or chronic problem), almost always can be relieved by appropriate medication and compassion. This brings us to the question of whether it is imperative to tell the patient the exact truth that his terminal illness will inevitably end fatally. Here again, East and West may differ. The relatives have a right to know the whole truth, and it is the moral obligation of the physician to apprise them of this truth. Many terminally ill patients either in critical care units or outside, know and feel that their illness is terminal, but barring rare exceptions, they do not wish to discuss death or dying with the physician. In fact, they will if possible, in no uncertain terms stop the physician from broaching the issue. I would agree that the ethical principle of patient autonomy includes the patient's right to know and understand the nature of his illness, so that an informed consent or dissent regarding management decisions is possible. Yet, a patient also has a

right to choose exactly how much he wants to know. If the physician is to exert beneficence, he must respect that right. Perhaps the patient's disinclination to discuss the end is due to a faint glimmer of hope that life will extend longer than what the physician feels or what medical science expects. I am of the opinion that under these circumstances, a physician has no right to systematically destroy that glimmer of hope, which keeps the patient more happy and peaceful toward the end of his life.

To die with dignity and to legalize euthanasia are slogans often linked together, as if one needs the latter to achieve the former. Legalizing euthanasia in our country, even in the most diluted form, could well open the floodgates to murder. Euthanasia however, under strict clauses and safeguards, has already been legalized in Holland. Perhaps in time to come, it may be similarly legalized in other Western countries as well. I am in no position to comment on the Western world, but for all the safeguards and guarantees against misuse that the Dutch for example have, is it not possible that a patient would want to end his suffering as a matter of a cult, or even as a matter of duty that needs to be performed in time to come? Is it ever possible to quantify suffering? Is not suffering often a state of the mind? And cannot a state of the mind be subject to changing social pressures and social mores? Can most doctors claim to have the knowledge, experience, the Ostlerian wisdom and perspective to be truly able to enlist themselves to the cause of euthanasia in a patient who states, I cannot bear the suffering I am going through? These are pertinent questions which are difficult to answer. Finally, when one legalizes a solution to a problem like euthanasia, would the good that accrues clearly outbalance the evil or harm that could possibly result from this legal sanction. This again is a question that physicians all over the world should seriously consider.

CHAPTER 3

Critical Care Scoring

Optimized distribution of medical and financial resources is of crucial importance in the delivery of health care, particularly in the poor developing countries of the world. To this end, the critical care physician often has to make decisions about which patients are likely to derive the maximum benefit from admission to a critical care unit.

Illness scoring systems have been introduced in the past three decades to formulate some degree of priority for intensive care unit (ICU) admissions in patients with acute illness or trauma. These scoring systems are useful for medical audit purposes and for comparison of therapy and results in groups of patients who roughly have the same degree of physiological derangements produced by critical illnesses. However, scoring systems have strong limitations, and critical care of individual patients should not be influenced by scoring protocols.

The commonly used trauma and critical care scores are briefly discussed below.

GLASGOW COMA SCORE

The Glasgow Coma Score (GCS) judges the extent of coma in patients with head injury. It is useful for pre-hospital trauma triage as also for patient assessment after hospitalization. The scale is based on eye opening, motor response and verbal response (Table 1), and can be tested and scored by the physician within a couple of minutes. The total score is the sum of each response and varies from a minimum of 3 to a maximum of 15. The lower the score the greater the severity of head injury in relation to central nervous system (CNS) function.

Table 1: Glasgow Coma Scale

Eye opening	*Motor response*	*Verbal response*
4 = Spontaneous	6 = Obedient	5 = Oriented
3 = To voice	5 = Purposeful	4 = Confused
2 = To pain	4 = Withdrawal	3 = Inappropriate
1 = None	3 = Flexion	2 = Incomprehensible
	2 = Extension	1 = None
	1 = None	

TRAUMA SCORE AND REVISED TRAUMA SCORE

These are useful for patients with trauma. The trauma score is based on the state of the cardiovascular and respiratory systems and on the GCS (Table 2). Values are given to each parameter and these are added to give the total trauma score, which ranges from 1 to 16. The lower the score the greater the risk for mortality.

The trauma score was found to underestimate the prognostic significance of head injuries. This led to the development of the revised trauma score (RTS), which is now widely used to assess the severity of trauma. The RTS is based on the GCS, the systolic blood pressure (SBP) and the respiratory rate. Coded values are given for the above parameters and summed up (Table 3). Higher values have a better prognosis and lower values a poor prognosis.

CRAMS SCALE

The circulation, respiration, abdomen, motor, speech (CRAMS) scale is another trauma triage scale frequently

Table 2: Trauma score

A. Systolic blood pressure	*B. Respiratory rate*	*C. Respiratory effort*	*D. Capillary refill*
>90 4 70–90 3 50–69 2 <50 1 0 0	10–24 4 25–35 3 >35 2 <10 1 0 0	Normal 1 Shallow or retractions 0	Normal 2 Delay 1 None 0
E. Glasgow Coma Scale			
1. *Eye opening* 4 = Spontaneous 3 = To voice 2 = To pain 1 = None	2. *Motor response* 6 = Obedient 5 = Purposeful 4 = Withdrawal 3 = Flexion 2 = Extension 1 = None	3. *Verbal response* 5 = Oriented 4 = Confused 3 = Inappropriate 2 = Incomprehensible 1 = None	(1 + 2 + 3) 14–15 5 11–13 4 8–10 3 5–7 2 3–4 1
Trauma score (A + B + C + D + E) = _____			

Table 3: Revised trauma score (RTS)*

Glasgow Coma Scale (GCS)	*Systolic blood pressure (SBP) (mm Hg)*	*Respiratory rate (RR) (breaths/min)*	*Coded value*
13–15	>89	10–29	4
9–12	76–89	>29	3
6–8	50–75	6–9	2
4–5	1–49	1–5	1
3	0	0	0

*RTS = 0.9368 GCSc + 0.7326 SBPc + 0.2908 RRc, where the c refers to coded value.

used to decide which patients require urgent admission to a trauma unit (Box 1). Patients with a low CRAMS score need urgent critical care.

INJURY SEVERITY SCORE

This system assigns numerical scores to different body regions that may be injured. A manual of codes provides information on the scoring of each injury. The worst injury in each region is given a numerical value. This is squared and added to numerical values from each of the other anatomical regions. The total score ranges from 1 to 75 and correlates with the mortality risk. The injury severity score (ISS) has some important limitations. It considers only the highest score from each body region, and considers injuries with equal scores to be of equal importance irrespective of the anatomical region injured. The ISS is frequently used as a measure of overall trauma, and forms a rough guide to mortality risk in the injured patient.

Box 1: CRAMS scale*

Circulation—
- Normal capillary refill and blood pressure (BP) >100 mm Hg 2
- Delayed capillary refill or 85 < BP < 100 mm Hg 1
- No capillary refill or BP <85 mm Hg 0

Respiration—
- Normal 2
- Abnormal (labored or shallow) 1
- Absent 0

Abdomen—
- Abdomen and thorax nontender 2
- Abdomen and thorax tender 1
- Abdomen rigid or flail chest 0

Motor—
- Normal 2
- Response to pain (other than decerebrate) 1
- No response (or decerebrate) 0

Speech—
- Normal 2
- Confused 1
- No intelligible words 0

*Score <8 indicates major trauma; score >9 indicates minor trauma.

ACUTE PHYSIOLOGY, AGE, CHRONIC HEALTH EVALUATION

The acute physiology, age, chronic health evaluation II (APACHE II) score is one of the most frequently used critical

1

scales in critical illnesses. It is used in order to stratify prognosis and outcome in groups of patients, and to determine success of different forms of treatment.[1-6] The APACHE II score uses twelve easily measured variables [Acute Physiology Score (APS)] and takes into consideration background disease or premorbid health (Table 4). The worst scores in the first 24 hours following ICU admissions are used. The twelve parameters considered are—

1. Temperature (°C).
2. Mean arterial pressure (MAP) (mm Hg).
3. Heart rate (beats/min).
4. Respiratory rate (breaths/min).
5. Alveolar-arterial oxygen gradient (A-aDO_2) if fractional inspired oxygen (FiO_2) is 0.5 or greater, or PaO_2 if FiO_2 less than 0.5.
6. Arterial pH.
7. Serum sodium (mmol/L).
8. Serum potassium (mmol/L).
9. Serum creatinine (mg/dL).
10. Hematocrit (%).
11. Leukocyte count (cells/mm^3).
12. Glasgow Coma Score.

Depending on the degree of derangement, a weighted score is given to each parameter. Sedated, ventilated patients are given a GCS of 15 when neurological problems seem unlikely.

Scores are also assigned for increasing age, emergency postoperative or nonoperative admission, and for the presence of background diseases resulting in pre-existing organ dysfunction. Double weighting is assigned to derangements of serum creatinine in the setting of acute renal failure, due to marked increase in mortality in critically ill patients with

Table 4: APACHE II points (A + B + C below)

A. Acute Physiology Score (APS)									
Physiological variables	*High abnormal*			*Normal*			*Low abnormal*		
	+4	+3	+2	+1	0	+1	+2	+3	+4
Temperature rectal (°C)	≥41	39–40.9		38.5–38.9	36–38.4	34–35.9	32–33.9	30–31.9	≤29.9
MAP (mm Hg)	≥160	130–159	110–12		70–109		50–69		≤49
Heart rate (beats/min)	≥180	140–179	110–139		70–109		55–69	40–54	≤39
Respiratory rate (breaths/min)	≥50	35–49		25–34	12–24	10–11	6–9		≤5
(A-aDO_2) mm Hg if FiO_2 ≥0.5	≥500	350–499	200–349		<200				
PaO_2 mm Hg if FiO_2 <0.5					>70	61–70		55–60	<55
Arterial pH	≥7.7	7.6–7.69		7.5–7.59	7.33–7.49		7.25–7.32	7.15–7.24	<7.15
Sodium (mmol/L)	≥180	160–179	155–159	150–154	130–149		120–129	111–119	≤110
Potassium (mmol/L)	≥7	6–6.9		5.5–5.9	3.5–5.4	3–3.4	2.5–2.9		<2.5
*Creatinine (mg/dL)	≥3.5	2–3.4	1.5–1.9		0.6–1.4		<0.6		
Hematocrit (%)	≥60		50–59.9	46–49.9	30–45.9		20–29.9		<20
Leukocytes (cell/mm^3)	≥40		20–39.9	15–19.9	3–14.9		1–2.9		<1
Neurological points = (15-Glasgow Coma Score)									
B. *Age Points*	Age ≤44 0 point		45–54 2 points		55–64 3 points		65–74 5 points		≥75 6 points
C. *Chronic Health Points*	2 points for elective postoperative admission 5 points if emergency operation or nonoperative admission, if patient has significant chronic liver, cardiovascular, respiratory or renal disease or is immunocompromised								

*Points are doubled in acute renal failure.

Abbreviations: MAP, mean arterial pressure; A-aDO_2, alveolar-arterial oxygen gradient; FiO_2, fractional inspired oxygen.

acute renal failure. The maximum possible APACHE II score is 71. Increasing scores correlate with increasing mortality at each 5-point increment across a wide range of diseases.

The APACHE II scoring system is a useful scale in critical care medicine. Nevertheless, it is wrong to allow APACHE II scores to influence management in individual patients. A high initial APACHE II score in postoperative coronary artery bypass surgery is not necessarily associated with a high mortality.[6] It is also shown later in this book (see Chapter Multiple Organ Dysfunction Syndrome) that tropical problems may be associated with severe multiple organ dysfunction (and high APACHE II scores), and yet do not have the grim prognosis forecast by the APACHE II score. A critique of these scoring systems is given in the Chapter Multiple Organ Dysfunction Syndrome.

Several variants of the APACHE II scoring systems have been devised. These include Bion's sickness score,[7,8] mortality prediction models[9-11] and the therapeutic intervention scoring system.[12,13]

None of these scoring systems have any significant advantage over the more frequently used APACHE II score, and none of these should significantly influence decision-making in individual patients. There is also little or no difference in the predictive ability of each of these systems over a wide range of scores.[11]

The APACHE II scoring system (and its modifications) was not designed to judge individual patient outcomes. A new scoring system (the APACHE III score) has been introduced to objectively assess patient risk for death and other important outcomes related to patient stratification. This new system aims to provide (1) an APACHE III score; (2) a series of predictive equations that help to predict individual patient mortality at different times during the patient's stay in the ICU.

The APACHE III system is based on seventeen physiological variables or parameters, and includes within its ambit a coma scale, age and pre-existing comorbid conditions.[14] The APACHE III score is calculated by adding the coded variables for each category. A 5-point increase in the APACHE III score (range 0–299) is associated with increased risk of death. Further use and evaluation of this scoring system is necessary before it can be used routinely for triage decisions in critical care.

OTHER IMPORTANT SCORING SYSTEMS IN CRITICAL CARE

In the 1990s three other important scoring systems were devised to predict the outcome in critically ill patients. These were: (1) the sequential organ function assessment (SOFA) score, (2) the multiple organ dysfunction score and (3) the simplified acute physiological score I (SAPS I); this was further modified to SAPS II. Unlike the APACHE II scoring system, which is used only on admission of the patient to the ICU, the SOFA score, multiple organ function score and SAPS II score are determined daily in a critically ill patient till either recovery or death occurs. These scoring systems take into consideration two obvious facts: (1) organ dysfunction is a continuum, varying from very mild at one end of the spectrum to hopelessly severe at the other end; (2) organ dysfunction is a dynamic process and the degree of dysfunction or failure could vary with time.

Sequential Organ Function Assessment Score

The SOFA score is made up of scores from six organ systems graded from 0 to 4, depending upon the degree of dysfunction.[15] A SOFA score greater than 15 is associated with a mortality greater than 80%.[16] We use this scoring system in our unit and find it valuable. However, as explained in the Chapter Multiple Organ Dysfunction Syndrome, we have noted that in fulminant tropical infections (e.g. falciparum malaria), high SOFA scores do not necessarily predict death. The recovery rate in these infections is significantly higher than that predicted by the SOFA score (see Chapter Multiple Organ Dysfunction Syndrome). Table 5 gives the details of organ function assessment through the SOFA system.

Multiple Organ Dysfunction Score

The multiple organ dysfunction score was devised because of the direct relationship between the number of organs that fail to mortality in ICU patients.[17] The score for each patient is assessed daily, allowing a better prediction of morbidity and mortality (Table 6).

Simplified Acute Physiology Score

The SAPS I score was developed from a small database of about 700 patients in France, as a simplification of the APACHE scoring system.[18] The SAPS I score had a range from 0 to 56 and was based on physiological parameters, age and invasive or noninvasive ventilation. Predictive results using the SAPS I were found to be comparable to those using the APACHE I score. The main drawback of the SAPS I as an outcome prediction tool was that it did not take into consideration the specific diagnosis and background diseases or chronic health status of the individual.

About a decade later, the updated SAPS II score was developed from a large database of more than 13,000 patients from ICUs across Europe and North America.[19] The SAPS II score is calculated using seventeen variables—twelve physiological parameters, age, type of admission (emergency/elective), presence of acquired immunodeficiency syndrome (AIDS), metastatic cancer or hematologic malignancy. The main outcome measure predicted by the SAPS II is vital status at hospital discharge. It has been found to perform better than SAPS I and its performance is comparable to that of the APACHE II. Modifications of the SAPS II have been used to make it more applicable at local ICU levels and also for clinical trials in specific diseases and conditions such as sepsis.

The SAPS III is developed by the European Society of Intensive Care Medicine. The database for this score is expected to be very large, collected from ICUs all over the world. The SAPS III will consist of four modules: (1) a basic

Table 5: Sequential organ failure assessment (SOFA) score

	0	*1*	*2*	*3*	*4*
Respiration— • PaO_2/FiO_2	>400	≤400	≤300	≤200 with ventilatory support	≤100 with ventilatory support
Coagulation— • Platelets ($\times 10^3/mm^3$)	>150	≤150	≤100	≤50	≤20
Liver— • Bilirubin (mg/dL)	<1.2	1.2–1.9	2.0–5.9	6.0–11.9	>12.0
Cardiovascular— • Hypotension	No hypotension	MAP <70 mm Hg	Dopamine ≤5 or dobutamine (any dose)*	Dopamine >5 or epi ≤0.1 or norepi ≤0.1*	Dopamine >15 or epi >0.1 or norepi >0.1*
Central nervous system— • Glasgow Coma Score	15	13–14	10–12	6–9	<6
Renal— • Creatinine (mg/dL) • Urine output	<1.2	1.2–1.9	2.0–3.4	3.5–4.9 or <500 mL/day	>5 or <200 mL/day

*Adrenergic agents administered for at least 1 hour (doses given are in µg/kg/min).
Abbreviations: FiO_2, fractional inspired oxygen; MAP, mean arterial pressure; epi, epinephrine; norepi, norepinephrine.

Table 6: Multiple organ dysfunction score

	Points				
	0	1	2	3	4
PaO_2/FiO_2	>300	226–300	151–225	76–150	≤75
Serum creatinine (µmol/L)	≤100	101–200	201–350	351–500	≥500
Serum bilirubin (µmol/L)	≤20	21–60	61–120	121–240	>240
Pulse-adjusted heart rate*	≤10	10.1–15	15.1–20	20.1–30	>30
Platelet count (× 103/dL)	>120	81–120	51–80	21–50	≤20
Glasgow Coma Score†	15	13–14	10–12	7–9	≤6

*PAR = HR × (RAP/MAP); HR, heart rate; RAP, right atrial pressure; MAP, mean arterial pressure.
†The best estimate in the absence of sedation.
Scoring method: The most abnormal value for each parameter over a 24-hour period is selected for scoring purposes. The addition of scores of all six parameters gives the final score. It has been observed that scores between 13 and 16 carry a 50% mortality, scores between 17 and 20 carry a 75% mortality and scores >20 carry a 100% mortality.

evaluation module, (2) an extended outcomes module, (3) an infection module and (4) a resources module. Along with predictive models for patient outcomes, the score is also expected to provide a reliable tool for evaluation of individual ICUs with a special emphasis infection rates and cost-benefit ratios of investigations and therapies.

CRITICAL CARE SCORING IN THE FUTURE

The evolution and practice of better future scoring systems need to take into account: (1) factors which predict patient outcome, (2) effectiveness of therapy or management and (3) efficiency of delivered care.

Critical care is however a complex process. Patients receiving critical care constitute many variables related to different disease processes. The problem is further compounded by the fact that delivery of critical care in different parts of the world is influenced by cultural, social and economic factors. For these reasons, it is difficult to quantify critical care with measurable values and compare these values with different institutions in different countries of the world.

Present scoring systems are a valuable guide to patient outcome and indirectly on how management can affect outcome. Yet, it is our opinion that scores should not influence management decisions in individual patients. Clinical judgment should never be replaced by any scoring system or scale.

Cardiopulmonary Resuscitation and Cerebral Preservation in Adults

- Cardiopulmonary Resuscitation and Cerebral Preservation in Adults

CHAPTER 4

Cardiopulmonary Resuscitation and Cerebral Preservation in Adults

GENERAL CONSIDERATIONS

A sudden unexpected cessation of effective cardiac pump function or beating of the heart is termed as cardiac arrest. This may be reversible if promptly managed, but otherwise invariably leads to death. Cardiac arrest quickly results in a respiratory arrest and resuscitation therefore involves establishing an effective stable circulation as well as maintaining effective ventilation. Similarly, respiratory arrest if unattended leads within a few moments to cardiac arrest, illustrating the inseparable link between the heart and the lungs. The approach to cardiopulmonary resuscitation (CPR) is therefore always an integrated one directed both to the heart and the lungs. One should in the same breath also consider cerebral preservation, because cessation of effective cardiac pump function results in severe hypoxia due to stoppage or markedly inadequate blood supply to all important organs of the body, most importantly to the brain and the heart muscle itself. Hypoxic brain damage and death therefore always result if resuscitation is delayed, is not implemented or is unsuccessful. In fact, for several reasons brain damage can result even after successful resuscitation. The preservation of brain function (cerebral preservation) during and after CPR is therefore crucial to allow a meaningful quality of life.

It is not the purpose of this chapter to enumerate the numerous causes of sudden cardiac arrest or cardiac death. Ischemic heart disease (IHD) remains the commonest cause in Western countries as also in India. In the sixties, 12% of all natural deaths in the United States of America were sudden, and 88% of all sudden natural deaths were due to cardiac causes.[1] A prospective study in the same country demonstrated that 50% of all coronary heart disease deaths are sudden and unexpected and occur within 1 hour of the onset of symptoms.[2] Cardiac arrest is a dreaded complication during surgery and anesthesia; it can also complicate investigational procedures—pleural, peritoneal or pericardial paracentesis, intravenous (IV) pyelography, cardiac catheterization and coronary or cerebral angiography. It can occur as a consequence of electrolyte and metabolic abnormalities, or may be caused by drugs—particularly antiarrhythmic drugs like quinidine, procainamide and digitalis. It is an important cause of death following trauma, blood loss, asphyxia (due to drowning, carbon monoxide poisoning, and inhalation of food or vomit), sudden large airways obstruction by a foreign body, and electrocution either by electric shock or lightning.

Closed chest compression in the management of cardiac arrest was introduced in 1960. Between 1960 and 2000 there was no change in the long-term survival after cardiac arrest. Evidence accumulated over the last decade has stressed on special aspects of emergency management responsible for successful resuscitation. Also, the importance of specific and meticulous intensive care after successful resuscitation is being increasingly recognized as being crucial to the prevention of brain damage and preservation of cerebral function.

An integrated approach to appropriate emergency resuscitation and postresuscitation intensive care has resulted in improved final outcomes and increased meaningful survivals.

This chapter briefly mentions the epidemiology and the basic mechanisms underlying cardiac arrest. It next describes the various aspects of emergency management of CPR as currently advised. It then deals with post-arrest care directed specifically towards preventing or minimizing brain injury. It ends with a brief discussion of neurological sequelae that can unfortunately occur even after successful resuscitation

and the prognosis of neurological recovery (after restoration of the circulation) based on clinical examination.

EPIDEMIOLOGY

It would be appropriate to state that for several reasons, very little is known about the epidemiology of cardiac arrest in our country. An out-of-hospital arrest in large cities of India is invariably fatal. For one there are very few lay people trained in basic life support and for another it may take hours (because of horrendous traffic) for an out-of-hospital arrest to reach a hospital.

In Western countries, the incidence of out-of-hospital arrests is estimated at 52.1 per 100,000 people per year with a reported median survival rate of 8.4%.[3] The incidence of in-patient hospital arrests is estimated at about 0.17 events per hospital bed per year,[4] survival to hospital discharge being just 17%. It is of note that 17% of episodes of respiratory arrest or compromise may progress to cardiac arrest.[5]

Only 44% of patients who suffer an arrest in the hospital have return of circulation and 60% of those resuscitated from cardiac arrest in hospital die prior to discharge from hospital.[4] Post-ischemic brain injury and multiorgan failure are the causes of these deaths. Failure to awaken contributes to withdrawal of care in Western countries in as many as 24–68% of patients after initial successful resuscitation.

BASIC MECHANISMS

The mechanisms underlying cessation of effective cardiac pump function, which if uncorrected lead to rapid loss of consciousness and death are—

- Ventricular fibrillation (VF).
- Ventricular tachycardia (VT) resulting in pulselessness and an unconscious state.
- Cardiac standstill or asystole; a markedly severe brady-arrhythmia has well-nigh the same effect as an asystole or standstill.
- Pulseless electrical activity (PEA) In this condition, though the electrocardiogram (ECG) or cardiac monitor show a normal or satisfactory electrical activity, the mechanical pumping action of the heart is either feeble or absent.

OBJECTIVES AND PRINCIPLES OF MANAGEMENT

- The chief objective is to restore and maintain stable, effective cardiopulmonary function resulting in effective transport of oxygen to the tissues of the body.
- To prevent or minimize brain damage not only during CPR but also after successful restoration of the circulation.
- Since irreversible brain injury or death can occur within 4–6 minutes of the onset of arrest, immediate treatment is mandatory. *Time is of essence and every single second counts.*
- A preplanned, well-organized management protocol is essential. Initially, it aims at Basic Life Support. In a hospital, particularly in an intensive care unit (ICU) setting, this graduates seamlessly almost pari passu to Advanced Cardiac Life Support.
- There is a window of approximately 4 minutes from the cessation of effective cardiac function (with absence of major pulses) and of respiration, after which hypoxic injury to the brain progresses rapidly, leading to irreversible death. Resuscitation attempts after 10–15 minutes of arrest have rarely been found to be successful, and most doctors hesitate to resuscitate when more than 10 minutes have elapsed after an unattended cardiac arrest. Permanent brain damage and a vegetative state are the sequelae even if the CPR is successful.
- Cardiopulmonary resuscitation in terminal malignancy or in terminal hepatic, renal, or pulmonary diseases offers a cruel extension of life for a short span, and should be avoided. The ethical issues involved are fairly clear, but should be decided in consultation with the patient's relatives, and one's own colleagues.

Management of the Individual Patient

The following steps are detailed for the management of the individual patient (Flowchart 1). In an in-hospital setting, and more so in an ICU setting, one step dovetails into the next, and more often than not, many steps are in simultaneous operation. It is important that in an ICU setting each doctor, nurse or paramedical person knows exactly what is expected of him or her, and that there is one individual to supervise and direct operations.

Recognition of Cardiac Arrest

A health-care provider (doctor, nurse, paramedical person) should assume that a person is in cardiac arrest if he or she is unresponsive and has abnormal breathing. Since prompt and continuous chest compression is of utmost importance, searching for the pulse should never be a lengthy process. Health-care providers, and this includes trained intensivists should spend a maximum of 10 seconds searching for the carotid or femoral pulse. If a definite pulse is not detected, chest compression should start immediately.[6,7]

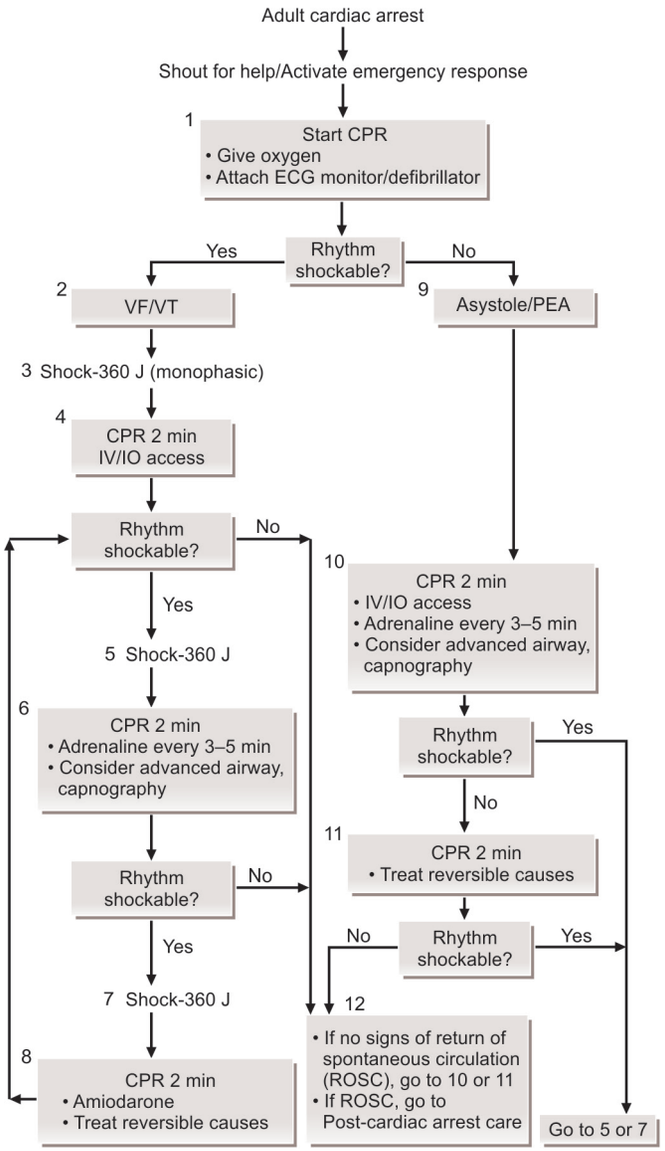
Lay people are instructed not to attempt to feel the pulse. They should assume cardiac arrest if the patient is unresponsive and has abnormal breathing and start chest compressions promptly.

Once a cardiac arrest is diagnosed in hospital and in the wards, the rescuer should promptly shout for help. There should also be a provision for an alarm that summons prompt help. This of course is unnecessary when an arrest occurs in the ICU where prompt help from two or more doctors together with nurses and paramedical personnel is always available.

Restoring Circulation

Restoring circulation is of crucial importance in CPR. This is specifically achieved by prompt uninterrupted well performed chest compressions. Chest compressions augment both the coronary and the cerebral circulation. Interruption in chest

Flowchart 1: Steps in adult cardiopulmonary resuscitation



Source: Adapted with permission from Adult Basic Life Support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Circulation 122.

compressions or incorrectly performed chest compressions strongly jeopardizes recovery, leading to a less favorable neurological outcome. In patients who suffer an arrest due primarily to a cardiac cause, chest compressions take precedence over ventilation. In patients who have experienced a primary pulmonary arrest rescue breathing should be started as soon as possible after commencement of cardiac compressions.

In 2010, the American Heart Association (AHA) drastically revised its guidelines for emergency CPR and emergency cardiovascular care.[8] This revision was based on research contributing to improved morbidity and mortality associated with cardiac arrest. Prior to 2010, the basic life support advocated was airway, breathing, circulation (ABC) in that order. The current 2010 guideline is circulation, airway, breathing (CAB) in this new order. The stress first and foremost is now rightly placed on the prompt restoration of circulation by immediately starting chest compressions. Delay in starting of chest compressions is thereby minimized. Care-givers who hesitate or are fearful of performing rescue breathing can start resuscitation more promptly and continue uninterruptedly if they are required to perform chest compressions as their first and immediate task. Another equally important aid in the restoration of circulation is the use of cardioversion and defibrillation in appropriate conditions. The current guidelines also advise on the use of drugs such as epinephrine, vasopressors, dopamine, atropine, antiarrhythmic, and other drugs. They do not however lay great emphasis on these medications, perhaps because they have not been shown to influence outcomes. On the other hand, prompt recognition of VF and prompt defibrillation is life-saving so that defibrillation in a number of patients is second in importance only to chest compressions. Unfortunately, in the large metropolitan cities of India, an out-of-hospital arrest can only be managed by cardiac compressions either by a layperson or by a doctor who happens to be present. The paucity of cardiac ambulances, the time taken by the ambulance to reach the victim, make timely availability of a defibrillator extremely unlikely. Invariably by the time an out-of-hospital arrest reaches hospital, meaningful recovery is extremely unlikely.

An in-hospital arrest, in the wards or in a department or during transfer of a patient from the ward to a department poses special problems. Chances of recovery are increased if there is an organizational system and a protocol that allows rescuers within the hospital to reach the victim as quickly as possible. This aspect is discussed later in the chapter. *However, in an ICU, features of basic life support and advanced life support are seamlessly dovetailed. This is because emergency equipment is waiting and ready* for use, and there are two or more rescuers attending to the crisis. One continues with chest compressions, the other handles the airway and ventilation, a third is ready if needs be to use the defibrillator and a nurse helps to gain access to one or more large peripheral veins in preparation for infusion of drugs.

This chapter will now discuss details of resuscitation of the circulation through closed chest compression and the appropriate use of defibrillation. It next discusses the care given to the airway and breathing and then deals with drugs that may help to restore circulation. Finally, there is a discussion on the post-arrest care (i.e. care after successful CPR). Specialized intensive post-arrest care is necessary chiefly to prevent or minimize brain damage and also to prevent damage to other organ systems.

Basic Life Support consists of—

- Continuous correctly delivered closed chest compressions at 80–100/minute.
- Defibrillation of the heart in patients with pulseless VT or VF.

- Ensuring patency of the airway (head-tilt, chin-lift maneuver).
- Ventilation (mouth-to-mouth or bag-mask ventilation) the ratio of chest compression to ventilator breaths being 30:2.

Advanced Life Support consists of—

- A combination of closed chest compressions and defibrillatory shocks for pulseless VT or VF.
- Securing IV access.
- Advanced Airway Management and Ventilatory Support.
- Pharmacological therapy—epinephrine, inotropes, vasopressors, antiarrhythmic drugs, atropine, and other drugs.

Closed Chest Compressions

Adequate perfusion of the heart (through the coronary circulation) and of the brain (through the cerebral circulation) is vital for meaningful survival. Chest compressions achieve this by building and maintaining coronary and cerebral perfusion pressures.[7,9] The coronary perfusion pressure is quantified by the pressure gradient between the aorta and the ventricular cavities (usually approximated by the central venous pressure or the pressure in the right atrium). Measurements of coronary perfusion pressure are not possible unless the patient has invasive monitoring devices (such as a central venous catheter) before the cardiovascular collapse. With mechanical compression of the chest, cerebral blood flow occurs during this phase of actual chest compression. However, the perfusion of the myocardium through the coronaries occurs during the relaxation phase. Coronary perfusion pressure (which is maximum at the end of the relaxation phase) is strongly correlated with myocardial perfusion and hence with the likelihood of successful resuscitation.[10] It has been estimated that in humans the coronary perfusion pressure should exceed 15–20 mm Hg for successful resuscitation. It is likely that a lesser degree of coronary perfusion pressure is unable to supply adequate nutrients and energy to the myocardium to allow recovery following cardiac arrest.

Position of the Patient and the Rescuer

Proper positioning of the care-giver and the patient is fundamental. In an out-of-hospital scenario, the care-giver kneels perpendicularly to the patient's torso. For the in-hospital cardiac arrest, the doctor or the rescuer should stand at the bedside at the level of the torso of the patient. A soft mattress defeats the very purpose of mechanical cardiac compressions as the mattress absorbs a great deal of the force exerted during compression. If the patient is on an air mattress, it should be promptly deflated.

Compression Technique

Place the heel of one hand on the lower half of the sternum and then place the heel of the other hand over the top of the first. In adults, depress the sternum with a downward force (the down stroke), for at least 2 inches and allow of proper recoil (the upstroke) before starting the next compression. The time for compression and recoil should roughly be equal, the chest being seen to re-expand fully before the next compression. The hands should be slightly removed (lifted) from the chest wall during the upstroke to ensure full and adequate recoil. Interruption of the recoil or inadequate recoil leads to increased intrathoracic pressures and a poor hemodynamic profile characterized by decreased coronary perfusion pressure, poor myocardial blood flow, decreased cardiac index and reduced cerebral blood flow.[11,12]

The recommended rate of delivery of chest compressions is at least 100/minute. The number of delivered compressions per minute is a predictor of return of spontaneous circulation (ROSC) and neurologically intact survival.[13,14] The best outcomes have been observed with at least 80 chest compressions per minute in in-hospital arrests and 68–89 compression per minute in out-of-hospital arrests.[13] It was believed earlier that external chest compression maintained circulation as a result of a squeeze or pressure on the heart between the sternum and the thoracic spine. This squeeze pushed blood out into the systemic and pulmonary circulations, followed by a filling of the heart when the pressure was released. The current concept is that external pressure on the chest leads to an increased intrathoracic and intrapleural pressure, and this positive pressure is responsible for propelling the blood forward. Release of external pressure leads to a fall in the intrathoracic and intrapleural pressures, allowing blood to fill the heart. This thoracic pump theory claims that the entire thorax acts as a pump to propel blood forward, possibly by reducing the afterload of the left ventricle. Afterload can be defined as the peak systolic transmural pressure, and increased intrathoracic pressure would reduce this transmural pressure, thus reducing the afterload, and promoting emptying of the ventricles.

The general guideline for compression to ventilation ratio is 30 chest compressions to two ventilations if there is a single rescuer. If there are two, then one rescuer can administer uninterrupted chest compressions while the other delivers ventilation (see later discussion) keeping the chest compression to ventilation ratio at 30:2. It is crucial not to waste time by inserting an artificial airway at the start of resuscitation as this significantly interrupts chest compression. An advanced airway should be inserted at least 3 minutes after uninterrupted chest compression and after attempted defibrillation, if this is found to be necessary.

Problems Preventing Effective Chest Compression

Chest compressions should start promptly and be delivered continuously with the right technique so as to maintain effective coronary and cerebral perfusion pressure. Even a short pause results in a sharp fall in the coronary and cerebral circulation pressures.[15] It has been noted that interruption in chest compressions are common, consuming 24–57% of the total resuscitation time.[16,17] It has also been noted that chest compressions must be continuous if they are to reach a threshold for successful defibrillation and

resuscitation[18] and counter the brain's extreme vulnerability to ischemic injury.

The following factors encroach upon and can significantly interrupt compression time—

- *Advanced Cardiac Life Support interventions (ACLS)* These can result in numerous pauses in chest compression. The insertion of artificial airways is observed to be responsible for 25% of all interruptions with a median duration of 2 minutes. Endotracheal intubation should not be attempted at the very start of resuscitation. It should preferably await restoration of the circulation or if deemed imperative should be attempted only after 3–5 minutes of continuous chest compression.
- *Frequent Pulse Checks form another Source of Interruption* Pulse check should not exceed 10 seconds; frequent pulse checks are not necessary and should be avoided unless there is other evidence of return of spontaneous circulation (ROSC), such as an increase in the patient's oxygen saturation as measured by an oximeter or an increase in the end tidal CO_2 ($EtCO_2$) measurement. Studies have shown that the patients with ROSC had a mean increase of 10 mm in the $EtCO_2$ as compared with patients with cardiac arrest who failed to survive. $EtCO_2$ measurement can therefore monitor ROSC, obviating the need to interrupt chest compressions.
- *Defibrillation* It is another often necessary procedure which interrupts chest compression. This interruption even while preparing for defibrillation leads to a sharp drop in the coronary perfusion pressure. Till recently the traditional method for defibrillation was to stop compression, analyze the ECG rhythm, charge the defibrillator and deliver the shock to the patient. This amounts to be an interruption of about 15 seconds. The correct method is to charge the defibrillator in anticipation of shocking the patient, chest compressions being continued throughout and being interrupted only during rhythm analysis and delivery of the shock. The average interruption time for chest compressions is thereby close to just 4 seconds. If rhythm analysis show that defibrillation is not warranted chest compressions are promptly restarted, thereby further saving on interruption time. Recent studies have shown that it is completely safe for a care-giver wearing standard examination gloves to continue chest compressions during the use of a biphasic defibrillator with self adhesive pads.[19] There is no danger of an electric shock to the rescuer with biphasic defibrillators in contrast to the legitimate fear with the use of monophasic defibrillators.
- Rescuer fatigue can result in imperfect technique of chest compression. The depth and even the frequency of chest compression may be compromised. A shallow depth fails to generate an adequate coronary and cerebral perfusion pressure. It is also associated with an impaired recoil which results in a reduced coronary artery blood flow and an increased intrathoracic pressure.

More often than not a rescuer fails to recognize or admit fatigue. Ideally, care-givers (i.e. rescuers) giving chest compressions should rotate every 2 minutes. This switch should be seamless the second rescuer being ready and in position on the other side of the patient when the first rescuer is relieved.

Hands-only Cardiopulmonary Resuscitation

If there is a single rescuer there is necessarily an interruption in chest compressions since he or she needs to deliver two rescue breaths after every 30 chest compressions. The performance of a hands-only CPR allows a single rescuer to focus solely on continuous uninterrupted chest compressions. It is believed that ventilation is not necessary in the first few minutes of resuscitation because blood oxygen levels remain adequate for some minutes after a cardiac arrest from a non-respiratory cause.[8] The safe and acceptable duration of oxygen levels in such circumstances is not known. However, chest wall recoil may provide some degree of ventilation and oxygenation during hands-only CPR.

It should however be noted that the hands-only CPR concept contradicts the early work demonstrating that airways collapse in most comatose patients, so that compressions alone cannot provide adequate ventilation.[20] Recent studies suggest that chest compressions generate tidal volumes less than the physiological dead space.[21]

Alternative Cardiopulmonary Resuscitation Techniques

Alternative techniques of CPR have been tried and described with uncertain success.

- High frequency chest compressions are delivered at a rate of greater than 120/minute. Two clinical trials showed improved hemodynamic profile but no improvement in outcome.[22]
- *Open cardiac chest CPR* Direct cardiac massage is resorted to in patients suffering cardiac arrest during thoracic or cardiac surgery as also in patients undergoing other surgery where closed chest compressions have been ineffective. Open chest CPR with direct cardiac massage is also used after cardiac arrest from a traumatic chest injury.

Open cardiac massage (which was the only method to treat cardiac arrest before 1960) has now been supplanted by closed chest compressions. At present, its main use is when the chest is already opened at surgery or when cardiac arrest occurs soon after thoracotomy or occasionally after a laparotomy (if prompt resuscitation through closed cardiac compression is unsuccessful). It should be noted that direct cardiac compression via a thoracotomy procedure produces roughly a threefold increase in coronary perfusion pressure compared to external chest compressions. Also VF and mechanical activity of the heart are directly visible so that direct defibrillation of the heart or direct ventricular pacing can be promptly used if necessary. Finally, cardiac tamponade causing arrest can be promptly relieved by pericardiotomy.

- Interposed intra-abdominal compression (IAC) is another procedure reported to help increase coronary and cerebral perfusion. It requires three rescuers (health care workers). The first provides chest compression; the second compresses the abdomen (with the same hand position and to the same depth) between the xiphoid process and the umbilicus during chest wall recoil. The third provides ventilation preferably with an advanced airway device. IAC results in improved coronary perfusion. An in-hospital trial demonstrated improved survival compared to CPR.[23] A further study is needed to validate this result.
- *A precordial thump* A precordial thump is a forceful blow to the anterior chest wall. It can occasionally stun the myocardium and convert VF or a pulseless VT into a more stable rhythm. The precordial thump is not advocated for unwitnessed cardiac arrest. It may occasionally be useful in witnessed, monitored cardiac arrest showing VF and pulseless VT if a defibrillator is not immediately available. It should not delay prompt chest compressions.

DEFIBRILLATION

The prompt delivery of transthoracic electric shocks is critical to survival in patients with cardiac arrest due to VF or pulseless VT. The earlier these rescue shocks are given the more likely are they to be effective. In fact, rescue shocks are highly effective when VF is of brief duration (1–2 minutes). The chance of successful defibrillation diminishes rapidly over time.[24] The probability of successful defibrillation declines by about 2–10% per minute starting with an estimated probability of 70–80% at time zero.[25] Thus, if a patient with VF is not shocked (defibrillated) within 10 minutes of the onset of collapse or arrest the probability of survival approaches zero.

Interestingly, resuscitation is more difficult and less likely if rescue shocks covert VF into asystole instead of converting VF into a stable organized rhythm. It is also to be noted that pulseless VT or VF may be resistant to cardioversion in the presence of severe hypoxia, acidosis or electrolyte imbalance.

Transthoracic electric shocks act by depolarizing the heart, thereby abolishing the VF wave fronts, and allowing the restitution of a stable cardiac rhythm. In all probability, a critical mass of the myocardium must be depolarized to produce this depolarizing effect. VF may however recur perhaps related to persistent foci within the myocardium which are not depolarized or perhaps because of heterogeneous areas of refractoriness within the heart muscle.[26]

CPR before Defibrillation

The rate of survival is noted to be higher among patients who have experienced an unwitnessed sudden cardiac arrest, if these patients have received CPR for 1.5–3 minutes followed by defibrillation.[27] In a witnessed sudden cardiac arrest, immediate defibrillation is crucial, the patient receiving chest compressions while the defibrillator is being prepared. Chest compressions prior to defibrillation perhaps improve the myocardial readiness for a successful cardioversion by promoting coronary artery perfusion and the supply of oxygen and other metabolic substrates to the myocardium.[16]

Method of Defibrillation

As soon as a defibrillator is available it is attached to the patient and if pulseless VT or VF is present, defibrillation is carried out with a shock of 200 joules. The shock is delivered through paddles (coated with a jelly), one paddle being held firmly in contact with the sternum and the other placed over the left side of the chest in the midaxillary line. The following points are of importance as they add to the likelihood of successful CPR—

- Most available defibrillators now deliver biphasic wave forms as these produce more effective depolarization and achieve defibrillation with less energy than monophasic wave forms.
- The paddles must exert a firm pressure (0.5–0.8 kg) over the sites of application on the chest wall; this decreases chest wall impedance, increasing delivery of the current to the myocardium.
- It is crucial that the transition from the chest compressions (which the patient is receiving) to the delivery of the shock is seamless. Therefore, chest compressions should be continued while the defibrillator is charged and compressions stopped only when the shock is just about to be delivered. Reducing the delay between the last compression and the delivery of a single shock has been associated with more successful resuscitation.[28] Following the delivery of the shock, chest compressions should promptly recommence, the transition from shock back to chest compressions again being seamless.

Prior to 2010, it was recommended that defibrillator shocks were delivered in stacks (2–3 at a time). The current recommendation is to deliver a single shock followed by immediate resumption of chest compressions. This recommendation leads to a minimum interruption of chest compressions, so crucial to successful resuscitation.

Rescue shocks may need to be repeated with multiphasic wave forms but they should be delivered singly in patients with recurrent VF or pulseless VT, with as short an interruption of chest compressions as possible.

- *Hands-on defibrillation* Uninterrupted chest compressions are crucial for recovery of spontaneous circulation. In most units (including ours), chest compressions are necessarily interrupted, though briefly (hands off) during the delivery of the rescue shock. This was due to the fear of electrocuting the rescuer. Recent studies have however shown that it is perfectly safe to continue compressions during the delivery of a defibrillatory shock when a biphasic defibrillator is used with self-adhesive electrodes, and the rescuer wears standard examination gloves.[19] The AHA has not adopted this practice in the 2010 guidelines, but it is likely that in the future, interruption of chest compressions may be recommended only and solely for the purpose of rhythm analysis.

- Current research has shown that quantitative analysis of VF wave forms can distinguish early VF from late VF.[29] Large amplitude wave forms suggest early VF and is associated with greater success in defibrillation. Recording conditions and body build may however affect the amplitude of wave forms. Future generations of defibrillators almost certainly will incorporate devices that provide a real-time semiquantitative analysis as to the probability of a successful cardioversion after delivery of a rescue shock. The intensivist would then use the information to shock VF if the probability of success is high or continue with chest compressions when the probability of success is low.

Pulse Check after Defibrillation[30]

Chest compressions should be resumed immediately after defibrillation. The pulse should not be checked after defibrillation. This is because even if the patient is successfully cardioverted, the myocardium is generally stunned and unable to generate adequate perfusion pressure. The pulse rate and rhythms can be checked at the next 2 minute interval, either at the time when the rescuer is changed, or when the next defibrillatory shock is ready to be delivered. The importance of uninterrupted cardiac compressions lies at the heart of the above recommendation.

If the patient lapses into repeated VF, many defibrillating shocks may need to be given, notwithstanding the fact that repeated shocks may directly damage the myocardium. We have had patients lapsing into repeated VF necessitating numerous defibrillatory shocks. In some of these patients the underlying cause turned out to be a blocked left anterior descending artery (LAD). Coronary angiography with angioplastic stenting of the LAD led to survival.

BASIC AIRWAY MANAGEMENT AND VENTILATION

The current AHA basic life support and the ACLS guidelines place circulation before airway and breathing in patients who experience sudden cardiac arrest from a cardiac cause. This is because in the early stages, patients with sudden cardiac arrest suffer from severe hypoxia to the heart and brain due to decreased or absent perfusion and not due to decreased ventilation. In the above situation oxygen reserves remain adequate for the first few minutes so that giving precedence to ventilation over circulation as was done prior to 2010, reduces the chance of survival. However, in patients who have suffered cardiac arrest from a primary pulmonary cause (drowning, severe respiratory failure, sudden obstruction to the upper airways) a patent airway and ventilation should be restored as quickly as possible. If there are two rescuers at work, this is easily possible as one attends to chest compressions and the other to the airway and ventilation. If there is just one rescuer, the task may prove difficult.

Though attention to circulation precedes that given to the airway and ventilation, it needs to be stressed that CPR cannot succeed if the airway is left obstructed and if ventilation is left unattended. This prevents oxygenation, causing or perpetuating cardiorespiratory arrest.

Obstruction of the airway can occur in any patient who is comatose, including a patient who suffers cardiac arrest from a primary cardiac cause. The airway can be opened by the simple maneuver of extension of the neck (head tilt) and forward displacement of the mandible (chin lift). Following this, positive pressure ventilation can be provided by mouth-to-mouth or bag-mask ventilation. A positive pressure breath of 400 mL delivered in 2–3 seconds is enough to cause a sufficient expansion of the chest. Hyperventilation and hyperexpansion of the chest can do more harm than good as this can impair venous return and decrease circulation during resuscitation. The optimal rate and timing of pressure breaths must be balanced against the fact that interrupting chest compressions frequently leads to a lesser survival rate. As mentioned earlier the ratio of 30 chest compressions to 2 breaths for ventilation has been recommended in the current guidelines.

The view that chest compressions alone without any artificial ventilation may be sufficient to accomplish resuscitation has been mentioned earlier. This view is debatable and is not acceptable to most intensivists.

Relevant AHA recommendations with regard to airway and ventilation are briefly mentioned below.

- The use of 100% oxygen is recommended during initial resuscitation as there is no evidence that it causes harm during short-term resuscitation.
- Chest compressions cause air to be expelled during compression and drawn into the lungs passively during the recoil. Therefore if the airway is patent, the passive inhalation of oxygen via a face mask suffices for several minutes after sudden cardiac arrest.
- Bag-mask ventilation can maintain adequate ventilation. It needs to be performed correctly and preferably needs two trained care-givers. One holds the mask firmly in place from the bridge of the nose on top to well below the mouth at the lower end, so that there is no leak of air or oxygen that is delivered. The other care-giver presses the bag providing a tidal volume of 600 mL over 1 second at the rate of 8–10 breaths per minutes.

An important complication of bag-mask ventilation is insufflation of the stomach. Normally the esophageal tone prevents air entering the stomach unless the upper airway pressure is close to 20 cm H_2O. However, in cardiac arrest, the esophageal muscle tone is decreased allowing insufflation of the stomach with air at an upper airways pressure of 5–8 cm H_2O. Overvigorous squeezing of the bag during the bag-mask ventilation can therefore prove dangerous. Gastric dilatation can cause vomiting, aspiration of gastric contents; it can also impair venous return and decrease lung compliance.

Advanced Airway Management and Ventilation

- Insertion or placement of an advanced airway (such as an endotracheal tube) should be avoided in the initial

phase of resuscitation as the procedure interrupts chest compressions. The procedure should be delayed until the patient fails to respond to initial CPR or defibrillation attempts, or inserted if necessary after there is a successful ROSC. In patients whose circulation has been restored, the presence of coma or respiratory failure is an indication for endotracheal intubation. Endotracheal intubation unquestionably secures a definite airway, but it often involves fairly long interruption in chest compressions even when performed by an expert. Alternative supraglottic airways such as the double-lumen tracheal-esophgeal tubes or laryngeal mask airways can therefore be used to temporarily control the airway during resuscitation. These devices can be inserted blindly in seconds without laryngoscopy and without interrupting the chest compressions. Intensivists therefore often use supraglottic airways as the first advanced airway during resuscitation. After endotracheal intubation, the patient is given ventilator support.

- Continuous wave form capnography together with clinical assessment is the best way to assess correct placement of an endotracheal tube. Capnography also helps to judge ROSC. A rise in the $EtCO_2$ by more than 10 mm Hg often heralds recovery of circulation and gives hope for a successful resuscitation.
- If the patient is ultimately on ventilator support, he or she should be provided 8–10 breaths per seconds. Higher ventilation rates and large tidal volumes (as has been mentioned earlier) increase intrathoracic pressure resulting in diminished venous return and a reduced cardiac output.

MONITORING CARDIOPULMONARY RESUSCITATION

The two most important parameters that need to be monitored are the continuous ECG recordings (through electrodes placed on the three limb leads and connected to an ECG monitor) and the presence of pulses.

ECG Callaway CW[31] gives an excellent practical division of ECG rhythms into organized and non-organized. Organized rhythms include supraventricular rhythms and VT. Non-organized rhythms include VF and asystole. Non-organized rhythms cannot support the pumping of the heart and therefore cannot support circulation. Callaway rightly points out that restoring cardiac electrical activity to an organized and stable rhythm is essential for successful resuscitation. Organized rhythms can support circulation unless the rate is too slow less than 30/minute or too fast greater than 180/minute. An organized rhythm in the absence of pulses is termed pulseless electrical activity (PEA), formerly termed electromechanical dissociation. The absence of perfusion and of pulses in the presence of an organized rhythm is due to severe damage to the heart muscle [as in massive myocardial infarction (MI)] or following cardiac rupture or following uncoupling of electrical and mechanical activity (as in prolonged circulatory arrest). Other important causes of PEA are massive pulmonary embolism, tension pneumothorax and cardiac tamponade.

Perfusion may not be absent but yet be very poor in pulseless VT, supraventricular tachycardia (SVT) and atrial fibrillation with a very rapid ventricular response. These rhythm disturbances though organized need prompt correction through rescue shock to improve the circulatory state.

In patients with a PEA, the rate of complexes in the ECG may be used to monitor resuscitation efforts. With increasing myocardial ischemia due to a fall in coronary perfusion, the rate of PEA will slow. If resuscitation is leading to improved coronary perfusion and improved supply of nutrients to the heart, the rate of PEA will steadily increase. Often narrow ECG complexes exceeding 80/minute herald return of pulses and successful resuscitation. Falling rates of ECG complexes in PEA signal failure to resuscitate.

The ECG monitor can also demonstrate the presence of asystole or VF. Reperfusion of the heart in asystole (through chest compressions and ventilation) may restore VF. Also an increase in the amplitude of fibrillating waves in VF points to improved coronary reperfusion. On the other hand, a deterioration of VF to asystole is observed when resuscitation attempts are unsuccessful.

Pulses The presence of a palpable pulse denotes mechanical activity of the heart and when combined with an organized stable rhythm as seen on the ECG monitor denotes successful resuscitation. The importance of not interrupting chest compressions to feel the pulse has already been stressed.

It should be noted that a satisfactory arterial pressure or a palpable peripheral pulse during chest compressions does not necessarily reflect coronary perfusion pressure because ventricular pressures are elevated simultaneously as well. Therefore, palpable pulses during chest compressions (through a necessary accompaniment to chest compressions) may be misleading. The clinician should look for other evidence of improved coronary perfusion—as for example a return of the ECG to an organized stable rhythm, a palpable pulse during a break in the chest compressions and a rise in the $EtCO_2$.

Oximetry Monitoring O_2 saturation through oximetry is useful to determine the presence or absence of hypoxemia during resuscitation.

Capnography It allows the intensivist to monitor the $EtCO_2$. A rise in $EtCO_2$ by 10 mm Hg often heralds a possible ROSC.

Arterial pH and, PaO_2 and $PaCO_2$ need to be monitored so as to allow if necessary any correction of metabolic or respiratory acidosis.

Serum electrolytes This again may well be important as hypokalemia, hyperkalemia; hypomagnesemia may well be responsible for arrhythmias or even arrest and need to be corrected for successful resuscitation.

Any other investigation which is necessary to determine the possible cause of cardiorespiratory collapse needs to be done as it is important to remove or counter the cause if successful resuscitation is to be achieved.

PHARMACOLOGICAL THERAPY

Drugs chiefly used in cardiac arrest are vasopressors, inotropes, and antiarrhythmic drugs. Sodium bicarbonate may need to be administered to patients who develop well marked metabolic acidosis. Electrolyte disturbances may need appropriate correction, particularly with regard to potassium, magnesium and calcium.

Vasopressors

There is evidence to show that vasopressors improve circulation during CPR. They act by raising systemic arterial pressure, increase coronary perfusion pressure so that restoration of pulses is more likely. Though current data in patients with out-of-hospital cardiac arrest concludes that no drug therapy influences long-term survival, vasopressors must nevertheless always be used. The two vasopressors in common use are epinephrine and vasopressin. Epinephrine increases coronary perfusion pressure and systemic arterial pressure through stimulation of α-adrenergic receptors. Epinephrine is administered intravenously in 1 mg increments (0.015 mg/kg). The duration of the action of epinephrine in cardiac arrest is brief lasting just a few minutes, so the dose needs to be repeated. Also the dose of 1 mg is perhaps too small to produce a significant effect on the circulation. The dose should therefore be stepped up and in most patients needs to be used at frequent 3–5 minute intervals.[8] A 15 mg dose compared to 1 mg in patients with out-of-hospital arrests showed a significantly higher rate of restoration of the pulses and admission to hospital in those receiving the larger dose.[32] Yet, the overall survival rate was the same in both groups. A dose of 7 mg when compared to 1 mg showed no difference either in restoration of pulses or in survival, both in patients with in-hospital and out-of-hospital arrests.[33] Though no definite dosage can be recommended, the drug is best used in progressive increments at 3–5 minute intervals in the hope of restoring circulation and palpable pulses.

Vasopressin acts on the vasopressin receptors raising the blood pressure and coronary perfusion pressure helping thereby to restore the pulses. It is administered IV as 40 unit boluses (0.5 mg/kg). Its action is longer lasting (10 minutes) than epinephrine, so it may be repeated if necessary at 10 minutes intervals. Both epinephrine and vasopressin are titrated with reference to the ECG wave forms, presence of pulses and changes in $EtCO_2$. There is no evidence to show that any one of these vasopressor is superior to the other. Nor does combination of these vasopressors confer added benefit.[34]

Inotropes

The inotrope most commonly used is dopamine, particularly in patients with a past history of IHD or in patients whose cardiac arrest is directly related to an acute myocardial infarction (AMI).

It must be stated that though clinical data and experience support an increased probability of restoring spontaneous circulation following the use of vasopressors during CPR, there is no clear evidence that their use, improves overall survival.

Antiarrhythmic Drugs

A vagally induced bradyarrhythmia may be corrected by IV atropine. However, the nervous system does not influence the heart rate once circulatory arrest has been present for 2–3 minutes. Once VF is established the only drug of use is amiodarone (5 mg/kg given as bolus). The drug works even better on pulseless VT. If a stable organized rhythm is restored after its use in VF or pulseless VT, the drug should be given prophylactically in an IV infusion (750–1000 mg) over 24 hours. Unquestionably the therapy of choice for VF or pulseless VT is a rescue shock. If, however, VF or pulseless VT persists after three rescue shocks, amiodarone should be given a try.

In earlier years, lidocaine, procainamide, and bretylium have been used for VF. These drugs have no effect once VF has occurred, though they may suppress the arrhythmia before its occurrence. Even as prophylaxis, amiodarone has replaced each one of these drugs. Occasionally, we have successfully used both amiodarone and lidocaine in separate infusions as prophylaxis for recurrent VT not controlled by either one or the other of these drugs.

All pharmacotherapy is given intravenously. It is however important to bear in mind that if the endotracheal tube is in place but if for some reason an IV line has not been secured, a few emergency drugs can be effectively administered via the tube. Medications given by this route should be given in a dose 2.5 times that recommended for IV use, and should first be diluted in 10 mL normal saline or distilled water. The emergency drugs which are thus absorbed and are effective after administration through the endotracheal tube are epinephrine, lidocaine and atropine.

Treatment of Metabolic Disturbances

Intravenous Bicarbonate is used to improve metabolic acidosis (pH <7.2). Cardiac function is believed to improve once metabolic acidosis has been corrected. Though the use of bicarbonate in the presence of acidosis has shown higher rates of successful resuscitation, there is as yet no evidence to show an improved outcome.

Hypokalemia and hyperkalemia are important trigger factors for VT, VF. Hyperkalemia can cause a sudden bradyarrhythmia, wide ventricular complexes with absent P waves. Marked ST changes may also be present. Pulseless electrical activity may supervene. This precipitating factor should always be kept in mind, particularly in patients with chronic renal failure who are on angiotensin-converting-enzyme (ACE) inhibitors. Correction of hyperkalemia in addition to the usual CPR procedures often leads to survival with good ultimate outcomes.

Similarly marked abnormalities in calcium, magnesium need correction as they may contribute to cardiac arrest.

Stopping Efforts to Resuscitate

Mere survival in a vegetative state can be an unfortunate sequel of CPR. The risk of organ dysfunction or failure in particular brain damage is related directly to the duration of ischemic insult. The ischemic time following an arrest includes the time from the onset of arrest to the start of CPR (arrest time) plus the duration of CPR efforts. In the study by the Brain Resuscitation Clinical Trial I Study group, Abramson et al. found that if the arrest time is less than 6 minutes and the CPR time does not exceed 30 minutes, half of the survivors had a good neurological recovery. If, however, the arrest time exceeds 6 minutes, a CPR lasting more than 15 minutes always resulted in a significant neurological impairment in the survivors. Though it is perhaps impossible to be dogmatic, this observation suggests that CPR should be continued for at least 30 minutes if the arrest time is less than 6 minutes. If the arrest time is longer than 6 minutes, the CPR should be terminated after 15 minutes.[35]

POST-CARDIAC ARREST MANAGEMENT

Good post-cardiac arrest intensive care after successful resuscitation is crucial for a good ultimate outcome (Flowchart 2). The single most important objective to bear in mind at this stage is the prevention of brain injury. Though brain ischemia and injury can occur during prolonged CPR, most of it develops as an active process over hours to days after resuscitation. In other words, it is a reperfusion injury.

Several cellular and molecular mechanisms contribute to brain injury.[36] During brain ischemia and soon after reperfusion there is an increased release of stimulatory amino acids, free radicals that harm both neuronal integrity and function. There are focal disturbances in blood flow and an inhibition of protein synthesis.[37] The activation of several extracellular and intracellular signaling pathways leads to specific changes in gene transcription.[38] Most importantly after 24–72 hours of reperfusion there is an activation of specific proteases which lead to neuronal death. Brain injury with neuronal death probably results as a culmination of all these metabolic changes observed after reperfusion is established. There is no drug as yet that has been shown to prevent or counter brain injury. Calcium channel blockers, magnesium, diazepam, thiopental have been tried in randomized trials but without benefit. This is because there are multiple mechanisms contributing to neuronal injury and death, and a single drug is not likely to act on all of these mechanisms. Perhaps different classes of drugs, each acting on different mechanisms causing brain damage may in the future be discovered. Today, the focus on post-cardiac arrest intensive care rests on—

- Achieving therapeutic hypothermia (32–34°C) for 12–24 hours after resuscitation.
- Maintenance of a cardiocerebral perfusion pressure.
- Early cardiac catheterization with a view to opening up and stenting critically blocked coronary vessels if these be present.

Management of Post-resuscitation Arrhythmias

After resuscitation, patients may develop arrhythmias. Atrial tachycardia is often met with. Flowchart 3 given below outlines briefly their management.

The management of postresuscitation bradyarrhythmias is given in Flowchart 4.

Also, refer to treatment of cardiac arrhythmias in the Section Cardiovascular Problems Requiring Critical Care.

Induced Hypothermia

Induction of mild hypothermia (32–34°C) for 12–24 hours after resuscitation produces a 24–30% relative risk reduction for death or poor neurological outcome.[39] Survival and neurological outcomes were favorable when hypothermia was used in patients resuscitated from VF or cardiac arrest. It is advocated that hypothermia should be used in all patients who remain comatose after resuscitation from a cardiac arrest whatever the initial rhythm. To be maximally effective cooling should be achieved within 6 hours after resuscitation and should be continued from 12 to 24 hours; rewarming should then be performed slowly (< 0.25°C/hour).

Hypothermia can be induced by either surface cooling or through endovascular devices. Surface cooling is achieved by ice packs and cooling blankets. Neuromuscular blockade

and sedation may help if shivering or other compensatory responses interfere with surface cooling.

Endovascular cooling through endovascular catheters perhaps allows more stable control over time. An efficient quick method of cooling is the bolus infusion of cold (4°C) IV crystalloid solution 30 mL/kg (unless contraindicated). Hypothermia can then be maintained by either surface cooling or endovascular cooling. Use of sedation and at times neuromuscular blockade enhance the cooling effect. There is a high incidence of seizures after cardiac arrest, hence neurophysiological monitoring should be in place if neuroparalytic agents have been used.

Hypothermia can lead to an increased incidence of infections if prolonged over 24 hours. Mild hypothermia can inhibit platelet function and coagulation but bleeding complications are rare. Elevation of pancreatic enzymes and a fall in creatinine clearance may be observed during cooling. All these disorders are corrected following rewarming.

Two important points in neurological care of the post-cardiac arrest patients is (1) to prevent any fever over the first 24–48 hours of brain injury; (2) monitor for seizures if an electroencephalogram (EEG) is available.

Maintenance of Cardiovascular Perfusion Pressure

After resuscitation from cardiac arrest, myocardial function is impaired. Hence, a degree of both vasopressor and inotropic support becomes necessary in patients where the resuscitation time has been 3–4 minutes or more. Dependence on support usually diminishes over 24–72 hours.

Following successful resuscitation, there is evidence to show that within the first 24 hours there is increased cerebral vascular resistance and impaired cerebral autoregulation.[40] Available data suggests that relative hypertension, with a mean arterial pressure of 80–100 mm Hg should be maintained, provided the heart can tolerate the increase in afterload. It has been noted that hypotension soon after resuscitation is associated with increased neurological damage in patients admitted to the hospital after cardiac arrest. Dopamine 5–20 μg/kg per minute and norepinephrine (0.01 μg/kg per minute) are often used to increase blood pressure and maintain an effective coronary cerebral perfusion.

Early Cardiac Catheterization

Every patient resuscitated from cardiac arrest is a candidate for cardiac catheterization with a view to opening and stenting

Box 1: Main focus in post-cardiac arrest care

- Hypothermia (32–34°C) for 12–24 hours—
  - Slow rewarming
  - Counter seizures; avoid and counter fever particularly in first 48 hours
- Maintain coronary cerebral perfusion—
  - Mean arterial pressure 80–100 mm Hg through use of dopamine, norepinephrine
- Consider early cardiac catheterization in patients with IHD

Abbreviation: IHD, ischemic heart disease.

one or more blocked coronary arteries. Most cardiac arrests are due to underlying IHD; hence most patients would require the above approach. Primary angioplasty can be conducted in patients undergoing hypothermia treatment. The presence of continuing coma is no contraindication to primary angioplasty.

Glucose Control

Elevated blood sugar levels are associated with poor outcome after cardiac arrest.[41] Available data suggests that the blood sugar should be maintained within 140–180 mg/dL. Stringent blood sugar control (72–108 mg/dL) is controversial and may do more harm than good.

Use of Anticoagulants

Cardiac arrest is characterized by an activated coagulation profile and diminished fibrinolysis. The profile resembles a mild form of disseminated intravascular coagulopathy, which may contribute to multiorgan dysfunction. The use of low molecular weight heparin has been advised by some workers to counter the above hematological change.

Finally meticulous intensive care needs to be given to all other organ systems, to correction of fluid, electrolyte disturbances and to prevention and treatment of possible nosocomial infections.

Salient features of intensive care following post-cardiac arrest resuscitation are briefly tabled below (Box 1 and Table 1).

Neurological Sequelae

In spite of expert management even in good centers, neurological sequelae are all too common—

- *Brain death* This is the most catastrophic sequel. Brain death has been accepted by an Act of Parliament, as the criterion for death, even in the presence of continuing heart action or beat.

Brain death is characterized by an unarousable state of coma, a flat EEG, and absent brainstem reflexes. These include absent doll's eye movements, no eye movements on stimulation of the labyrinth by cold water syringed into the auditory canal, and absent corneal, pupillary, gag and cough reflexes. There is also absence of spontaneous breathing. The apnea test is considered positive if there is no evidence of spontaneous ventilatory efforts for at least 3 minutes, and the $PaCO_2$ is greater than 60 mm Hg at the end of the test.

Table 1: Important features in the care of organ systems in post-cardiac arrest

CVS	• Counter arrhythmias • Amiodarone prophylaxis • Mean arterial BP 80–100 for the first 24–48 hours • Primary angioplasty in inpatients with MI or IHD
RS	• Avoid hypoxia • Avoid hyperventilation • Prevent and treat nosocomial infections
GI	• Consider early refeeding after hypothermia to prevent translocation of bacteria
CNS	• Hypothermia, CT to exclude an intracranial bleed or detect a massive recent infarct • Monitor (EEG) and counter seizures • Sedation + muscle relaxant if needed for hypothermia • Periodic CNS examination • MRI, EEG to help with prognosis
Infection	• Prevention and treatment of nosocomial infections
Metabolism	• Correction of fluid and electrolytes imbalance • Correction of acidosis with sodium bicarbonate

Abbreviations: CVS, cardiovascular system; MI, myocardial infarction; IHD, ischemic heart disease; RS, respiratory system; GI, gastrointestinal; CNS, central nervous system; CT, computed tomography; MRI, magnetic resonance imaging; EEG, electroencephalogram.

The local spinal reflexes may be preserved in a brain-dead individual. Deep tendon reflexes may thus continue to be elicitable. The heart and circulation can function effectively for as long as 2 weeks or even longer if ventilatory support is continued. Before the Act of Parliament, which legalized brain death as amounting to death (even if the heart continues to beat), there used to be tremendous pressure from concerned and at times angry relatives to continue with life support even though the futility and anguish of this was adequately explained. Prior to the legislation of brain death as death, the longest survival we have recorded after brain death has been close to 3 weeks. Gradually, multiple organ failure sets in. An interesting feature is the occurrence of diabetes insipidus perhaps due to involvement or injury to the hypothalamus and pituitary. Another noteworthy feature is the frequent occurrence of hyperglycemia in these patients. Failure of gastrointestinal (GI) function is characterized by absent peristalsis, yet without any associated distension. Perhaps there is a decrease and virtual cessation of secretion of digestive and other fluids within the GI tract. Invariably there is a final and merciful fall in the blood pressure, or the development of a malignant arrhythmia, which pulls the curtain on the tragic scene.

- *Alteration in the state of consciousness* It is a frequent sequel of CPR. This alteration may take the form of coma, a vegetative state, a locked-in state, or stupor. Coma is an unconscious state with absence of verbal communication, inability to respond to or to localize noxious stimuli,

and an absence of spontaneous opening of the eyes. A vegetative state is similar to coma except that the patient opens his eyes spontaneously, and may appear to look around. A locked-in state is due to a brainstem lesion in which though there is no movement of the limbs, the patient is aware of his surroundings; he cannot speak but can communicate with his eyes. Stupor is a comparatively benign sequel in which the patient is arousable by a noxious stimulus; significant and at times complete recovery can ensue from this stage. Mental obtundation and amnesia for present as well as past events are often observed for 24–48 hours after successful resuscitation; here recovery is the rule.

- *Cortical blindness* It is sometimes seen after recovery. This type of blindness is associated with an intact optic nerve and a normal retina. The condition usually improves over a period of time though full recovery may not occur. The longer it persists, the greater the likelihood of permanent impairment of vision.
- *Seizures* These are an important sequel in the first 24 hours. In the worst form, they present as a status epilepticus, which may be impossible to control and which carry a grim prognosis of impending brain death. Epilepsy partialis continuosa is characterized by repetitive clonic movements of a limb. These often disappear as further recovery of the central nervous system (CNS) ensues. Myoclonic jerks are irregular jerky movements, which can be localized or generalized. Myoclonic jerks particularly when generalized, or involving the eyes and facial muscles, carry a grim prognosis and generally forecast impending brain death.

Anticonvulsant therapy as outlined in a later chapter should be given, but more often than not, is ineffective, particularly in status epilepticus or in generalized myoclonus. Seizures uncontrolled by the conventional use of dilantin, or by the use of diazepam or lorazepam in a continuous IV infusion, can at times be controlled by 500–1000 mg of thiopentone, given intravenously as a slow infusion over 24 hours.

PROGNOSIS OF NEUROLOGICAL RECOVERY BASED ON CLINICAL EXAMINATION

- Persistent coma in the first few hours after CPR does not necessarily denote prolonged or permanent neurological damage. However, coma persisting beyond 6–8 hours is associated with a poor prognosis. A study on 500 patients by Levy et al.[42] showed that if coma persisted for 1 day, only 10% of patients showed good neurological recovery. The recovery rate was less than 5% when coma persisted for a week; no patient recovered neurological function when coma persisted over 2 weeks. A Glasgow coma score of less than 5 on the 3rd day of coma is also of ominous prognosis and almost always indicates a poor outcome or a permanent severe neurological deficit.[43]
- Brainstem reflexes (doll's eye movements, response to cold water irrigation of the external auditory canal, pupillary and corneal reflexes) are often absent immediately after successful resuscitation. Their return within 1–2 hours is a good prognostic sign for possible recovery. The absence of pupillary or corneal reflexes at 6–24 hours after arrest carries a grim prognosis. Levy et al.[44] noted that not a single patient with absent pupillary or corneal reflexes 24 hours following CPR, was restored to a good quality of life.

The data given above is useful not only in predicting prognosis, but in identifying patients in whom critical care is likely to prove futile. In the West, care after restoring circulation is invariably stopped if clinical findings (as mentioned above) supplemented at times by EEG and imaging studies point to a hopeless quality of life. In our part of the world, it is often impossible to do so, as very often close relatives insist on continuing care at whatever cost and whatever the anticipated sequel unless one can give proof of the presence of brain death.

Basic Cardiorespiratory Physiology in the Intensive Care Unit

- Basic Cardiorespiratory Physiology in the Intensive Care Unit

CHAPTER 5

Basic Cardiorespiratory Physiology in the Intensive Care Unit

INTRODUCTION

All important organs and organ systems in the human body are interrelated and interdependent. This interrelation and interdependence is most marked and evident between the heart and circulation on the one hand, and the lungs on the other. The heart (circulatory system) and the lungs (respiratory system) form a single inseparable unit whose purpose is to supply oxygen to the tissues, and to remove carbon dioxide produced during tissue metabolism.

In any and every critical illness, adequate oxygen delivery or oxygen transport to tissues is crucial for proper function of different organ systems, and for survival. Oxygen delivery is controlled by, and is dependent on the cardiorespiratory system as a whole. Poor function or failure of this system is a common theme in numerous critical illnesses in the intensive care unit (ICU). Cardiorespiratory failure invariably heralds a decline in the clinical state of a critically ill individual. Cardiac failure has repercussions on pulmonary function and gas exchange. Respiratory failure sooner or later worsens cardiac function. A vicious spiral of deteriorating cardiorespiratory function spells death in any critical illness. It is therefore important for the intensivist to be aware of basic cardiopulmonary functions and the factors, which affect these functions, particularly in relation to critical care medicine.

This chapter briefly describes factors regulating cardiac function. It then very briefly outlines basic concepts of gas exchange within the lungs, which relate to the assessment and care of critically ill patients. It then goes on to stress the importance of oxygen content of blood, oxygen transport, and the interrelationship, as illustrated by the Fick principle, between oxygen consumption, oxygen transport, and tissue needs for oxygen.

FACTORS REGULATING CARDIAC OUTPUT

The regulation of the cardiac output (Q_T) is complex, particularly in critically ill individuals, and is dependent on tissue factors, neurohormonal factors, and on intrinsic cardiac mechanisms.

Tissue Factors

The cardiac output is basically governed by the tissue needs for oxygen and nutrients. Each organ has a built-in autoregulation of blood flow through arteriolar dilatation and vasoconstriction. The mechanism of this autoregulation is incompletely understood. It is related to local release of vasodilator substances and other locally operating vasoregulatory mechanisms.

Neurohormonal Influences

Neurohormonal factors also play a crucial role in regulating cardiac output. Increased sympathetic activity is very important for increased cardiac output in stressed states. Neural and hormonal influences mediate compensatory mechanisms in a patient in acute circulatory failure. These neurohormonal compensatory mechanisms are life-saving as they override local autoregulatory tissue mechanisms, reduce flow to the skin, muscles and the splanchnic circulation, and maintain an adequate flow to the brain, heart and other vital organs during shock.

INTRINSIC CARDIAC MECHANISMS

The heart has a significant reserve, which enables it to increase its cardiac output whenever necessary. This reserve may be

impaired or totally absent in patients with cardiac disease. Increase in cardiac output can be brought about by an increase in the heart rate and in the stroke volume. The stroke volume is governed by the following factors—

- Preload or the end-diastolic fiber length, or the end-diastolic ventricular volume (Frank-Starling's law).
- Contractility or the force of myocardial contraction, as determined by inherent contractile properties of the myocardium, and by neurohormonal influences.
- Afterload which is the degree of wall tension developed during ventricular ejection.

Preload

This is the degree of stretch of myocardial fibers at end-diastole, just prior to myocardial contraction. The Frank-Starling law states, the energy of contraction however measured, is a function of the length of the muscle fibers.[1,2] The greater the stretch of muscle fibers within physiological limits, the stronger the force of contraction. The resting length of myocardial fibers is related to end-diastolic ventricular volume. Thus increased venous return increases the stretch of muscle fibers, increases the diastolic volume, and is translated into an increased cardiac output. The heart can therefore vary stroke volume and Q_T in response to changes in venous return and tissue needs. The Frank-Starling mechanism is an intrinsic property of muscle, and is independent of neural and hormonal factors. The normal heart can handle an increase in venous return to 2–3 times normal, even if denervated.[3] When a further increase in Q_T becomes necessary, neurohormonal factors must come into play.

Venous return by its influence on the preload, is one of the most important factors governing cardiac output. Venous return is governed by several factors. An important factor is the difference between the mean systemic pressure and the right atrial pressure. The mean systemic pressure is the volume weighted average pressure in the entire circulation—arteries, capillaries and veins, and is chiefly determined by the total blood volume and the tone of the vessels. It averages about 7 mm Hg. The greater the difference between the mean systemic pressure and the right atrial pressure, the greater the venous return. The relationship between the mean systemic pressure and the right atrial pressure is illustrated in graphic form by Guyton (Fig. 1).[4] An increase in right atrial pressure without a corresponding increase in the mean systemic pressure sharply reduces venous return. Venous return stops when right atrial pressure equals mean systemic pressure. This is exactly the circulatory disturbance underlying cardiac tamponade.

The veins are far more distensible than the arteries, so that a small increase in venous tone results in a large volume of blood being returned to the heart. Similarly, a decrease in venous tone leads to pooling of blood in the peripheries, with a decrease in the volume of blood returned to the heart. Thus, venous pressure constitutes a very large portion of the mean systemic pressure, and is the most important factor in determining venous return. Venous pressure in turn is largely dependent on volume of blood within the veins, and on venous tone.

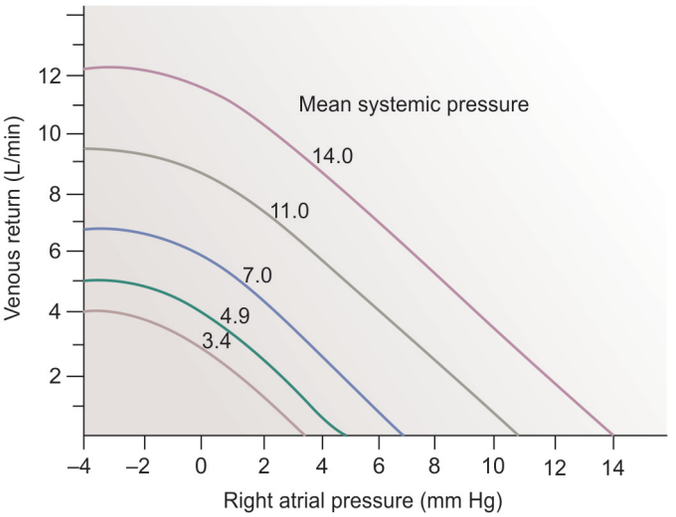

Fig. 1: Effects of mean systemic pressure and right atrial pressure on venous return to the right heart. The greater the difference between the mean systemic pressure and the right atrial pressure, the greater the venous return. Increase in right atrial pressure without a corresponding increase in the mean systemic pressure causes a sharp fall in venous return

Measurement of Preload and Its Significance in Critical Care Medicine

It is difficult to measure end-diastolic volume in critically ill patients in the ICU. The next best option is to measure end-diastolic pressure or the filling pressure of the ventricle, as an indirect measure of the preload. The higher the filling pressure within physiological limits, the greater the preload and the greater the force of ventricular contraction. The upper normal limit of the left ventricular end-diastolic pressure is 15–17 mm Hg. Cardiac output can be augmented in critically ill patients by increasing the left ventricular filling pressure to an optimum of 15–17 mm Hg, and in some instances to even 20 mm Hg. A further increase in the filling pressure will not increase cardiac output, but will lead to an increase in backward pressure and pulmonary edema. In a critically ill patient, a high left ventricular filling pressure (measured clinically as the pulmonary capillary wedge pressure) is usually related either to myocardial dysfunction, or to fluid overload.

Can one equate left ventricular end-diastolic pressure (LVEDP) to left ventricular end-diastolic volume (LVEDV)? The relation between LVEDP and LVEDV is dependent on the following—

- The venous return and volume of blood distending the left ventricle at end-diastole.
- The compliance or degree of stiffness or distensibility of the ventricle.

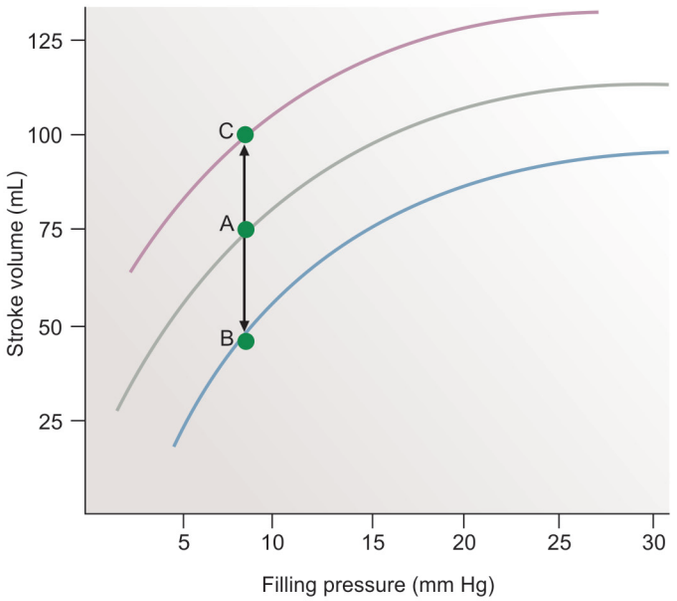

Fig. 2: Ventricular function curve showing effect of ventricular compliance on stroke volume and end-diastolic filling pressures. It should be noted that a reduction in ventricular compliance causes a fall in the stroke volume (A→B), without any change in the filling pressure. Similarly, an increase in ventricular compliance results in an increased stroke volume (A→C) for the same filling pressure

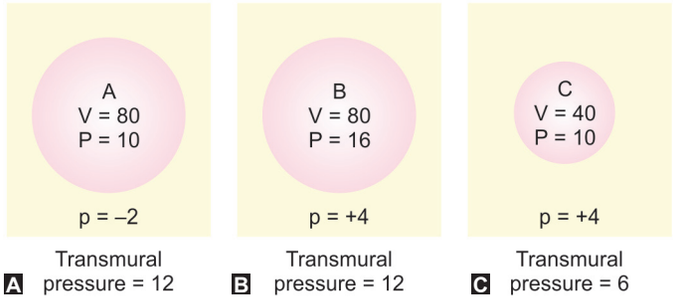

Figs 3A to C: Influence of transmural pressure on pressure-volume relationships in the ventricle. In B, as compared to A, the intrapleural pressure (p) has risen from -2 to +4 mm Hg, and the intraventricular pressure (P) has increased to the same extent (from 10 to 16 mm Hg). The transmural pressure gradient remains the same, and therefore the intraventricular volume (V) is unchanged. If however, as in C, the rise in intrapleural pressure (pressure surrounding the heart) is not associated with a corresponding rise in intraventricular pressure, the transmural pressure gradient is reduced, and the intraventricular volume falls
Source: Modified from Clemmer TP (1988), as in Fig. 1

- The transmural pressure, i.e. the pressure surrounding the ventricle.
- The volume of the right ventricle, which shares a common wall (the septum) with the left ventricle, and a common limiting pericardial sac.

Venous pressure and its relation to venous return has already been briefly discussed earlier. It is a major factor influencing both ventricular end-diastolic filling pressure and end-diastolic volume.

Compliance of the Ventricle Altered compliance or distensibility is also important in determining fiber length. Compliance can be regarded as the change in end-diastolic volume (ΔEDV) in relation to change in end-diastolic pressure (ΔEDP).

$$\text{Compliance} = \Delta EDV/\Delta EDP$$

A fall in compliance (i.e. a decrease in diastolic distensibility), will lead to a rise in end-diastolic pressure for any given diastolic volume. If a ventricular function curve of stroke volume against end-diastolic filling pressure is plotted, the stroke volume will fall for the same filling pressure, if the compliance is reduced. When ventricular compliance is markedly reduced (stiff, very poor distensibility), two effects follow: (1) the stroke volume is sharply reduced because the ventricular end-diastolic volume is reduced; (2) the high left ventricular end-diastolic pressure needed to distend the stiff ventricle leads to pulmonary congestion and edema. The decrease in stroke output that accompanies a decrease in ventricular compliance is termed diastolic dysfunction or diastolic heart failure, as it is independent of any change in the systolic function (i.e. contractility) of the ventricle. In clinical medicine, it is important that a fall in stroke volume due to decreased compliance (poor distensibility) is not wrongly attributed to a reduction in contractility.

In a similar fashion, a decrease in ventricular compliance would lead to an increase in end-diastolic volume, and to an increased stroke volume for the same filling pressure (Fig. 2).

Ventricular compliance does alter in critical illnesses. Compliance is reduced for example, in ischemia to the ventricle, in hemorrhagic and septic shock, and following the use of inotropic drugs like dopamine, epinephrine, and isoproterenol.[5] Compliance on the other hand is increased after relief of ischemia, in cardiac dilatation, and after drugs such as nitroglycerin and nitroprusside.[6-8]

Transmural Pressure Transmural pressure also influences the pressure-volume relationships in the ventricle. This is illustrated in Figures 3A to C. The intrapleural pressure has risen from –2 to +4 mm Hg; the intraventricular pressure (P) has increased to the same extent (from 10 to 16 mm Hg). The transmural pressure gradient remains the same, and therefore the intraventricular volume (v) is unchanged. If however; the rise in intrapleural pressure (pressure surrounding the heart) is not associated with a corresponding rise in intraventricular pressure, the transmural pressure gradient is reduced, and the intraventricular pressure falls. The measured stroke volume is thus the same with a higher LVEDP. This could be wrongly interpreted as a fall in contractility, or to a decreased compliance, when in point of fact it is related to an increase in the intrapericardial or intrapleural pressure. The former can result from pericardial effusion, and the latter may occur in patients on ventilatory support, particularly when positive end-expiratory pressure (PEEP) is being used.

Volume of the Right Ventricle Acute dilatation of the right ventricle can shift the interventricular septum towards the left ventricular cavity, reducing left ventricular end-diastolic volume without any apparent change in left ventricular end-diastolic pressure. This has been observed to occur following a sharp increase in pulmonary vascular resistance due to pulmonary embolism, in acute respiratory failure, and with use of high levels of PEEP. Acute right ventricular dilatation may thus reduce left ventricular filling and cardiac output.

In summary, the left ventricular filling pressure (the pulmonary capillary wedge pressure as measured through a Swan-Ganz catheter) is a good index of the preload. However, when interpreting pressure readings, or when manipulating filling pressures through volume infusions, the influence of the compliance of the ventricle, as also of the intrapleural and intrapericardial pressures should be given due consideration. Septal shifts due to acute right ventricular dilatation may also compromise left ventricular end-diastolic volume, and interfere with left ventricular filling, for reasons stated above.

Contractility

Stroke volume can be increased not only by augmenting preload, but also by increasing contractility. This is accomplished by the use of inotropes that increase both isometric force, and the velocity of isotonic muscle shortening at all loads. Neurohormonal mechanisms within the body, by stimulating beta-1 agonist receptors in the ventricles, also increase contractility with improved emptying of the ventricles, for any given diastolic length.

Afterload

This is an important factor governing stroke volume. Afterload is the ventricular wall tension generated during systolic ejection of blood from the ventricles. The aortic pressure is an important determinant of left ventricular afterload. Increasing the afterload moderately in a normal heart, causes a slight fall in the ejection fraction. This results in a compensatory increase in fiber length and diastolic volume, with stronger contraction and an improved ejection fraction. On the other hand, an increased afterload in a diseased heart, which has poor contractility, can be disastrous. It results in a profound fall in the ejection fraction, and in the forward flow from the heart.

The relationship of a changing afterload to a failing heart is more clearly illustrated by the application of Laplace's law,

$$T = \frac{Pr}{2h}$$

where T is the wall tension (afterload). T is not only directly related to the intracavitary pressure (P), but also directly related to the radius of the chamber (r), and inversely to (h), the thickness of the ventricular wall. Thus, T (wall tension or afterload) increases with the increased radius of a dilated heart. It is reduced with hypertrophy or increased thickness of the ventricular wall.

Influence of Pleural Pressure on Afterload

Negative intrapleural pressures increase transmural pressure and increase ventricular afterload. Negative pressure surrounding the heart acts by impeding the inward movement of the ventricular wall during systole.[9] This is responsible for a reduced cardiac output and reduced systolic blood pressure during the inspiratory phase of spontaneous breathing. When the fall in inspiratory-related pressure during systole is greater than 15 mm Hg, it is termed pulsus paradoxus. There is nothing paradoxical about this observation, as it is merely an exaggeration of a normal response.

Positive intrapleural pressure can reduce the afterload, by promoting the inward movement of the ventricular wall during systole, thereby facilitating ventricular emptying. It is likely that the beneficial effects of closed chest compressions performed during cardiac resuscitation are related to sharp swings in positive pleural pressure, which exert a massage-like action and propel blood outwards from the heart into the systemic circulation.

It is to be however noted that the reduction in afterload effect produced by a positive intrapleural pressure during the inspiratory phase of positive pressure ventilation is negated by the obstruction to venous return caused by the inspiratory rise in intrapleural pressure. In fact the sum effect is a decrease inspiratory cardiac output because of decreased venous return (see Chapter Mechanical Ventilation in the Critically Ill Patients).

Cardiac Rate and Rhythm

The rate is also important in determining cardiac output. A rate greater than 100/minute adversely affects cardiac output, and a marked bradyrhythm acts likewise. Loss of atrial kick may sharply reduce cardiac output in patients with a poor cardiac reserve. Rhythm disturbances even in a normal heart can reduce output; they can be catastrophic in diseased hearts.

HEART FAILURE

This has been dealt with at length in subsequent chapters of the book. A few basic concepts need to be stressed at this juncture.

Cardiac failure, in brief, is a failure of the pumping action of the heart. Left ventricular failure leads to two recognizable features—

1. Pulmonary edema, with or without systemic venous congestion. Pulmonary edema is associated with an increase in end-diastolic left ventricular pressure to greater than 15 mm Hg, and often as high as 30 mm Hg.
2. Poor forward flow resulting in poor tissue perfusion. Cardiac failure may produce pulmonary edema, or poor forward flow, or both. It is important to consider these two aspects of cardiac failure as separate facets, even when both are present at the same time. Death from acute cardiac failure can be due to a severe fall in cardiac output,

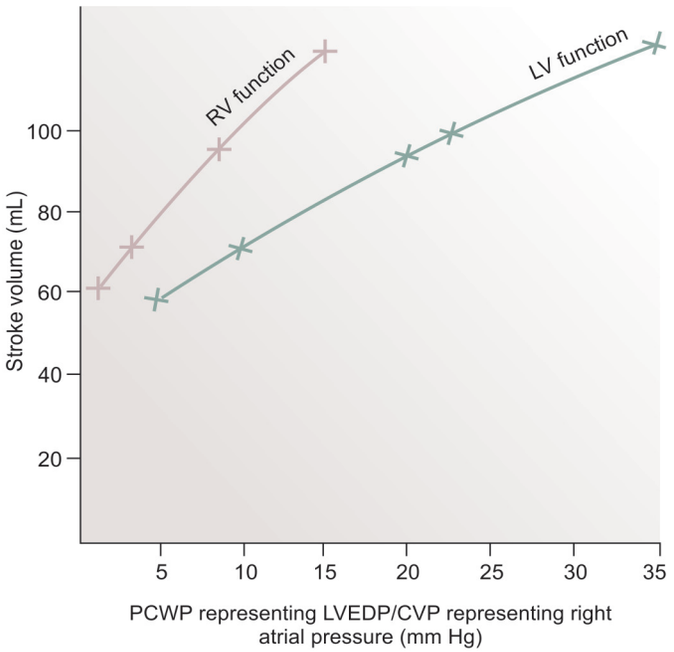

Fig. 4: Left and right ventricular function curves in an overinfused hypervolemic patient. Note that very high left and right ventricular filling pressures that cause pulmonary edema and systemic venous congestion can occur in the presence of good pump function with high stroke volumes and cardiac output

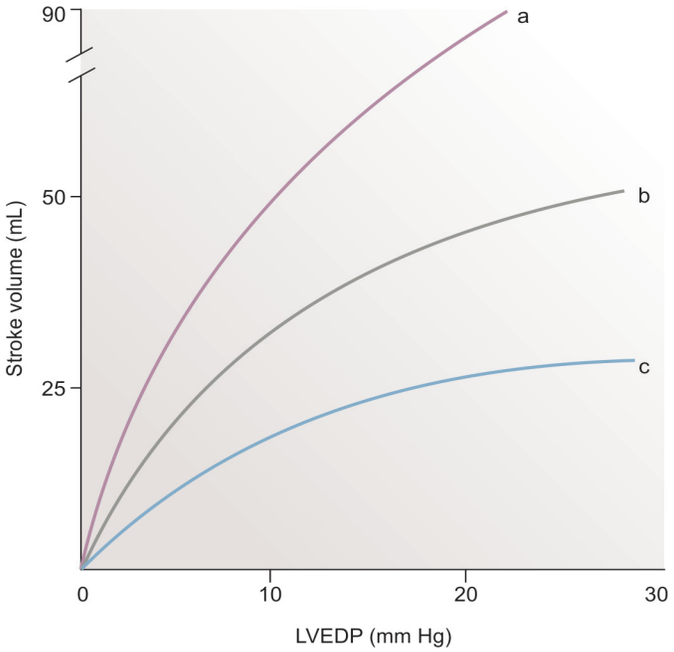

Fig. 5: Relationship of stroke volume to left ventricular end-diastolic pressure (LVEDP) in subjects with normal myocardial function (a), and in patients with moderate (b) and severe (c) left ventricular dysfunction. Note that in patients with myocardial dysfunction, a rising LVEDP produces a smaller degree of rise in the stroke volume, as compared to normal subjects

forward flow and tissue perfusion, without pulmonary edema. This can only be appreciated if the interrelation between left and right ventricular function curves is clearly understood,[10] and if both ventricles are considered as an interlocked single functioning unit.

An explanation of the two above-stated facets of acute cardiac failure has been given in the Chapter Cardiogenic Shock.

A final thought provoking statement that needs to be made, is that the presence of increased filling pressures with pulmonary edema and systemic venous congestion, does not necessarily mean failure of the heart as a pump. This situation (increased filling pressures with pulmonary edema and systemic venous congestion), can also arise in an over-transfused or over-infused hypervolemic patient. Measurements of cardiac output in such a patient shows high stroke volume and cardiac output readings (in accordance with Frank-Starling's principle), pointing to good pump function. This is illustrated in Figure 4.

Left ventricular function curves in moderate and severe left ventricular failure are illustrated below by plotting stroke volume against LVEDP, and stroke volume against increasing afterload (Figs 5 and 6).

The description of the applied physiology of the circulatory system given above has been chiefly related to the heart and its function. There are other components to the circulatory system that need to be considered.[11] These components include the following—

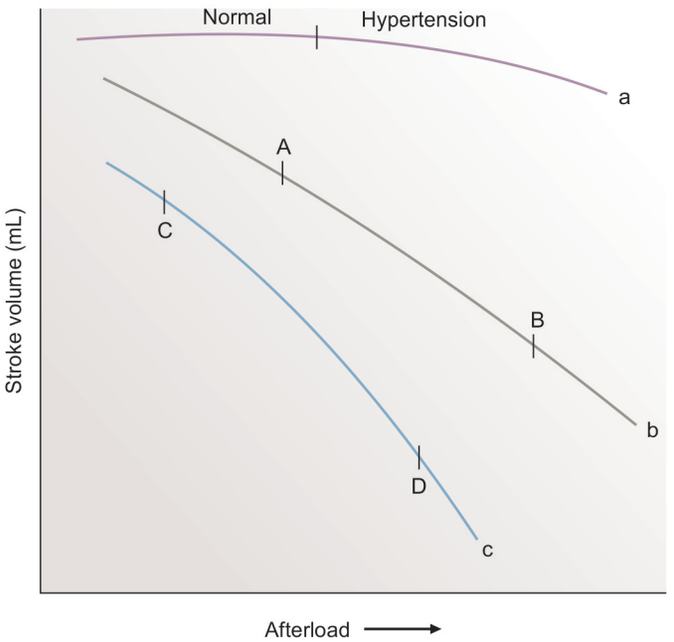

Fig. 6: Relationship of stroke volume to afterload in subjects with normal myocardial function (a), and in patients with moderate (b) and severe (C) myocardial dysfunction. In subjects with normal myocardial function, increase in afterload results in hypertension without much change in the stroke volume (SV) or cardiac output (CO). In contrast, in patients with moderate or severe myocardial dysfunction, an increase in afterload produces a sharp fall in the SV and CO, the SV being inversely proportional to the afterload or outflow resistance. It is important to note that the blood pressure may remain constant at points A and B on curve b, and points C and D on curve c, even though the SV is sharply reduced

- Intravascular volume which regulates mean circulatory pressure and venous return.
- The arteriolar bed, the tone of which chiefly determines afterload, arterial blood pressure and distribution of systemic blood flow. A marked fall in arteriolar tone causes severe hypotension. A marked rise impedes left ventricular ejection and tissue perfusion.
- The capillary network where fluid and nutrient exchange between the intravascular and extravascular compartment occurs. Damage to capillary endothelium results in increased capillary permeability with loss of intravascular volume and tissue edema.
- The venules which are responsible for 10–15% of the vascular resistance.
- Arteriovenous connections. Opening of these connections allows blood to bypass the capillaries and produces tissue hypoxia.
- Venous capacitance which contains 80% of the intravascular volume. Decrease in venous tone or increase in venous capacitance reduces mean circulating pressures, filling pressures within the heart, and effective circulating volume. Increase in venous tone or decrease in venous capacitance has exactly the contrary effects—an increase in the venous pressure and an increase in the filling pressures of the heart.
- *Viscosity of blood* Blood viscosity is chiefly due to circulating erythrocytes (hematocrit). Increase in the hematocrit means increased viscosity, entailing greater work for the heart to move blood through the circulatory system. This increase in work load may have significant clinical implications in patients with ischemic heart disease or in patients with poor myocardial reserve.

Viscosity of blood increases following a loss of plasma or fluid from the vascular system. Blood viscosity also increases following repeated packed cell transfusions, a fall in body temperature, and a decrease in the flow rate of blood. This rise in viscosity can further reduce flow through the circulation and thereby promote ischemic injury. Prevention of an undue rise in viscosity is therefore of particular importance in critically ill patients. The degree of viscosity is best gauged by monitoring hematocrit values which should not exceed 40–45% as the upper limit.

Finally, the right heart, which pumps into the low resistance, low pressure pulmonary circuit, is intrinsically and inevitably locked to the left heart which pumps into the high resistance, high pressure systemic circuit. It is a closed system, and by sheer necessity the stroke volume pumped by the two sides of the heart must be equal.

BASIC CONCEPTS OF GAS EXCHANGE

Efficient gas exchange in the lungs requires—

- An adequate alveolar ventilation evenly distributed to both lungs.
- Even ventilation-perfusion ratios of 0.8 to 1. Uneven ventilation-perfusion ratios or ventilation-perfusion mismatch is an important cause of hypoxia or poor arterial oxygenation. A ventilation-perfusion mismatch is characterized clinically and physiologically by two features: (1) An increase in dead space—ventilation of unperfused or poorly perfused alveoli which are hyperventilated in relation to the blood perfusing them; (2) an increase in venous admixture, i.e. perfusion of atelectatic alveoli causing a true right to left shunt. Alveoli which are hypoventilated in relation to blood perfusing them, also contribute to a shunt effect.
- Diffusion of oxygen across the alveolar wall into the capillaries perfusing the alveoli, and of carbon dioxide from the capillaries out into the alveolar space. A severe diffusion defect may contribute to a low PaO_2 but is hardly ever its sole cause. Most pathologies producing a diffusion defect also lead to an uneven compliance within the lungs and thereby to a ventilation-perfusion mismatch.

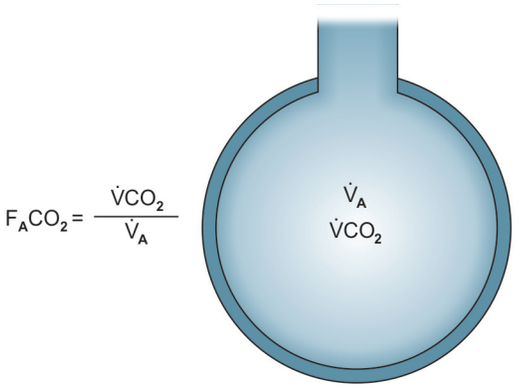

Fig. 7: Concept of alveolar ventilation

Alveolar Ventilation

The pressure of CO_2 in arterial blood ($PaCO_2$) is the best indicator of alveolar ventilation. This basic fact in respiratory physiology is explained below. Consider for purposes of illustration an alveolus of volume $\dot{V}_A$ (Fig. 7). It contains a volume of CO_2 ($\dot{V}CO_2$). The fractional concentration of CO_2 (F_ACO_2) in this alveolus is given by the volume of CO_2 divided by the volume of the alveolus.

$$F_ACO_2 = \frac{\dot{V}CO_2}{\dot{V}_A}$$

The CO_2 released into the alveolus from the blood perfusing it, will be cleared from the alveolus by ventilation; the greater the ventilation the lower the concentration of CO_2 in the alveolus. The alveolar concentration will be a balance between the alveolar ventilation and the rate at which the CO_2 is evolved ($\dot{V}CO_2$).

$$F_ACO_2 = \frac{\dot{V}CO_2}{\dot{V}_A}$$

The fractional concentration of CO_2, F_ACO_2 (0.05–0.06), exerts a pressure equal to the same fraction of the barometric pressure (PB).

$$\frac{P_ACO_2}{PB} = \frac{\dot{V}CO_2}{\dot{V}_A}$$

$$P_ACO_2 = \frac{\dot{V}CO_2}{\dot{V}_A} \times 0.863$$

0.863 is the correction factor that takes into account the barometric pressure and the different units in which $\dot{V}CO_2$ and $\dot{V}_A$ are expressed. This is the alveolar ventilation equation. It shows that the P_ACO_2 is directly proportional to the CO_2 produced, and inversely proportional to alveolar ventilation ($\dot{V}_A$). If $\dot{V}CO_2$ is constant, then P_ACO_2 is inversely proportional to $\dot{V}_A$.

$$P_ACO_2 \propto \frac{1}{\dot{V}_A}$$

There is good evidence to show that $PaCO_2$ (pressure of CO_2 in arterial blood) is very close to the average alveolar PCO_2 i.e. P_ACO_2. Thus

$$P_ACO_2 = PaCO_2 = \frac{\dot{V}CO_2}{\dot{V}_A} \times 0.863$$

The $PaCO_2$ is thus inversely related to $\dot{V}_A$. A high $PaCO_2$ (>48 mm Hg) denotes hypoventilation; a low $PaCO_2$ (<35 mm Hg) denotes hyperventilation; a normal $PaCO_2$ (35–45 mm Hg) denotes normal alveolar ventilation. It should be evident from the above equation that if the normal $PaCO_2$ of 40 mm Hg is doubled to 80 mm Hg, it means that the alveolar ventilation is just half of what is normally necessary to deal with the CO_2 produced by the body. It is to be also noted that the $PaCO_2$ may rise if the $\dot{V}CO_2$ rises and if the patient for some reason cannot increase his alveolar ventilation to get rid of the extra CO_2.

Concept of Dead Space

The anatomical dead space is that constituted by the trachea and the bronchi right up to, but not including, the gas exchange unit of the lung. It is the volume of inspired air which fills the airways and is breathed out unchanged. Air entering alveoli which have no blood perfusing them, also does not take part in gas exchange and is breathed out unchanged. This is wasted ventilation and constitutes alveolar dead space. The sum of the anatomical dead space and the alveolar dead space is termed the physiological dead space, though admittedly there is nothing physiological about this dead space. Figure 8 illustrates the concept of anatomical and alveolar dead space.

Effective alveolar ventilation is only that ventilation entering perfused alveoli. Hyperventilated alveoli will contribute to the overall concept of alveolar dead space.

Ordinarily as much as 30% of tidal volume is dead space ventilation. This may increase considerably in patients with diseased lungs. The quantum of dead space can be calculated by the following equation:

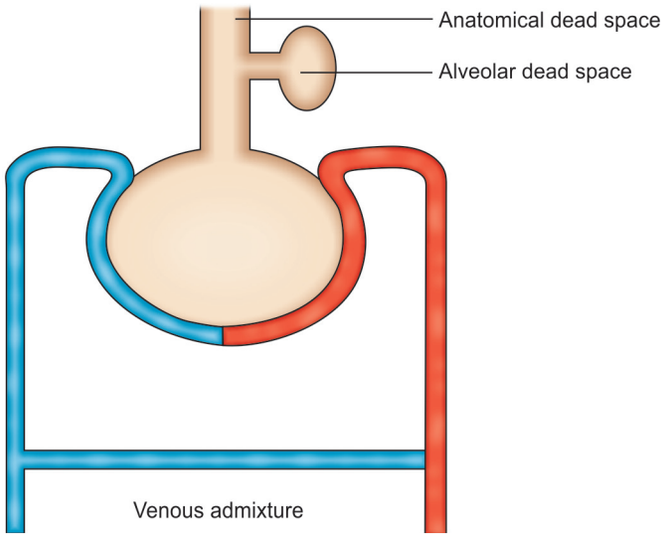

Fig. 8: Concept of anatomical and alveolar dead space and venous admixture (right to left shunt within the lungs)
Source: From Udwadia FE. Diagnosis and Management of Acute Respiratory Failure. Mumbai: OUP; 1979.

$$\frac{V_D}{V_T} = \frac{PaCO_2 - P_ECO_2}{PaCO_2}$$

where P_ECO_2 is the pressure of CO_2 in expired gas.

Alveolar Oxygen

Fresh oxygen from inspired gas enters alveoli during ventilation; the oxygen diffuses through the alveolar wall into the blood perfusing the alveoli. For any given concentration of oxygen in inspired gas (FiO_2), the alveolar concentration of oxygen (F_AO_2) will be a balance between alveolar ventilation ($\dot{V}_A$) and the oxygen taken up ($\dot{V}O_2$) by the blood perfusing ventilated alveoli.

$$FiO_2 - FAO_2 = \frac{\dot{V}O_2}{\dot{V}_A}$$

In terms of partial pressure,

$$PiO_2 - P_AO_2 = \frac{\dot{V}O_2}{\dot{V}_A} \times 0.863$$

We have already defined $\dot{V}_A$ (under Alveolar Ventilation) in terms of $PaCO_2$.

$$P_AO_2 = PiO_2 - PaCO_2 \times \frac{\dot{V}O_2}{\dot{V}CO_2} \times 0.863$$

The ratio $\dot{V}O_2/\dot{V}CO_2$ is in fact the respiratory exchange ratio R, and R in a steady state equals the metabolic respiratory quotient (RQ). Thus

$$P_AO_2 = PiO_2 - PaCO_2 \times 1/R$$

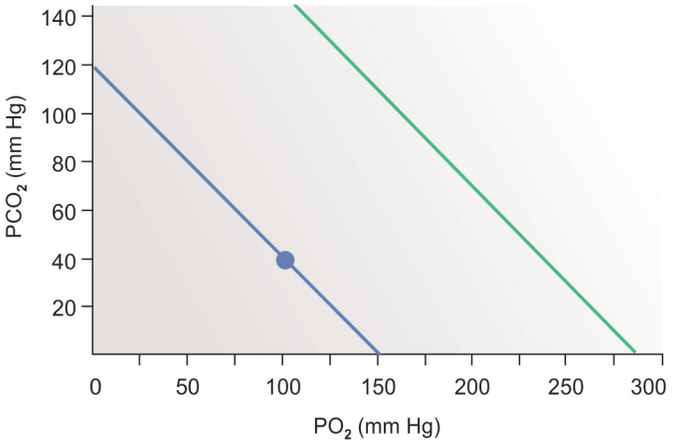

Fig. 9: O_2-CO_2 diagram. The slope of the line depends on the Respiratory Quotient (RQ, normally 0.8). For any given $PaCO_2$, the alveolar PO_2 can be read, and for any given P_AO_2, $PaCO_2$ can be read. The line to the left illustrates the P_AO_2-$PaCO_2$ relationship in the alveoli when breathing air (PiO_2 = 149 mm Hg). The circle marked on this line shows the normal alveolar PO_2 when breathing air (RQ = 0.8). The line to the right illustrates the P_AO_2-$PaCO_2$ relationship with an RQ of 0.8 when breathing 40% oxygen (PiO_2 = 285 mm Hg)

Source: From Udwadia FE. Diagnosis and Management of Acute Respiratory Failure. Mumbai: OUP; 1979.

If carbohydrates are preponderantly burnt as fuel, R = 1; if fats are burnt as fuel R = 0.7; if carbohydrates and fats are both burnt as fuel, as is usually the case, R = 0.8.

The above equation is a simplified form of the alveolar air equation. It is of great use because—

- It allows a quick determination of alveolar oxygen pressure (P_AO_2) if the PiO_2 and the $PaCO_2$ are known.
- If the P_AO_2 is known and the PaO_2 is available through an arterial blood gas measurement, the alveolar-arterial oxygen gradient can be calculated as the difference between P_AO_2 and PaO_2. The upper normal of this gradient is 15 to at most 20 mm Hg. In most normal individuals it averages 10 mm Hg.
- The alveolar equation points to a linear relationship between P_AO_2 and $PaCO_2$. The O_2-CO_2 diagram or line is further elaborated upon in the Chapter Acute Respiratory Failure in Adults (Fig. 9). From this diagram one can quickly plot the expected P_AO_2 if the $PaCO_2$ is known for any given inspired oxygen concentration. If the alveolar-arterial oxygen gradient is taken as 10–15 mm Hg, then for any given $PaCO_2$ one can read off the PaO_2. This is true provided the alveolar-arterial oxygen gradient is not abnormally increased.
- A consideration of the alveolar air equation shows that at a given inspired oxygen concentration and a given RQ, the alveolar PO_2 is dependent on alveolar ventilation. A lower alveolar ventilation would thus lead to a lowered alveolar PO_2, and hence a lowered arterial PO_2.

The alveolar air equation helps the physician to check on blood gas measurements. If the value of the measured $PaCO_2$ is taken as correct, the alveolar equation allows one to compute the P_AO_2. If the PaO_2 reported by the laboratory is higher than the P_AO_2, it is obviously incorrect.

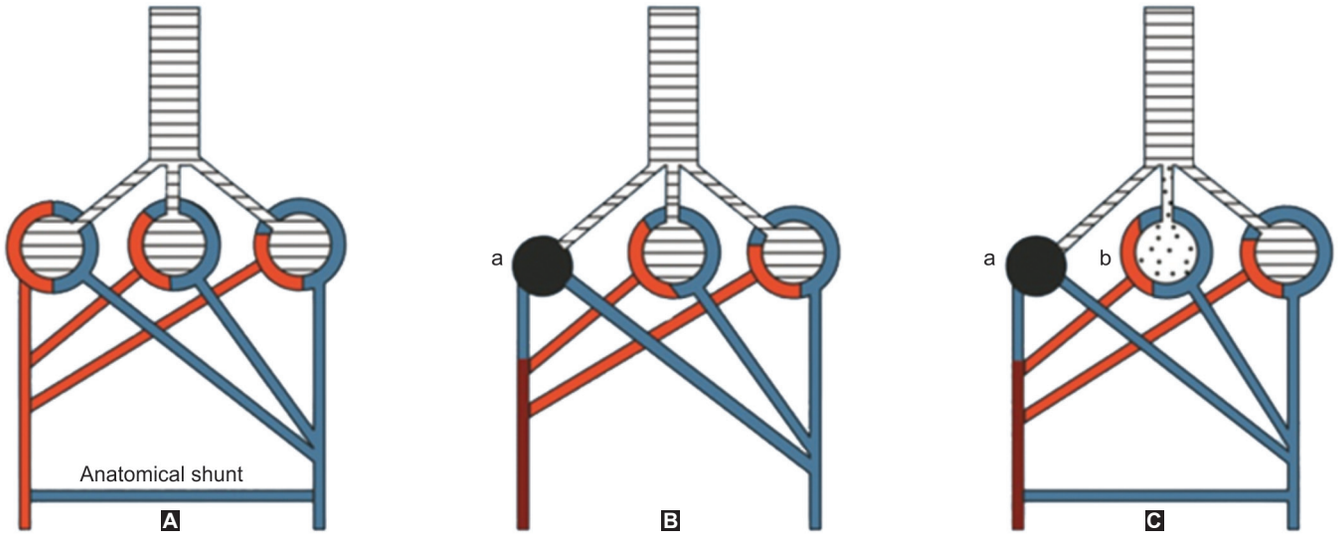
The Alveolar-Arterial Oxygen Gradient

The normal range of the alveolar-arterial oxygen gradient has already been mentioned. An increased alveolar-arterial oxygen gradient denotes an impairment of gas exchange across the alveolar capillary membrane. When however a low PaO_2 is due to hypoventilation, or is related to breathing at high altitudes, then there is no increase in the alveolar-arterial oxygen gradient since the P_AO_2 is also proportionately low. A lowered PaO_2 from any other cause (V/Q mismatch, increased shunt, impaired diffusion), is always associated with an increased alveolar-arterial oxygen gradient. Also the greater the alveolar-arterial oxygen gradient, the greater the disturbance in gas exchange within the lungs. This observation should however be viewed in its proper perspective. Thus an alveolar-arterial gradient of 20 mm Hg (upper limit of normal), when it occurs on the steep part of the oxygen dissociation curve will denote a gross disturbance in pulmonary gas exchange.

Let us consider a patient with chronic bronchitis in severe hypercapnic respiratory failure. If the P_AO_2 of this patient is 50 mm Hg and the PaO_2 is 30 mm Hg, the gradient of just 20 mm Hg (upper limit of normal) would suggest that the hypoxia is chiefly due to alveolar hypoventilation. However, at a PO_2 of 50 mm Hg the oxygen saturation is 85%; at a PO_2 of 30 mm Hg the oxygen saturation is about 55%. Thus the oxygen saturation has fallen 30% between the alveoli and the arterial blood. Normally the fall in oxygen saturation does not exceed 2%. It is evident that there is a serious disturbance in gas exchange in this patient, even though the alveolar-arterial oxygen gradient is not unduly increased.

Venous Admixture

If deoxygenated blood perfuses atelectatic alveoli and bypasses ventilated alveoli, the oxygen content of the blood leaving the lungs will be less than that leaving ventilated alveoli. This constitutes the concept of venous admixture (Figs 10A to C). Venous admixture at the bedside has two components—a true right to left shunt due to perfusion of totally atelectatic alveoli, and a shunt effect observed in alveoli which are hypoventilated in relation to blood perfusing them i.e. alveoli with low ventilation-perfusion ratios. A true right to left shunt (also called a true venous admixture) is unchanged by increasing inspired concentration of oxygen. The shunt effect produced by alveoli with lowered ventilation-perfusion ratios will however be abolished by suitably increasing the inspired oxygen concentration. The simple bedside test of noting the degree of rise in PaO_2 with 100% inspired oxygen, thus distinguishes between a true right to left shunt within the lungs, and a shunt effect produced by ventilation-perfusion inequalities. More often than not, a right to left shunt as



Figs 10A to C: (A) Anatomical shunt (portion of cardiac output bypassing pulmonary capillaries). (B) True right to left shunt in the lungs caused by perfusion of atelectatic alveoli (Alveolus a). (C) An overall shunt due to perfusion of atelectatic alveoli (Alveolus a) to a lowered ventilation/perfusion ratio causing a shunt effect (Alveolus b) and the anatomical shunt

Source: From Udwadia FE. Diagnosis and Mangement of Acute Respiratory Failure. Mumbai: OUP; 1979.

also ventilation-perfusion inequalities are present in the same patient. This is further elaborated upon in the Chapter Acute Respiratory Failure. The mathematical calculation of the venous admixture or shunt is given by the following equation:

$$\frac{\dot{Q}_s}{\dot{Q}_T} = \frac{CcO_2 - CaO_2}{CcO_2 - CvO_2}$$

where $\dot{Q}_s$ is the shunt fraction, $\dot{Q}_T$ the cardiac output, CcO_2 the capillary oxygen content, CaO_2 the arterial oxygen content and CvO_2 the mixed venous oxygen content.

In practice, end-capillary oxygen content is calculated from the alveolar PO_2 by assuming that P_AO_2 is equal to end-capillary PO_2. Arterial oxygen content is either derived from the PaO_2, or estimated by an oximeter. Mixed venous oxygen content is obtained by sampling blood from the pulmonary artery through a Swan-Ganz catheter.

The normal $\dot{Q}_S/\dot{Q}_T$ is generally not more than 5%. A shunt fraction exceeding 30% is serious, and a shunt fraction approaching 50% indicates a gross degree of venous admixture, and carries a grim prognosis.

Concept of Oxygen Content and Oxygen Transport

The heart lung combine working in unison ensures oxygenation of arterial blood. But this is not enough. Blood should have an adequate oxygen content, and what is more the oxygen within the blood should be efficiently delivered or transported to tissue cells all over the body. This principle should never be lost sight of in the management of critically ill patients in the ICU.

Oxygen Content

One gram of hemoglobin (Hb) combines with 1.39 mL of oxygen at full saturation—

$$O_2 \text{ content} = 1.39 \times Hb \times \frac{\% \text{ saturation}}{100} + 0.003 \times PO_2$$

where the solubility coefficient of oxygen at 37°C is 0.003 mL/100 mL blood/mm Hg.

The percent saturation of Hb in arterial blood is related to the PaO_2. Oxygen content thus depends on Hb concentration and the PaO_2. The amount of oxygen in solution in plasma is very low (0.3 mL) due to its relative insolubility. Anemia will decrease O_2 content in a linear fashion so that a reduction in Hb from 15 g to 7.5 g/100 mL will reduce arterial oxygen content by one half, i.e. from 21 mL to 10.5 mL. However, a fall in PaO_2 from 90 mm Hg to 45 mm Hg, i.e. by 50% results in just a 20% reduction in the arterial oxygen content. It is evident that significant changes in hemoglobin concentration have a greater influence on CaO_2 than changes in PaO_2.

It is mentioned above that the PaO_2 has an important influence on arterial Hb saturation. There are two other situations (rare though they be) that can also influence Hb saturation. In methemoglobinemia, the iron in the Hb molecule is oxidized to its ferric state; reversible oxygen binding is not possible and Hb is unavailable for oxygen transport. Again in carbon monoxide poisoning, the Hb molecule avidly binds to carbon monoxide, and cannot bind to oxygen, nor offer effective transport. Both these situations are characterized by a normal Hb, a normal PaO_2, but a lowered percent Hb saturation with oxygen, a poor oxygen content and transport.

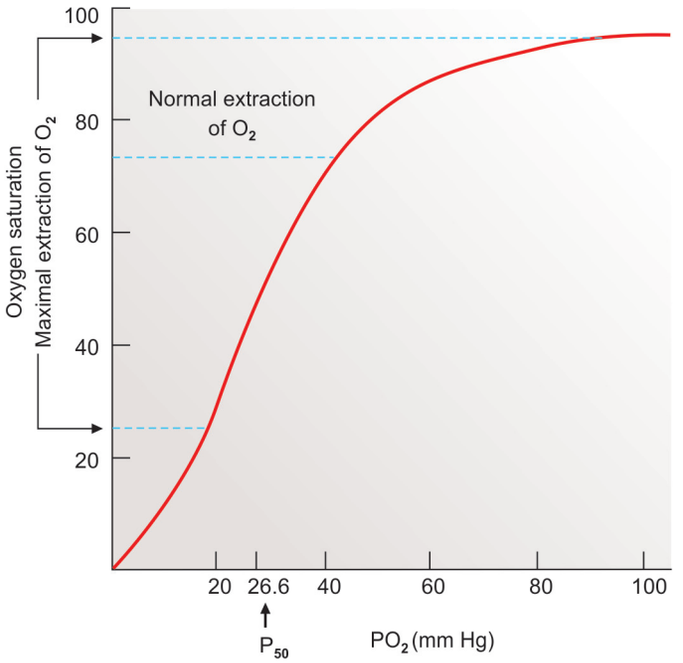


Fig. 11: The normal oxyhemoglobin dissociation curve (P_{50} = 26.6 mm Hg). At a normal PaO_2, O_2, saturation is close to 100%. At a PaO_2 of 40 mm Hg (venous blood), O_2 saturation is about 75%. Maximum O_2 extraction allows a reserve down to about 25%, corresponding to a PaO_2 of 15–20 mm Hg

Oxygen Transport

Transport of oxygen to tissues is a vital function of the cardiorespiratory system. A normal arterial oxygenation or oxygen content does not ensure adequate oxygen transport. The latter is crucially dependent on cardiac output.

$$\text{Oxygen Transport} = \text{Cardiac Output} \times \text{Arterial Oxygen Content}$$

$$DO_2 = \dot{Q}_T \times CaO_2 = \dot{Q}_T \times (1.39 \times Hb \times SaO_2) \times 10$$

It is to be noted that the dissolved oxygen component is removed and that the factor 10 converts the result to mL/minute. If the cardiac index (cardiac output/body surface area) is used instead of the cardiac output, the DO_2 is expressed as mL/minute/m^2. The normal range for DO_2 is 520–570 mL/minute/m^2.

Good critical care should therefore help provide both an adequate cardiac output and satisfactory CaO_2 to ensure the necessary oxygen transport for the needs of the tissues.

Fick Principle

The interrelationship between oxygen transport and oxygen utilization ($\dot{V}O_2$) was described by Fick in 1872.

$$\dot{V}O_2 = \dot{Q}_T \times C(a\text{-}\bar{v})O_2$$

i.e. oxygen consumption = cardiac output × arteriovenous oxygen content difference. The normal range for $\dot{V}O_2$ is 110–160 mL/minute/m^2.

An increase in oxygen consumption ($\dot{V}O_2$) by the tissues is brought about by an increase in the $\dot{Q}_T$, so that the arteriovenous oxygen content difference remains the same (normally about 4–5 mL). If for some reason the cardiac output does not increase appropriately, then the step-up in $\dot{V}O_2$ is met by an increase in oxygen extraction by the tissues, i.e. by an increase in the arteriovenous oxygen content difference. The equation in Fick's principle thus remains unaltered, and well balanced. A widened arteriovenous oxygen content difference (i.e. a lowered $P\bar{v}O_2$ and $S\bar{v}O_2$) occurs in the following conditions in critical care medicine—

- An inadequate cardiac output for tissue needs.
- A very low arterial oxygen content, as with severe anemia.
- When tissue demands for oxygen are so great, that the normal circulatory system cannot keep pace with excessive tissue demands. This could happen for example in patients with uncontrolled seizures in fulminant tetanus.

Table 1: $P\bar{v}O_2$ and $S\bar{v}O_2$ as indicators of cardiac output and tissue perfusion adequacy

$P\bar{v}O_2$ (mm Hg)	*$S\bar{v}O_2$ (%)*	*Clinical state*
36–42	71–79	Normal range
>45	>80	Septic shock
<30	<50	Lactic acidosis
<17	<20	Neural damage

Abbreviations: $P\bar{v}O_2$, mixed venous oxygen tension; $S\bar{v}O_2$, mixed venous oxygen saturation of hemoglobin.

As mentioned above, the increased extraction of oxygen by tissues from the blood, leads to a lowered $P\bar{v}O_2$ and $S\bar{v}O_2$. The normal $P\bar{v}O_2$ is 35–40 mm Hg, and the $S\bar{v}O_2$ is 75%. There is a reserve which allows for a fall in $P\bar{v}O_2$ to 15–20 mm Hg, and the $S\bar{v}O_2$ to 2–30%, in conditions characterized by a very low $\dot{Q}_T$, while still enabling diffusion of oxygen at a level that prevents cellular death (Fig. 11).

In critical care settings, the $P\bar{v}O_2$ and the $S\bar{v}O_2$ can thus act as indicators for adequacy or inadequacy of cardiac output and tissue perfusion (Table 1).

Underlying Fick's principle is the concept that $\dot{V}O_2$ is governed by tissue needs and not by oxygen delivery (DO_2). However, as will be illustrated later, below a critical level of oxygen delivery, $\dot{V}O_2$ does depend on oxygen supply.[12,13] It was earlier believed that in certain pathological states like sepsis, septic shock, acute respiratory distress syndrome, $\dot{V}O_2$ was dependent on DO_2 at all levels of oxygen delivery. The current though not universal consensus is that this is not really so (see Chapter Acute Lung Injury and Acute Respiratory Distress Syndrome). Nevertheless, the importance of ensuring adequate oxygen transport in the management of these critically ill patients cannot be overemphasized.

Oxygen Extraction Ratio (O_2ER)

The oxygen extraction ration is the ratio of oxygen uptake to oxygen delivery ($\dot{V}O_2/DO_2$). It signifies the fraction of oxygen taken up by the tissues; the normal O_2ER is 0–0.3, i.e. 20–30%. Oxygen extraction can vary. It increases when the increased demand for oxygen by tissue is not met by an increase in

cardiac output. In trained athletes the O_2ER may be as high as 0.8 at maximal exercise.[14] In diseased states like severe sepsis, multiple organ dysfunction, acute respiratory distress syndrome, oxygen extraction by tissue cells can be poor in spite of adequate oxygen supply. This is discussed at length in subsequent chapters on these topics.

CHAPTER 6

Procedures in the Intensive Care Unit

JD Sunavala *MD, FCCP. Consultant Physician, Breach Candy Hospital, Jaslok Hospital and Parsee General Hospital, Mumbai, Maharashtra, India*

ENDOTRACHEAL INTUBATION

Endotracheal (ET) intubation can be performed orally or nasally through the larynx and into the trachea. The main indications of ET are—

- Relief of airway obstruction, e.g. facial burns, smoke inhalation, epiglottitis or vocal cord edema.
- Protection of airway, e.g. prevention of aspiration, incoordination of swallowing muscles, obtunded and comatose patients.
- Ventilatory support, e.g. acute respiratory failure, during general anesthesia, flail chest (also see Chapter Airway Management).

ORAL ENDOTRACHEAL INTUBATION

Intubation by mouth is preferred over nasal intubation as it allows a larger ET with less airflow resistance. However, oral intubation is less comfortable to the patient producing excessive secretions. Conscious patients find it difficult to tolerate the ET and they may constantly gag or bite on the tube.

Instrument tray for oral ET should include the following—

- Laryngoscope with both straight (Miller) and curved (MacIntosh) blades, ranging from size 0 (neonates) to 4 (adults). It is vital to check that the blades attach to the handles well and that both batteries and the bulb are in place, so that it lights sharply (brightly) on snapping open the blades of the laryngoscope.
- ET tubes, come in sizes ranging from 2 to 10. The size refers to internal diameter (ID) of the tube in millimeters and it comes in 0.5 mm increments (Table 1). Along the body of the tube, a radio-opaque line runs lengthwise for the proper verification of tube placement on X-ray. Markings in millimeters are also shown along the body for easy determination of the depth of insertion. Distal end of the tube has a cuff, which is connected to a balloon at the proximal end which is used to regulate volume of air in the cuff via a 10 mL or larger syringe.

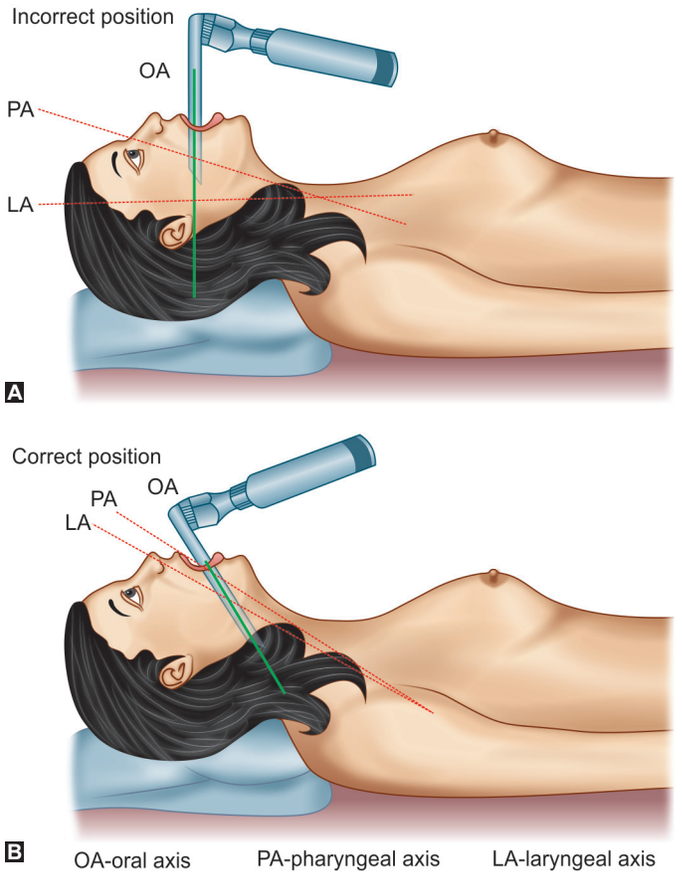
  Portex tubes are the most commonly used tubes, but stiff rubber ET tubes (Rush) should also be handy, as they may prove useful in difficult intubations.
- Syringes, lubricants, securing tape, flexible guiding stylet, topical anesthetic, Magill forceps, suction catheters and an AMBU bag with proper connections should also be provided.

Procedure for Oral Intubation

After assessing the patient, clearing the mouth of any foreign body, such as dentures and checking the ET and laryngoscope, place the patient in sniffing position by tilting the head back so that the oral, pharyngeal and laryngeal axes are aligned. This is usually achieved by raising the head by about 10 cm with pads under the occiput while shoulders remain on the table (Fig. 1). Always explain the procedure to the patient and reassure him if he is conscious. Next, lubricate the deflated

Table 1: Estimation of size of ET

Patient	*Size (mm)*
Neonates <1,000 g	2.5
Neonates 1,000–3,000 g	3–4
Child 1–2 years	4–5
Child 2–12 years	4.5 + (age/4)
Average adult female	7.5–8.5
Average adult male	8–9



Figs 1A and B: Positions for endotracheal intubation

cuff at the distal end of the ET. It is always best to ventilate and preoxygenate the patients with 100% O_2 using an AMBU bag and a face mask. If ET intubation is not successful in 30 seconds, ventilate the patient once again using 100% O_2. Now hold the laryngoscope handle with the left hand (Fig. 1) and insert the blade into the right side of the mouth; sliding the blade to the base of the tongue and simultaneously swapping the blade to the left. Maneuver the tip of the straight (Miller) blade underneath the epiglottis, or the tip of the curved McIntosh blade at the vallecula. Lift the handle and blade up anteriorly to display the tongue and attached soft tissues. Now you should be able to locate the larynx and vocal cords and under direct vision insert the ET. Check for airflow at the proximal end and auscultate for breath sounds and then inflate the cuff. It is always best to confirm proper tube placement with an X-ray chest.

NASAL INTUBATION

The initial preparations and head positioning are the same as for oral intubation. This is a blind technique, and intubation is done by inserting the ET tube (size smaller than one would use for oral intubation) through a nostril. This should be advanced slowly and when the distal end can be seen through the mouth it is laryngoscopically guided by Magill forceps into the trachea. In a fully conscious and cooperative patient, the tube may be advanced slowly during inspiratory efforts and when the distal end approaches the trachea air movement can be felt and heard through the tube. At this point, the tube is gently pushed into the trachea releasing a gush of air almost audible through the tube. Tube placement should be immediately confirmed by ensuring bilateral breath sounds and later by X-ray chest.

COMMON PROBLEMS AND ERRORS OF ET INTUBATION

The commonest error is wrong placement of the tube. The tube could be wrongly pushed so that its tip lies in a bronchus (usually the right bronchus) instead of the trachea (above the carina). If undetected and uncorrected, this could cause a disastrous collapse of the unventilated lung. The tube could also lie with its tip in the oropharynx, or pushed down into the esophagus instead of the trachea. This is immediately detected by the absence of breath sounds on manually ventilating the patient. Instead one can see the stomach getting distended. It is mandatory to always confirm correct tube placement by auscultating both lungs for good air entry and confirming the location of the tip by an X-ray of the chest. Measurement of the end-tidal CO_2 ($ETCO_2$) is also useful in confirming the placement of the ET.

The ET should be *secured* firmly to avoid displacement. Usually an adhesive tape or a commercially made harness is used but too often moisture and secretions gather between the tape and skin and loosen the tape creating a risk of self-extubation. It is hence important to check the fit frequently and to use adhesive tapes of good material.

Ischemic injury and tissue necrosis may occur if the *cuff pressure* is too high and exceeds the capillary perfusion pressure in the trachea. The ET pressure should be less than 25 cm H_2O to allow adequate capillary pressure and for patients with hypotension, it should be kept even lower. To ensure and monitor proper cuff pressure, a Posey cufflator with an inbuilt manometer is available.

To avoid suction-induced hypoxia, the patient is preoxygenated and the suction time kept less than 15 seconds.

Certain specific problems can be encountered when using the laryngoscope, especially in oral intubation. A common mishap is aspiration of dentures if one has forgotten to check and remove them. Trauma to the teeth and soft tissue can also occur. This can be avoided by being more gentle and careful during the procedure. Also, with experience, one can guide and maneuver the tube over the laryngoscope's blade with greater skill, especially in difficult intubations. Complications of ET intubation have been dealt with in the Chapter Airway Management.

The general criteria for extubation are listed in Box 1. For care of ET tube and extubation see Chapter Airway Management.

Box 1: General criteria for extubation

- Rapid breathing test—
  f/V_T <100 min/L (VT is tidal volume in liters)
- ABG—
  Acceptable blood gases on FiO_2 <0.4 and spontaneous minute ventilation <10 L/min. PaO_2/FiO_2 >250 mm Hg
- Ventilatory pressure—
  Maximum inspiratory pressure > –20 cm H_2O
  VC >15 mL/kg
- Cardiopulmonary assessment—
  Stable cardiac and pulmonary status

Cricothyroidotomy[1-3]

Cricothyroidotomy is a bedside surgical procedure, which can be life-saving when performed for the correct indication.

Indications

Surgical cricothyroidotomy is indicated in all patients who require immediate intubation, which cannot be performed because of the following problems—

- Severe maxillofacial problems.
- Poor visualization of vocal cords due to local edema, blood or abnormal anatomy.
- Cervical spine lesions requiring immobilization and where the neck cannot be manipulated.

Equipment

- Kelly or Crile clamp.
- Scalpel.
- Antiseptic solution and surgical gloves.
- Tracheostomy tube (no. 6 size).

Procedure

The most important part of the procedure is the correct identification of the cricothyroid membrane. The cricoid cartilage is the first small notch on sliding the index finger upward in the midline from the sternal notch. The firm membrane between it and the thyroid cartilage (Adam's apple) is the cricothyroid membrane.

The patient should be supine with the neck in neutral position and the thumb and index finger of the non-operating hand should stabilize the trachea-laryngeal complex by firmly fixing the thyroid cartilage as shown in Figure 2. A 3–4 cm vertical or transverse incision should be made through the skin, dermis and cricothyroid membrane. This should identify the cricothyroid space, which should be dissected and opened transversely by means of a sharp knife. In spontaneously breathing patients, a successful incision of the membrane should immediately be followed by a gush of air. The index finger should be immediately inserted in the space and a clamp is next inserted to spread the membrane and enlarge the space. Now by pulling the clamp upward the trachea is elevated and a tracheostomy tube (no. 6 size) is inserted under the clamp and the clamp is removed.

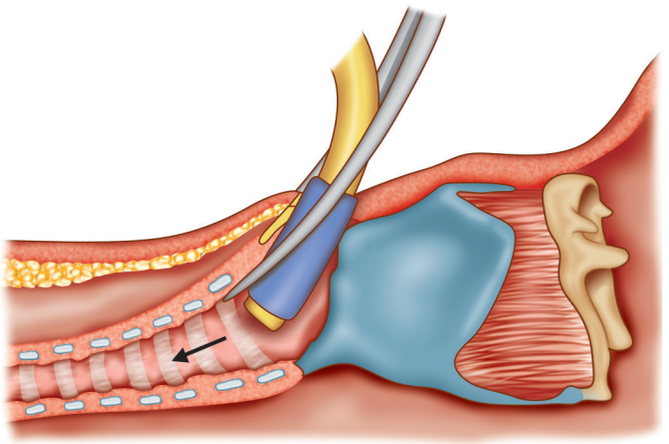


Fig. 2: Procedure for cricothyroidotomy

Complications

- Laceration of the anterior jugular veins is a potential complication because of their paramedian and superficial location which is in close proximity to the incision. With a vertical incision, the likelihood of injury to the veins is less. However, in the event that the vein is injured, the bleed can be stopped with manual pressure or may require suture ligation.
- Oropharyngeal injury is a major complication and can occur if the scalpel penetrates the posterior wall of the trachea. This is avoided by dissecting the cricothyroid membrane with a finger or a blunt clamp but never by using a sharp and penetrating instrument like a knife. Observing proper fixation of the thyrolaryngeal complex and taking an adequate incision enabling good visualization of the thyroid and cricoid cartilage is very important in avoiding this mishap.
- Bleeding from adjacent structures is probably the most common problem but can be avoided or minimized by staying in the midline during the surgery.

Percutaneous Dilatational Tracheostomy

Indications

- As an elective procedure when it is desirable to shift from ET intubation to a tracheostomy. In this situation, the ET tube is left in position and removed only at the appropriate time.
- To secure an airway in an emergency, when ET intubation fails or when ET intubation is not considered feasible for technical or anatomical reasons.

It is to be noted that though percutaneous dilatational tracheostomy (PDT) is perhaps more expedient than a formal tracheostomy in a dire emergency, it carries a greater risk of perioperative cardiopulmonary complications and death. It requires not only expertise, but also experience and should not be performed if these are not available. PDT should also be avoided in children and in obese patients.

Procedure

The two most commonly available kits for this procedure are—

1. Cook kit and
2. Portex kit.

In an elective PDT, the ET tube is left in place throughout the procedure and removed only at the appropriate time. The procedure begins with a small 2 cm vertical incision made mid-distance between the cricoid cartilage and sternal notch. After separating the pretracheal muscles, the trachea is palpated through the incision. Next a needle attached to a 10 mL syringe filled with saline is digitally guided and inserted in the midline through the second and third tracheal rings, with constant suction on the syringe while inserting. On entering the trachea bubbles of air are aspirated into the syringe and at this point it is vital to hold the needle still and disconnect the syringe (Fig. 3).

Once the needle is stabilized a guidewire is gently passed through its lumen and the needle then withdrawn. A dilator is next passed over the guidewire to dilate the existing tract. After removing the dilator a guiding catheter is passed over the guidewire and inserted into the trachea. Progressive dilatations are now done starting from 12 Fr dilator up to the largest 36 Fr and these are all done over the guidewire and the guiding catheter. Serial dilatations should be done at a correct angle and with minimal force to avoid injury to trachea or creating a false pretracheal passage. After the largest dilator is inserted and withdrawn a digit is inserted through the incision into the trachea for palpating the ET. An assistant is asked to withdraw the ET slowly and stop withdrawal when the tip of the tube is right over the palpating finger. A Shiley tracheostomy tube (no. 8) fitted snugly with a 28 Fr dilator is now introduced over the guidewire and guiding catheter complex into the trachea. Once the tracheostomy tube is in place the guidewire, the guiding catheter and the 28 Fr dilator are all withdrawn. The balloon of the tracheostomy tube is inflated and the tube placement is confirmed by auscultation and only then the ET is removed.

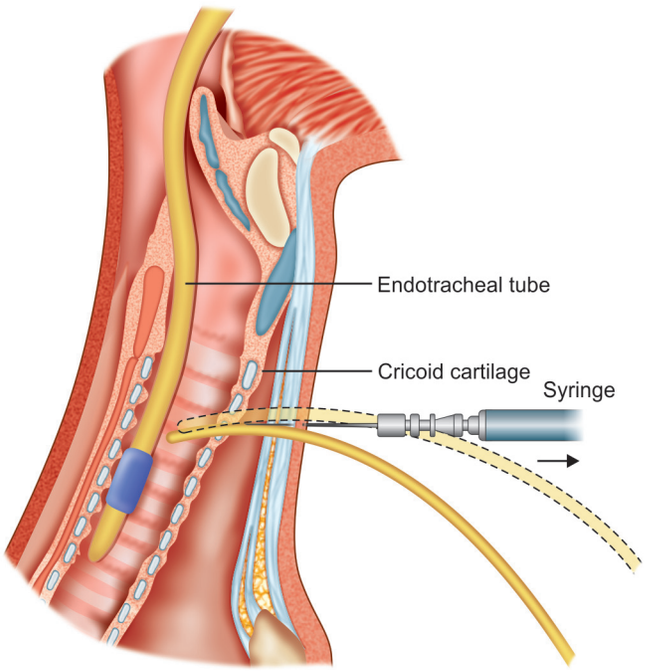

Fig. 3: Procedure for percutaneous dilatational tracheostomy (PDT)

Complications

- Incorrect placement of needle. This may be avoided by introducing the needle under digital guidance.
- Perforation of the posterior wall of the trachea by dilators. This can be avoided by not applying unnecessary force to the dilator whilst putting it into the trachea and placing the dilator at the correct angle.
- Bleeding into the trachea. This can occur with a low placement of the tube causing injury to the thoracic inlet vessels; though rare, the most lethal is an injury to the innominate artery. If such a complication should occur direct pressure should be applied until the patient is moved to the OT for surgical repair.

The sophistication, ease and safety of this technique have made it an increasingly popular procedure that can be performed by a trained intensivist at the bedside. There is however an ongoing debate whether this is truly as safe as it was predicted and whether it is cost effective. In any case, it is always an asset for an intensivist or the on-call surgeon to be familiar with the technique.

PERCUTANEOUS TECHNIQUES FOR CENTRAL VENOUS CATHETERIZATION[4]

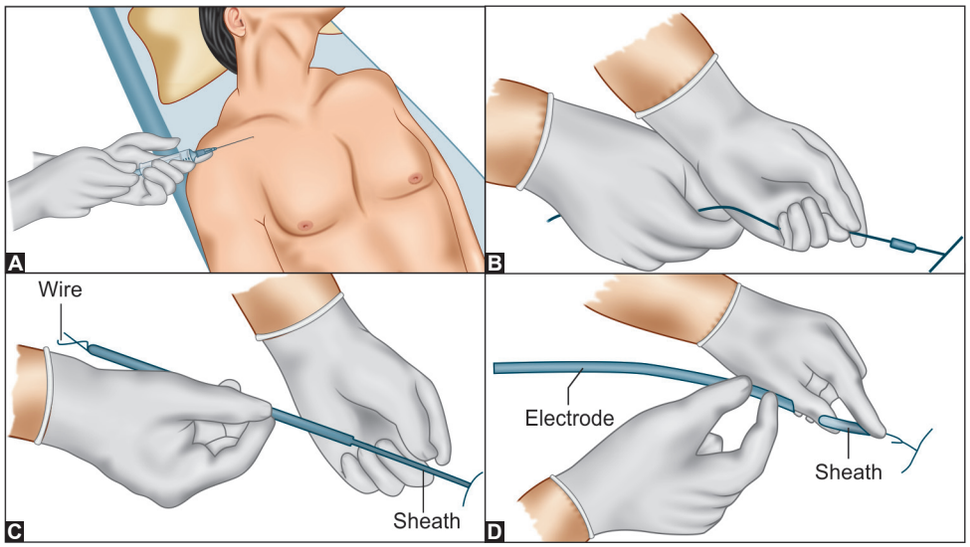
Presterilized sets of special catheters with associated devices are now available as presterilized sets for percutaneous entry into larger veins, e.g. the subclavian, internal jugular, femoral or brachial veins.

Catheter-over-needle devices are most commonly used, and are designed to eliminate the risk of the needle cutting through the catheter; the greatest danger of catheter-through-needle devices is the shearing of the catheter if it is accidentally withdrawn through the needle. These devices consist of catheters of variable length, which can be easily passed through the needle lumen, and can be advanced through the peripheral veins into the central veins.

Both these devices allow placement of a catheter in the central veins by direct puncturing of the vessel. However, if a Swan-Ganz or a pacing catheter needs to be passed through the vein, one may have to use special Introducer Sets. These are usually expensive units consisting of a needle, guidewire and a dilator over, which a polythene sheath is tightly wrapped. These sets require use of the modified Seldinger technique for introduction of the wide-bore introducer sheath in the vein, through which the catheter can then be passed.

Modified Seldinger Technique (Figs 4A to D)

The site of the puncture is infiltrated with 1% lidocaine. The vein is cannulated percutaneously with an 18-gauge thin-walled needle, following the appropriate landmarks and techniques for individual veins as described later.



Figs 4A to D: Modified Seldinger technique of inserting a guidewire and introducer set via subclavain vein puncture. (A) Direction of needle and site of puncture; (B) Insertion of guidewire; (C) The introducer sheath (with dilator) is first advanced over the guidewire. Next, with the sheath well in, the guidewire and dilator are removed; (D) An electrode or catheter is inserted through the sheath

Blood is aspirated from the needle to confirm its entry into the vein, following which the soft end of a J-tip 0.035 inch guidewire is inserted through the needle, and advanced into the superior vena cava (if the subclavian or internal jugular vein is used), or the inferior vena cava (if the femoral vein is used). The guidewire should slide effortlessly through the vein, and should never be forced. After the guidewire is satisfactorily inserted (check that it is not inserted too far in as it may produce ventricular ectopics), the introducer needle is removed, and a small nick is made near the puncture to facilitate the passage of the dilator. The tapered vein dilator carrying an introducer sheath is then advanced over the guidewire with a twisting motion through the skin and subcutaneous tissue, into the vessel. Finally, the wire and dilator are removed, leaving the wide-bore introducer sheath in the vein, through which the Swan-Ganz or pacing catheter can be passed. The sheath should be secured well with sutures. Some of the introducer sheaths have a one-way valve at the proximal end to prevent backflow of blood, and a side port to allow continuous infusion of fluid to prevent clotting. Throughout this procedure, care should be taken to ensure that the proximal end of the guidewire always remains outside, and does not migrate into the vein. If for any reason, during the procedure, the guidewire needs to be removed and reinserted, the whole procedure should be repeated from the beginning; the needle should never be reintroduced over the guidewire as it can shear the wire.

Techniques for Specific Veins

Subclavian Vein Catheterization

The patient lies flat or in a slight head-low position. Correct positioning is important; both arms should be stretched straight by the sides, and the patient should be lying on a firm flat surface so that both the shoulders are in the same plane. The site of puncture is a point just below the junction of the middle and inner thirds of the clavicle.

The skin is now punctured at the selected site, with the point of the needle directed toward the suprasternal notch; the plane of the needle should be horizontal to the ground and parallel to the parietal pleura (Fig. 5). The needle is advanced with a gentle suction on the syringe until the subclavian vein is entered, often with a distinct give. It is sometimes necessary to slightly change the angle of the needle, in which case it is always essential that the needle is completely withdrawn before re-entering in a new direction. Once the needle is in the

vein, depending on the catheter design, proceed either with the modified Seldinger technique, or directly introduce the catheter through the needle, or slide it from over the needle.

Complications Pneumothorax is the commonest major complication of this procedure. The incidence of pneumothorax can be reduced by avoiding large-bore needles, multiple punctures, and by disconnecting the ventilator at the time of venipuncture. Other serious complications include air embolism, catheter-induced infection, perforation of the superior vena cava and hemothorax (due to accidental puncture of the subclavian artery).

Internal Jugular Venipuncture[5]

The patient is placed in the Trendelenburg position, and the skin cleaned and carefully draped. The site of puncture is located two finger breadths above the clavicle at the outer border of the sternomastoid, with the patient's head rotated to the opposite side. The needle with the syringe attached is directed toward the suprasternal notch. Aspiration of blood indicates entry into the vein. Air embolism and thrombophlebitis are the main complications encountered in this procedure. Accidental puncture of the internal carotid artery can also occur. Pneumothorax is rarely observed following this procedure.

Femoral Venipuncture[6]

The femoral vein can also be entered percutaneously. The site of puncture is below the inguinal ligament, just medial to the point where the femoral artery pulse can be palpated. Wound infection is generally more common, and there is an increased risk of thrombophlebitis when the femoral vein is used.

Arterial Catheterization[7]

Except in unavoidable circumstances, it is wise to choose the radial artery for catheterization,[8] as the risk of occlusion of a proximal artery, such as the femoral or brachial, could prove disastrous. It is vital to assess the patency of the radial artery by Allen's test prior to catheterization, as it is important to be sure that a competent ulnar artery is present. This is done as follows—

- The examiner compresses both arteries, when the patient makes a tight fist to squeeze all the blood out of the hand.
- The patient then extends the fingers, and the examiner observes the blanched hand.
- Compression on the ulnar artery is released, and the examiner observes the hand filling with blood. If filling does not occur, the ulnar artery is presumed to be nonfunctional.

Technique of Radial Artery Catheterization

The wrist is hyperextended and a small area over the radial artery is cleaned and prepared with alcohol and betadine solution. A small area on both sides of the artery is anesthetized with 1% lidocaine solution. The artery is palpated with the forefinger and middle finger of one hand, and the needle (we prefer a catheter-over-needle device), is now inserted percutaneously toward the artery. As the needle touches the vessel wall the arterial pulsations are damped; the needle is now advanced further through the wall into the lumen of the artery. As soon as the blood gushes out, the catheter is advanced slowly over the needle, and the needle is then removed. The catheter hub is attached to a continuous flush system (Intraflo) via a pressure tubing. The hub of the catheter should be fixed firmly to the skin, and an antibiotic ointment dressing applied over the point of arterial puncture.

Maintaining tight compression over the puncture site, and proper attention to asepsis will go far in avoiding the two commonest complications of arterial puncture, viz. local hematoma formation and infection. Clotting of the catheter can be prevented by using a low dose continuous heparin infusion.

TEMPORARY BEDSIDE PACING[9,10]

The most commonly used external pulse generators are ventricular inhibited (demand) units; these generally permit programming of the rate between 50–150/minute, and have a sensing facility, which allows use in full demand or in the asynchronous mode. Temporary pacing leads (both unipolar and bipolar) are available in various sizes (5–7 Fr); however, pacing with a bipolar lead is more common.

In extreme emergencies, transthoracic temporary pacing can be done by introducing a wire into the myocardium through a chest wall needle.

Technique

Lead Insertion

The pacing electrode may be introduced into the vein percutaneously or by venous cut down. The commonly used veins are the basilic vein in the antecubital fossa, the subclavian, internal jugular or femoral veins. The choice of vein depends on the doctor's expertise. However, it should be noted that inserting a lead through a cut down in the antecubital fossa usually involves considerable manipulation, whereas insertion through the internal jugular, subclavian or femoral veins provides a more direct route to the atrium and requires less manipulation. A left subclavian or femoral approach is preferable, as the curvature of the lead is shaped so as to allow an easier entry into the right atrium and from there into the right ventricle.

The electrode tip is advanced to its final position at the right ventricular (RV) apex, either under fluoroscopic guidance or by intracardiac ECG monitoring. However, not many hospitals in developing countries can afford a portable image intensifier, and not all critically ill patients can be shifted to the X-ray department. Hence, one should learn to position the lead by intracardiac electrogram monitoring.

Lead Positioning (by Intracardiac Electrogram Monitoring)

After entering the vein, the proximal tip of the electrode is attached to lead V_1 of the standard ECG machine with the aid of an alligator clip cable. Lead V_1 shows a prominent P wave as the pacing electrode advances toward the heart, being inverted in the high atrium and biphasic in the midatrium. Entry of the pacing electrode into the right ventricle is facilitated by forming a loop in the right atrium, and then rotating the catheter either clockwise or anticlockwise, so that the distal end of the lead flips across the tricuspid valve. As the electrode tip crosses the tricuspid valve and enters the RV cavity, the intracardiac ECG changes markedly. An rS ventricular pattern with very deep S and deep T waves appears; this may necessitate decreasing the standardization by half. When the catheter tip abuts on the endocardial surface of the RV wall, an elevated ST segment is observed due to a current of injury. Ventricular ectopic beats are commonly observed when the catheter tip traverses the tricuspid orifice; rarely ventricular fibrillation may occur, necessitating withdrawal of the pacing catheter tip and prompt defibrillation if necessary (Fig. 6).

Once the electrode is correctly positioned at the apex of the right ventricle, the lead is connected to the battery-operated pacemaker box. It is now necessary to test the electrical threshold of stimulation, and if the pacemaker is set for demand mode, the ability of the electrode tip to sense the R waves.

The electrical threshold is tested by slowly reducing the amperage of the pacemaker till the paced QRS complexes disappear, and only the pacemaker spikes and the patient's own spontaneous beats are present. The amperage is now slowly increased till pacing is re-established, this being the electrical threshold. If pacing does not occur at an electrical threshold of less than 2 mA, it may be best to reposition the electrode. The pacemaker rate depends on the clinical needs of the patient, and is generally kept between 70–80 beats/minute.

To test the sensing function in the demand mode, the sensing dial is turned clockwise (in most pulse generators) to full demand mode, and then gradually turned toward the asynchronous mode till sensing is just lost. In this way we can measure the R wave amplitude to ensure adequate sensing of cardiac activity. Unfortunately, most temporary pulse generators do not write the exact values over the dial, but the full demand mode would usually indicate 1 mV, and the opposite asynchronous mode about 20 MV. Ideally an R wave less than 6 mV should be sensed. If this does not occur, indicating that the sensing threshold for the R wave exceeds 6 mV, the lead should be repositioned.

Indications for Temporary Pacing

Temporary pacing with an external pulse generator remains an important therapeutic option, and an experienced physician can readily initiate temporary pacing in emergency situations. The two main indications for this procedure are as follows—

Therapeutic

These can be broadly classified into three major groups—

1. In patients with life-threatening bradyarrhythmias (e.g. severe sick sinus syndrome, second degree, third degree, or high degree AV blocks, slow junctional or idioventricular rhythms), where it is mandatory to maintain an adequate cardiac rate.
2. In patients with symptomatic bradycardias or symptomatic conduction defects. These patients commonly present with recurrent Stokes-Adams attacks, syncope or near syncope, which may be due to second or third degree AV blocks or sinus dysfunction.
3. In selected cases with intractable tachyarrhythmias, where overdrive temporary pacing is used to terminate or prevent the tachycardia. However, this is only a temporary measure and helps to buy time till the tachycardia can be controlled by medical therapy.

Prophylactic

Temporary pacing may help in preventing the occurrence of sudden death in the following subsets of patients with acute myocardial infarction—

1. In patients with inferior myocardial infarction associated with Wenkebach's phenomenon or a second degree heart block, where the possibility of a complete heart block is anticipated.
2. In patients with extensive anterior wall infarction with recently acquired bifascicular blocks (especially those with right bundle branch block associated with a block in the left posterior inferior division, or in patients with a new bundle branch block associated with transient complete heart block).
3. Patients with underlying conduction defects, such as chronic heart blocks, bifascicular blocks or brady-arrhythmias, who are otherwise asymptomatic, may require temporary pacing at the time of major surgery.

Complications of Pacing

Infection at the local site, phlebitis and thrombosis of peripheral veins are the commonest complications. Systemic infection, lead perforation through the ventricular wall, diaphragmatic pacing and pacemaker-induced arrhythmias are other major complications that need to be promptly recognized and treated.

Pacing Failure

Malfunction of a temporary pacemaker may result in complete or intermittent failure to capture. Here the ECG will show regular pacing spikes without pacemaker captures; the commonest cause of this is a displaced lead, which will require repositioning. A total lack of output on the other hand, manifests on the ECG as absence of both spikes and pacing captures, and is generally caused by either a loose connection, lead fracture, battery failure or a fault in the pacemaker itself.

Sudden cessation of pacing in a patient with marked bradyarrhythmia or absent intrinsic rhythm due to any of the above-mentioned causes can result in cardiac arrest. In such an eventuality, the first priority should be the re-establishment of cardiac rate and rhythm. All ICU personnel should be familiar with the following emergency protocol in case of sudden pacemaker failure—

i. Check if patient is asymptomatic.
ii. Check whether all generator connections are tightly fitted.
iii. Increase pulse generator output to highest setting.
iv. Replace pulse generator battery.
v. Turn patient on left side.
vi. If cardiac arrest occurs, continue cardiopulmonary resuscitation till such time as the fault is corrected, or the lead is repositioned.

Other less common causes of pacemaker failure are failure to sense, and RV perforation. Failure to sense occurs if the pacemaker continues to function at a fixed rate, even though it is set on demand mode. The commonest cause of sensing failure is a slight displacement (may be only a few millimeters) of the electrode tip; it is mandatory that the lead be repositioned immediately to avoid a potential though rare danger of ventricular tachycardia or fibrillation. Perforation of the RV by the electrode tip leads to a total loss of pacing, or frequent failure to capture and to sense, and is seen on the ECG as a marked change (>90 degrees) in the electrical axis of the pacemaker spike, or in the QRS axis of the paced ECG. Stimulation of the phrenic nerve may occur, producing contractions of the diaphragm or of the intercostal or abdominal muscles. A pericardial friction rub is heard at times; hemopericardium with cardiac tamponade is a rare complication.

CHEST TUBE DRAINAGE[11]

Intercostal tubes are used to aspirate air or fluid from the intrapleural space. At times, as in a tension pneumothorax, intercostal drainage needs to be performed as an emergency procedure. This is basically a bedside procedure which can be performed easily and safely in the ICU, and all senior resident doctors looking after ICU patients should familiarize themselves with the techniques of chest tube insertion.

Emergency Procedure

A tension pneumothorax can cause a very rapid hemodynamic deterioration, leading to cardiopulmonary collapse and death, if not relieved immediately. Inserting a chest tube may be time-consuming, and a needle should be immediately inserted to relieve the pressure. A 16 gauge angiocath (catheter-over-needle device) is inserted in the second intercostal space, anteriorly in the midclavicular line. Once the pleural space is penetrated, the air under tension is immediately released and the pneumothorax is decompressed. At this point the needle is removed, leaving the catheter in the pleural space. The catheter hub is connected to a long tubing, the other end of which is placed underwater so that the air can bubble out in a more controlled manner. This is however a temporary procedure, and preparation for an immediate chest tube placement must be made for more efficient decompression of the pnemothorax.

Drainage System

A conventional 2 or 3 bottle system is commonly used for evacuation of intrapleural air and fluid as shown in Figure 7. Each bottle is placed in a series. The first is the trap bottle which collects the fluid from the pleural space and at the same time allows air to pass through to the next bottle, i.e. the water seal bottle. This second bottle acts as a one-way valve, allowing air to escape from the pleural space, but preventing atmospheric air from entering the pleural space when negative pleural pressure is created during inspiration. The inlet tube in the second bottle is placed underwater, thereby creating a back pressure on the pleural space, which is equal to the submerged depth of the inlet tube. This back pressure, called the water seal pressure, is usually 1–2 cm of H_2O, and should ideally suffice to reinflate the lung. Further negative pressure, if required, can be provided by applying a central suction. However, for reasons of safety, a third bottle called the suction control bottle, is added in the series. This bottle has an underwater tube, which is open to the atmosphere, as shown in Figure 7. The depth of this tube column determines the safety, by setting a limit on the negative pressure that is imposed on the pleural space. For example, if this column is 15 cm under water, any negative pressure greater than –15 cm H_2O from a central suction, will result in a constant bubbling of air into the third bottle, and prevent the subatmospheric pressure from exceeding –15 cm H_2O.

Procedure for Chest Tube Insertion

A chest tube tray containing sterile drapes, local anesthetic, medium and large Kelly clamps and other material, such as sutures, antiseptic solution and dressing materials, should be

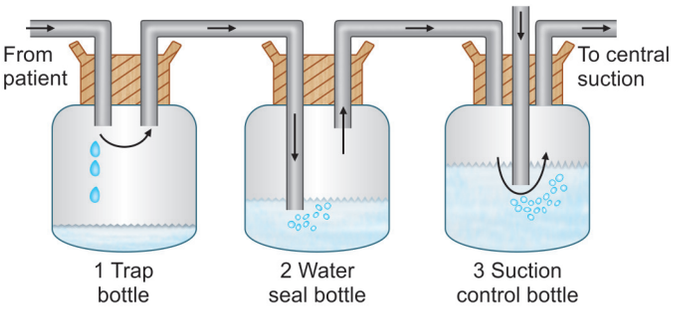

Fig. 7: Three-bottle pleural drainage system (see text for discussion) (→ = flow of air)

kept ready. Chest tubes of various sizes are available from 12 Fr to 42 Fr. Larger sized tubes are used for traumatic hemothorax or hemopneumothorax, whereas smaller tubes ranging 12–22 Fr may be used for spontaneous pneumothorax. The tube itself is made of a transparent material, with multiple side holes over the distal third of its length; there is also a radio-opaque strip at the distal end of the tube to mark its placement in the pleural space. These tubes are available in a trocar for tunneling through the intercostal space. In case these special tubes are not available, a simple Malecot's catheter may be used.

The patient should lie flat with the involved side elevated by a pillow, and arms flexed over the head. After infiltrating the skin with lidocaine (1% or 2% solution), a skin incision is made at the appropriate site of tube insertion, which is usually in the fifth or sixth intercostal space in the anterior axillary line. Some operators prefer the second intercostal space in the midclavicular line, but the penetration of muscles and breast tissue is more difficult at this site. After incising the skin at the appropriate puncture site, the muscles and tissues are penetrated by either a blunt dissection using clamps and index finger to enter the pleural space or the tube is directly inserted with the help of a trocar. Rotating movements are used whilst advancing the tube with the trocar.

Once the pleural space is entered, the tube is advanced upward in the direction of the apex for treatment of a pneumothorax, and toward a post-basal position for drainage of fluid, with the last side hole inserted 2 or 3 mm into the chest to ensure dependent drainage. Prior to insertion, the approximate length of the tube that should lie within the thoracic cage is estimated, and the position where the tube should emerge from the chest wall is marked with a silk tie.

Once the tube is properly placed in the pleural space it is fastened to the skin with 1-0 or 2-0 silk sutures, using a mattress stitch. Before fixing the tube, ensure that the last side hole is in the pleural space. The ends of the suture are not cut, but are wrapped around the tube, and secured with a tape so that they can be used later to close the wound after the tube is removed.

Throughout the procedure the proximal end of the tube is kept clamped and is opened only when the tube is finally connected to the drainage system. The placement is confirmed by the drainage of fluid, or by the bubbling of air in the drainage bottle.

Precautions

There is no absolute contraindication for inserting a chest tube. Coagulation abnormalities however should be corrected before insertion of the tube; in case of emergency, fresh frozen plasma or platelet transfusions may be given during the procedure.

A chest tube should never be inserted at the bedside for the purpose of draining a massive hemothorax. Accumulated blood in a massive hemothorax acts as a seal preventing further bleeding from the source, and insertion of a chest tube may precipitate catastrophic hemorrhage. Hence, a massive hemothorax should always be drained in the operation theater where facilities for controlling such a bleed, if necessary with an open thoracotomy, are available.

Complications

Common complications of chest tube drainage include improper positioning of the chest tube, inadequate drainage, bleeding, nerve damage, injury to the diaphragm, infection, surgical emphysema, and problems in the drainage system. Use of the correct technique of insertion and placement, and proper chest tube management whilst the tube is in place, will go a long way in preventing most of these complications.

Incessant pain may occur after re-expansion of the lung and may evoke a vasovagal response manifesting as bradycardia or hypotension. Intercostal nerve blocks or intrapleural lidocaine may help; parenteral analgesics may be needed if pain persists. Strong sedatives should however be avoided. Another major complication is re-expansion pulmonary edema following rapid evacuation of a large, long-standing pleural collection. Symptoms usually occur within 6 hours after rapid drainage. This complication can be avoided by slow evacuation of large collections.

After Care of Chest Tube Drainage

1. The bottle should never be raised above the chest level, as fluid may drain back into the pleural space and lead to infection, or cause a drowning disaster in the presence of a bronchopleural fistula. However, if the kind of drainage system demonstrated in Figure 7 is used, this complication can be avoided, because the draining tube never comes in contact with the water in the bottle.
2. The fluid level in the tube should oscillate with each breath. Failure to oscillate may be due to blockage or a kink in the chest tube, or may be due to full expansion of the lung.
3. The intercostal tubes should always be clamped whilst changing the bottles.
4. The original level of water in the bottle should always be marked, so that hourly drainage can be measured.
5. Very high negative suction via a suction pump should be avoided. Ideally, a suction control bottle should be added to the drainage system as a safety measure, as described earlier.

Chest Tube Removal

Chest tubes should be removed when there is minimal drainage (<100 mL/24 hours), and the chest X-ray shows complete re-expansion of the lung after clamping the outside tube for 24 hours. Check X-rays of the chest should be repeated after removal of the tube. Appearance of a small pneumothorax or minimal surgical emphysema is common, and often resolves by itself.

PERICARDIOCENTESIS[12]

Pericardiocentesis carried a high risk of morbidity in the past when done as a blind procedure. However, in the last decade the incidence of complications has decreased dramatically, largely due to improved imaging and monitoring techniques. However, bedside imaging facilities are not always available, and hence each and every resident doctor working in the ICU or emergency department of a hospital, should be familiar with the technique of blind pericardiocentesis, as this is the procedure of choice in the face of a life-threatening emergency like cardiac tamponade. Cardiac tamponade occurs when increasing accumulation of pericardial fluid produces cardiac chamber compression limiting ventricular filling, and significantly compromising the stroke volume. In such a situation, blind pericardiocentesis is justified as any delay in pericardial drainage may prove fatal.

Technique of Blind Pericardiocentesis (Fig. 8)

This procedure should always be performed in an intensive care setting with continuous ECG monitoring. The three approaches to the pericardium are subxiphoid, apical and parasternal.

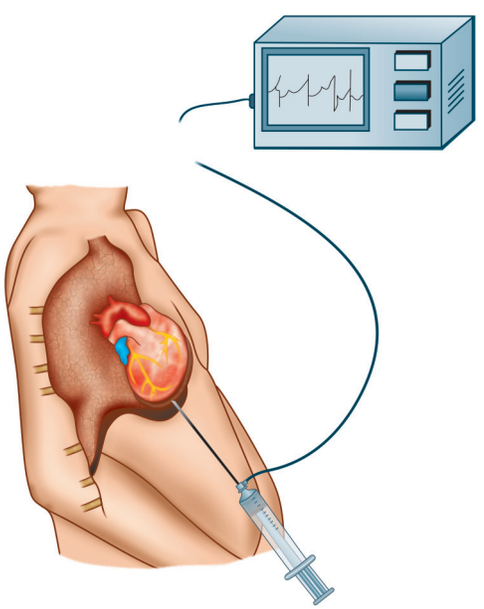

Fig. 8: Technique of blind pericardiocentesis

The *subxiphoid approach* is probably the safest as it avoids the pleura, the coronary and internal mammary arteries. The patient should be premedicated with atropine, and placed in an upright or semi-reclining position, as this allows pooling of blood inferiorly and anteriorly in the pericardial sac.

An area just left of the xiphoid tip is prepared and infiltrated with a local anesthetic. A 16–20 gauge spinal or cardiac needle attached to a syringe filled with local anesthetic is used, and the hub of the needle is connected to the V lead of an ECG via an alligator clip. The needle tip is introduced between the xiphoid and the left costal margin, so that it passes under the inner aspect of the rib cage, and the needle is then slowly advanced, with the tip pointing toward the left shoulder.

Whilst advancing the needle, a gentle suction is continuously applied to the syringe, and periodically small amounts of local anesthetic are injected. This helps to keep the needle patent, and also anesthetizes the deeper tissues. A resistance is felt on penetrating the diaphragm and pericardium. If a current of injury pattern, with ST-segment elevation, is recorded on the V lead tracing of the ECG (signifying the needle has touched the epicardium), the needle should be withdrawn slightly and readvanced in a more medial direction. Once fluid is aspirated, a soft catheter should be inserted with the help of a guidewire, and the needle withdrawn.

The apical approach is from the fourth or fifth intercostal space, 2 cm medial to the outer edge of the cardiac dullness, perpendicular to the chest wall. The needle bore is aimed at the right sternoclavicular joint. There is minimal risk of injuring the coronary arteries with this approach as there are no large vessels near the apex of the heart; however, the risk of ventricular or pulmonary lacerations are greater with this method.

The parasternal route lies 2 cm lateral to the sternum in the fifth intercostal space. The greatest danger of this approach is injury to the internal mammary artery, and hence this method carries a significantly greater morbidity than the two other approaches described earlier.

INTRA-AORTIC BALLOON PUMP[13]

Intra-aortic balloon pump (IABP) is the only accepted method of mechanical circulatory assistance available at present. It is now being increasingly used for sustaining patients with potentially reversible cardiac problems affecting the pumping function of the LV, when pharmacological therapy has failed to restore adequate coronary artery and systemic perfusion. The goal of balloon assistance is to provide temporary support to the LV when corrective surgery is planned in the near future, or spontaneous ventricular recovery is anticipated.

Intra-aortic balloon pump works on the principle that a balloon catheter inserted in the thoracic aorta inflates during diastole, and deflates during systole. The inflation improves diastolic-dependent coronary perfusion and myocardial

oxygen consumption, whereas the sudden deflation occurring in systole decreases the aortic end-diastolic pressure and lessens the workload on the LV, thereby decreasing the myocardial oxygen demand. Common indications for the use of IABP are—

- Immediate postoperative support after CABG surgery or other open heart surgery.
- Inpatients with unstable angina or impending infarction who are refractory to medical therapy and are awaiting bypass surgery.
- In acute myocardial infarction with cardiogenic shock.
- In patients with mechanical complications of acute myocardial infarction, which warrant surgical intervention, e.g. acute ventricular septal rupture, papillary muscle dysfunction or rupture.
- In patients with high risk for PTCA.
- In hemodynamically unstable patients who are awaiting surgery after a failed angioplasty.

Absolute contraindications for the use of IABP are dissecting aortic aneurysms, aortic regurgitation, irreversible brain damage and end-stage heart disease.

Equipment and Procedure

The two basic equipments required for this procedure are: (1) a drive unit and (2) intra-aortic balloon catheters. The operation of a drive unit is based on recognition of the variability of the interval between the electrical and mechanical events of the cardiac cycle. Hence, the precise timing of both inflation and deflation in relation to the events of the cardiac cycle becomes the most important function of the drive unit. The large-bore catheter has a 30 cm long polyurethane balloon wrapped tightly around its intra-aortic end, and has two concentric lumens running through its length. The central lumen leads to the catheter tip allowing a J tip safety guidewire that helps to introduce the balloon. This central lumen also allows recording of critical arterial pressure in the proximity of the balloon tip, thus eliminating the need of a separate arterial pressure line to obtain waveforms required for balloon pump timing. Concentric to the central lumen is the helium channel, through which the balloon is inflated with helium to a capacity of 30–40 mL.

Before selecting the groin through which the balloon catheter is to inserted, all the pulses in both lower extremities are compared and graded, and the leg with the greater pulse velocity is selected. A Swan-Ganz thermodilution catheter, and an intra-arterial line to record arterial waveforms, should also be inserted. However, separate arterial lines may not be necessary in most catheters, which allow intra-aortic waveform recording through their central lumen. The entire balloon device is inserted into the femoral artery at the groin, either percutaneously or by performing an arteriotomy. The balloon is then advanced up the aorta until the tip lies 1 cm below the origin of the left subclavian artery. Fluoroscopic guidance should be used whenever available, as it assures more precise placement.

Complications

The most commonly encountered complications in order of frequency are vascular (limb ischemia), infections, failure to place the balloon catheter, and bleeding.

Weaning

The balloon assistance should be withdrawn gradually by either decreasing the frequency of balloon inflations per cardiac cycle, or by stepwise reduction in the volume of the balloon. Weaning can usually be completed within 60 minutes provided the patient remains hemodynamically stable. If the patient's condition deteriorates, full volume IABP is resumed, and weaning may be reattempted after 6–24 hours.

INTRACRANIAL PRESSURE MONITORING

(Also see Raised Intracranial Pressure of Chapter Neurological Problems).

Indications[14]

Traumatic brain injury if Glasgow Coma Score less than 8 (after resuscitation). In addition, there should be evidence of an abnormal CT scan or in case the CT scan is normal, two or more of the following should be present—(a) age greater than 40 years; (b) unilateral or bilateral posturing; (c) systolic blood pressure greater than 90 mm Hg.

In patients with metabolic and other causes known to cause elevated intracranial pressure, such as subarachnoid hemorrhage, stroke, intracranial mass, hydrocephalus, hepatic encephalopathy and coma, poisonings.

Methods

Intracranial pressure (ICP) monitoring can be done by three methods—

1. Ventriculostomy with intraventricular catheter (IVC).
2. Subarachnoid catheter.
3. Subdural bolt.

Ventriculostomy

In this technique, an IVC can be placed through a craniostomy in the operation theater, or by a twist-drill ventriculostomy in the OT or in the ICU. The most preferred side is the posterior frontal lobe of the non-dominant hemisphere, and the catheter is passed through the brain to a depth of 6–8 cm. On finding CSF, the IVC is attached to a three-way stopcock that leads to a pressure transducer through one port and an external drainage system through another. The pressure transducer is connected to a monitor, which provides continuous digital and waveform display of the ICP.

The ICP baseline gently dips up and down with respiratory or ventilatory excursions. Zeroing of the pressure transducer should be done at the level of the external auditory meatus.

The IVC is the most accurate method of measuring ICP.[15] It can also be safely used to slowly drain CSF from the ventricles. However, it is difficult to perform in cases of head trauma as the ventricles are shrunken in size and the catheter is then left in the brain parenchyma. The main disadvantage is that it is more invasive and there are increased chances of infection. Most units use prophylactic antibiotics when IVCs are used.

Subarachnoid Catheters

A subdural catheter can be inserted into the subarachnoid space inside the skull by the same technique described for IVCs. This method can be used to monitor the ICP but not for drainage of CSF.

For one-time measurement of ICP, a catheter into the subarachnoid space in the L3–L4 space can be used, provided obstructive hydrocephalus has been ruled out by imaging techniques. However, CSF cannot be drained by this method.

Subdural Bolt

In this technique, a hollow self-tapping bolt is inserted into a burr hole in the skull at the bedside, and the dura at the base of the bolt is perforated with a spinal needle, so that CSF fills the bolt. Pressure tubing filled with saline is then connected to the bolt and communication with an external transducer is established.

This technique is used when the first two techniques are difficult. Also, this method is associated with a lower infection rate as compared to ventriculostomy. However, this method cannot be used for drainage of CSF.

Fiberoptic ICP monitors, which use miniature transducers incorporated into their ends can also be used to measure ICP.

Several parameters, such as cerebral blood flow velocity (CBFV) in different parts of the brain circulation, measured through the use of transcranial Doppler, have been suggested for estimating the ICP noninvasively.[16] However, as yet, none of these methods are reliable enough to substitute for invasive ICP monitoring.

CHAPTER 7

Cardiac Monitoring in Adults

JD Sunavala *MD, FCCP. Consultant Physician, Breach Candy Hospital, Jaslok Hospital and Parsee General Hospital, Mumbai, Maharashtra, India*

GENERAL CONSIDERATIONS

The most important aspect of cardiac monitoring is frequent clinical assessment, which includes physical examination and intelligent observation. Proper evaluation of important symptoms, such as chest pain, dyspnea, cough and monitoring of vital signs, is of prime diagnostic value in emergency situations. Accurate inspection of the jugular veins in the neck can give a good idea of the central venous pressure (CVP) in the absence of a central venous catheter. This clinical observation should also be used frequently to countercheck the reliability of any invasive CVP measurement. Repeated chest auscultation is essential to rule out signs of early pulmonary edema. Monitoring of urine output is imperative for the assessment of renal perfusion. Relevant blood tests and routine chest X-rays though essential aspects of cardiac monitoring are beyond the scope of this chapter, which focuses mainly on monitoring techniques, which involve instrumentation. These include: (i) ECG monitoring; (ii) invasive hemodynamic monitoring; (iii) noninvasive or minimally invasive methods of hemodynamic monitoring using various modalities; (iv) assessment of volume responsiveness; (v) discussion on hemodynamic variables, pulse wave analysis and their clinical applications.

ECG MONITORING[1]

Bedside detection of cardiac arrhythmias, and of ST segment changes to some extent, are the most important objectives of continuous ECG monitoring. There are certain technical details to be observed for skin preparation and electrode placement in order to ensure the accuracy and the optimal benefit from the graphic information. Shaving and careful skin preparation to achieve proper electrode contact is essential. Further, electrodes should be so placed that they do not interfere with physical examination, the recording of a 12-lead ECG, or the use of a defibrillator. Electrode wires should always be checked for breaks or fractures, as this may result in artifacts.

Selection of the Monitoring Leads

With the advent of complicated cardiac surgeries, invasive interventions, such as angioplasties, electrophysiological studies and implantation of technologically advanced pacemakers; the goals of ECG monitoring have expanded beyond the simple heart rate and basic rhythm to the detection and diagnosis of various complex arrhythmias. The standard 12-lead ECG is not practical for continuous patient monitoring. Hence, electrode placements at alternative sites are used. These offer various advantages such as: (i) minimizing the number of electrodes; (ii) wider chest space available for auscultation and defibrillation; (iii) improved detection of certain complex arrhythmias, ST segment shifts and correct measurements of QT intervals.

The current monitors provide 3-lead or 5-lead trunk cables but the *EASI*[2] lead configuration used by many workers is an alternative to the commonly used 5-electrode or the Mason-Likar lead monitoring system. The EASI system enables continuous 12-lead ECG monitoring using only five electrodes (four recording electrodes and one grounding electrode). In this EASI system, the E lead is placed in the inferior most aspect of the sternum. A and I are placed on the left and right mid-axillary line respectively and S is placed on the sternum manubrium. The 5th lead, which is the grounding electrode can be placed anywhere on the torso. The cable trunk has a

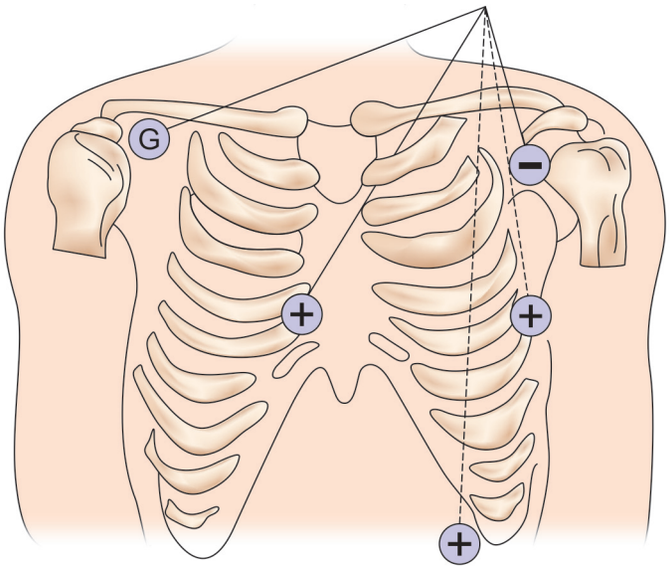

Fig. 1: MCL_1 hook-up shown by uninterrupted lines representing positive, negative and ground electrodes. MCL_6 and M_3 are obtained by simply changing the positive electrode from the V_1 position to the two positions as shown by broken lines, leaving the negative and ground electrodes undisturbed

color coding of the individual electrodes. In comparison with the 12-lead electrodes, there was 100% agreement for rhythm identification; however, because of the differing amplitudes between the EASI and standard ECG systems, chamber size did not compare well. The major advantages of this system are the easy and rapid application of the leads, with improved patient comfort and least waveform interference and it also has excellent reproducibility for serial comparisons.

Further, innovations have been tried with some special lead configurations. The modified CL_1 (MCL_1) hook-up (Fig. 1) has been the most popular lead used for monitoring since many years and is a simple, excellent alternative, which gives similar information to V_1. The V_1 or MCL_1 lead is excellent for studying atrial activity by displaying well formed P waves and also for the study of QRS complexes. Here the positive electrode is placed at the V_1 position, the negative electrode at the left shoulder, and the ground electrode may be placed at any site, but is usually placed at the right shoulder. As seen in Figure 1, this leaves sufficient space over the precordium for physical examination and for emergency cardioversion. In addition, since it closely resembles V_1, this lead offers several diagnostic advantages—

- It displays well-formed P waves.
- It is easy to distinguish between left bundle branch block (LBBB) and right bundle branch block (RBBB).
- It is the best lead for distinguishing between a ventricular ectopic originating from the left ventricle (LV) with a positive QRS deflection, and one originating from the right ventricle with a negative QRS deflection.

More information can be provided by using a left chest lead MCL_6 (which simulates V_6), or M_3 (modified lead III). This can be easily done without disconnecting the entire MCL_1 hook-up as shown in the Figure 1. Lead V_6 or MCL_6 is an important lead for differentiating between aberration and ectopy whenever V_1 fails to reveal this. A sinus beat in V_6 always begins with a small q wave; disappearance of this q wave with onset of tachycardia, is characteristic of left ventricular tachycardia rather than sinus tachycardia with aberrance. V_6 or MCL_6 is also very useful in monitoring ischemic ST segment changes, especially in patients with unstable angina, as this lead represents the main left ventricular free wall.

In rare instances when one wants to demonstrate the polarity of the P wave, M_3 (which simulates Lead III), will have to be used. For instance a retrograde P wave will show up clearly in M_3 in case of a junctional rhythm, whereas both sinus and retrograde P waves are predominantly positive in MCL_1.

This easy method of changing leads comes handy in monitoring pacemaker patients, as one lead may not show a pacemaker artifact; however, on changing the lead configuration, this will become clearly evident. This is more useful during bipolar pacing, where the pacemaker spikes or artifacts are not as prominent as in unipolar pacing.

As recognition of the P wave is the key to diagnosis of arrhythmias in bedside monitoring, all efforts should be made to magnify the P wave so as to render it easily recognizable. Certain invasive methods, such as inserting intra-atrial electrode catheters or *esophageal electrodes*, can greatly enhance the P wave, which may have been virtually indiscernible with surface leads. However, these forms of monitoring may not be feasible, particularly in very sick patients, and another noninvasive special lead, viz. S_5 should be tried. This was first introduced by French cardiologists, and is easily obtained by placing the positive electrode in the fifth intercostal space close to the sternum (just below V_1 position), and the negative electrode on the manubrium of the sternum. This lead may sometimes succeed in magnifying the P wave, and if so, it is preferable to invasive means of monitoring.

At times, it would be interesting to study lead *aVR* or any other lead which shows the smallest ventricular complex as elusive P waves or small pacemaker spikes are often more prominently seen in these leads, provided there is minimum baseline disturbance.

ECG Monitoring in Pacemaker Implanted Patients

Pacemaker malfunction of temporary pacing and of the basic single chamber implanted pacemaker have been described in the previous chapter. However, present day devices, like AV synchronous or biventricular pacemakers, need various lead configurations to decipher the small pacing spikes and waveform configurations for detailed analysis. Often a 12-lead ECG may have to be taken frequently for this purpose.

Unlike in ventricular pacing where pacemaker spike precedes the QRS complex which has an LBBB configuration, in atrial pacing, it precedes the P wave and the P wave morphology may change depending on the location of the atrial lead but the PR interval and the configuration of the QRS complex are independent of the atrial pacemaker and are determined by the intrinsic characteristics of the patients

conduction system. Fusion beats show a QRS morphology that is in between the native and paced QRS complex. A pseudofusion is shown by a pacing spike appearing just after the beginning of a native QRS complex giving the appearance of a pacing capture. However, here, as the pacing stimulus is delivered during the refractory period, it does not capture the heart.

In AV sequential pacing, the pacemaker spikes are seen before the P wave and QRS complex. If, however, the inherent atrial rate is faster than the programmed lower rate of the pacemaker, there will be no pacing spike seen prior to the P wave as the P wave originates from the sinus node or from an ectopic atrial focus. The QRS morphology will however depend on the programming of the pacemaker device and atrioventricular conduction and may represent either a paced QRS morphology or a morphology of a normal beat.

In biventricular pacing also known as cardiac resynchronization therapy (CRT) the pacing leads are placed in the right atrium, right ventricle and coronary sinus (pacing the LV). Hence, the QRS complex will show an indeterminate bundle branch block morphology or could even be narrow in configuration.

Pacemaker malfunction due to loss of captures is recognized on the ECG by absence of P wave or a QRS complex following a pacemaker spike. Non-capture could be intermittent or persistent. Pacemaker malfunction can also occur due to undersensing or oversensing of intrinsic cardiac activity. In undersensing where the pacemaker fails to sense the native electrical signal there will be a pacing spike with or without a capture depending on the refractoriness of the tissue and which will have no relation to the underlying cardiac activity. Oversensing usually occurs with unipolar leads when pacemaker senses far field external signals not arising from the representative cardiac chamber. In oversensing, the device inhibits pacing resulting in asystole unless there is an intrinsic cardiac activity. This can occur due to electromagnetic interference such as from electrocautery or interference from electrical myopotentials produced from the diaphragm or pectoral muscles.

HEMODYNAMIC MONITORING

Hemodynamic monitoring is in essence an invasive method of monitoring arterial, central venous and pulmonary artery pressures (PAPs). Measurement of cardiac output (CO) and saturation of oxygen in mixed venous blood ($S\bar{v}O_2$) are other important aspects of hemodynamic monitoring. With the information gained from the above parameters, one can calculate the ventricular work load, vascular resistances, oxygen transport (DO_2), and oxygen consumption ($\dot{V}O_2$); this data can be extremely useful in the management of critically ill patients. However, mere numerical values are of limited value, and a balanced clinical approach in the interpretation and application of these values cannot be overemphasized. Further, as doctors caring for seriously ill patients, we witness life at its most poignant, intimate and critical moments. It is thus obligatory, that we learn to use these invasive techniques with sensitivity and skill.

There are varied indications for hemodynamic monitoring which will be discussed under the appropriate procedures. Traditionally, hemodynamic monitoring is synonymous with pulmonary artery catheterization and thermodilution method of measuring CO which, however, remains the gold standard against which other methods are validated.[3] Today with the advent of new technology less invasive methods are available which are also capable of measuring continuous CO beat by beat, using several pulse contour devices. However, the fundamental goal of monitoring remains constant—the early detection, and the prompt restoration to normal of inadequate perfusion. Various invasive and minimally invasive monitoring systems available are highlighted in Table 1.

PRESSURE MONITORING SYSTEM

The equipment required for direct pressure monitoring consists of three main components: (1) the transducer, (2) pressure lines and (3) the pressure monitor (Fig. 2).

A transducer is a device that converts the mechanical energy created by the arterial or venous pressure waves into electrical energy, which in turn gets displayed on the monitor as a waveform. Most transducers available are strain gauge devices or quartz transducers. Quartz transducers are more frequently used today as they are conveniently designed, more durable, and less affected by ambient conditions. The latest in transducer technology are the disposable or single-use units, and most of these are modifications of strain gauge devices.[4]

Pressure lines include the tubings, connecting stopcocks, the pressure infusor bag and a continuous flush valve device also commonly known as intraflo.

The pressure infusor bag is a hollow pressure bag wrapped around a heparinized saline intravenous bag, which can be inflated to high pressures. Intraflo is a flushing device, which under constant pressure (around 300 mm Hg) assures a continuous flow of heparinized solution at a rate of 3 mL/hour through the system. This prevents clotting and backflow, and also provides for the manual flushing of the fluid column as and when necessary.

The pressure monitor is an amplifier system which can display waveforms and digital readouts on a screen, in addition to having recording facilities. With improving technology, the bedside pressure monitors available today are highly sophisticated, significantly smaller in size and extremely reliable. Even so, monitors may not always be 100% accurate; in fact, one recent study has shown that errors of 5–10 mm Hg are frequent, and gross errors of 30–40 mm Hg are not uncommon. In order to minimize such errors and obtain accurate pressure data, the ICU personnel must familiarize themselves with the equipment, and be able to set up the system with accuracy and speed; they should also be competent in detecting and solving problems encountered during monitoring.

Table 1: An overview of hemodynamic monitoring modalities

Modality	*Device*	*Features and requirements*	*Variables monitored and derived*
Invasive—			
• Pulmonary artery catheterization and thermodilution technique	Edwards Lifesciences	PAC and thermodilution catheter, specific transducer and pressure plus CO monitor	CO, PCWP, CVP, RAP, RVP, PAP, SVR, PVR, SV, LV-SW, RV-SW, DO_2, $S\dot{v}O_2$, O_2ER
Less invasive, minimally invasive and noninvasive—			
• CVP	Edward Lifesciences, Arrow, etc.	Seldinger introduction set	CVP
• MvO_2	Edward Lifesciences	Continuous CO monitor and PAC	CCO, MvO_2
• $S\dot{c}VO_2$	Edward Lifesciences	Continuous CO monitor and CVP line	CCO, $S\dot{c}VO_2$
Pulse pressure analysis—			
• Calibrated	PiCCOplus	Thermistor-tipped arterial cath and CV line	CCO, SVV, CVP, PPV, GEDV, EVLW
	LiDCOplus	Lithium dilution set and arterial cath and CV line	CCO, SVV, PPV, CVP
	EV1000/Volume view	Thermistor-tipped arterial cath and CV line	CCO, SVV, CVP, GEDV, EVLW
• Uncalibrated	LiDCOrapid	Arterial cath	CCO, SVV, PPV
	FloTrac/Vigileo	Arterial cath	CCO, SVV
• Noninvasive	Nexfin	Finger pressure cuff	CCO, SVV, PPV
Doppler—			
• TOE	CardioQ/CardioQ-ODM (Deltex medical)	Esophageal probe	CCO
• TTE	USCOM (Australia)	Transthoracic probe	CO(I)
Applied fick principle—			
• Partial CO_2 rebreathing	NICO (Novametrix)	Rebreathing loop	CO every 3 min.
• Dye dilution	DDG analyzer (Nihon Kohden)	Specific cauteneous sensor	CO(I)
Bioimpedance/bioreactance—			
• Endotracheal bioimpedance	ECOM (Conmed corp)	Specific endotracheal tube and arterial cath	CCO
• Thoracic/whole body impedance	BioZ (Cardio dynamics)	Specific electrodes	CCO
• Thoracic bioreactance	NICOM (Cheetah med)	Specific electrodes	CCO, SVV
• Plethysmographic variability (noninvasive)	MASSIMO	Specific transcutaneous probe	PVI

Abbreviations: CO, cardiac output; CO(I), intermittent CO; CCO, continuous CO; CVP, central venous pressure; RAP, right atrial pressure; RVP, right ventricular pressure; PAP, pulmonary arterial pressure; PCWP, pulmonary capillary wedge pressure; SVR, systemic vascular resistance; PVR, pulmonary vascular resistance; SV, stroke volume; LVSW, left ventricular stroke wall; DO_2, O_2 delivery; MvO_2, mixed venous SaO_2; $S\dot{c}VO_2$, central venous SaO_2; O_2ER, oxygen extraction ratio; PPV, pulse pressure variation; SVV, stroke volume variation; GEDV, global and diastolic volume; EVLW, extra vascular lung water; PVI, plethymographic variation index; TOE, transesophageal; TTE, transthoracic echo; SvO_2, saturation of mixed venous oxygen.

Assembly and Calibration of the Monitoring System

The pressure monitoring system is assembled as shown in Figure 2. Care should be taken to remove all air bubbles from the tubings and the dome of the diaphragm whilst setting up the pressure lines. The extension tube connecting the intraflo to the catheter should be a stiff, non-distensible pressure tubing of approximately 100 cm length. Once the system is connected and ready for monitoring, it should be balanced, calibrated and placed at the correct reference point.

Reference point There is always a hydrostatic pressure gradient in a fluid-filled system, consisting of blood in the vessels interfaced with a column of saline in the catheter, tubings and transducer. For instance, if the transducer is manually raised or lowered, there are bound to be changes

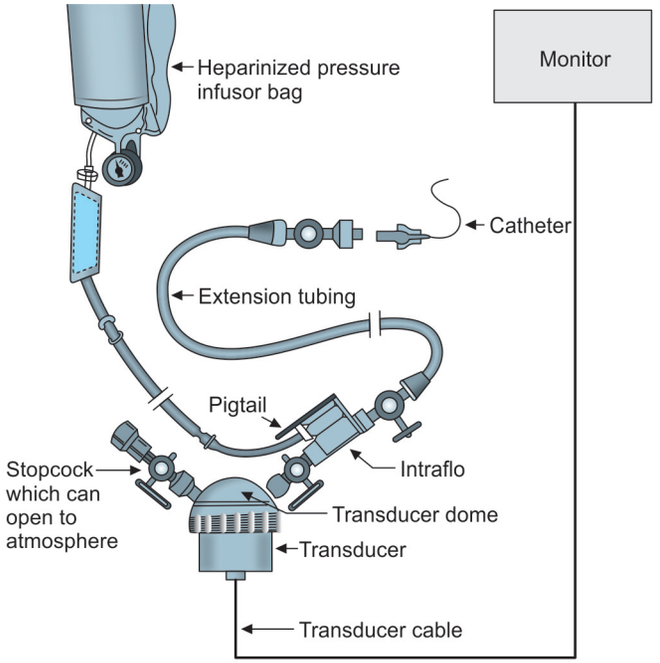

Fig. 2: Assembly of the pressure monitoring system

in pressure recordings, proportional to the weight of the fluid column applied to the transducer diaphragm. In order to eliminate this undesired pressure head, the transducer diaphragm and the catheter tip, which are considered as two ends of the pressure line, should always remain exactly at the same level. By convention, we relate central hemodynamic pressures to the level of the heart, or more specifically to the mid left atrium (LA), at which level the catheter tip is supposed to lie. For a patient in the supine position, the mid-chest level is accepted as a reference line approximating the left atrial level. However, whilst nursing patients in semi-upright positions, an exact point of reference becomes necessary. This is represented by a point on the mid-axillary line at the level of the fourth intercostal space. Before beginning zero referencing procedures, the transducer must be placed at this appropriate reference point, called the zero reference point. This is the accepted reference point for measurement of PAPs and CVP monitoring; however, in case of arterial monitoring the transducer should be at the level of the cannulated artery, which should also be at the heart level.

The exact procedure for zero referencing or balancing is shown in Box 1. The transducer calibration procedure tests the transducer by exposing it to a known pressure (Hg manometer), unlike zero referencing, which balances the transducer output with the atmospheric pressure.

Eliciting of a waveform response (Fig. 3) is another rapid bedside method of checking the integrity of the monitoring system. Normally on pulling and releasing the pigtail of the intraflo, the waveform on the monitor shows a rapid rise with an equally rapid return to a point below the baseline (undershoot), followed by a short period of oscillations. If this return to the baseline is slow with inadequate oscillations,

Box 1: Zero referencing procedure

- Place the transducer dome at the level of the zero reference point
- Adjust the two transducer stopcocks so that one is open to the atmosphere, and the other closed toward the patient
- The digital readout and oscilloscope display on the screen should now both read 0 mm Hg
- If they do not, follow the particular machine instructions so as to achieve a zero balance
- Once properly zeroed, close the stopcock which is exposed to the atmosphere, and open the line to the patient. The waveform that follows is now ready for interpretation

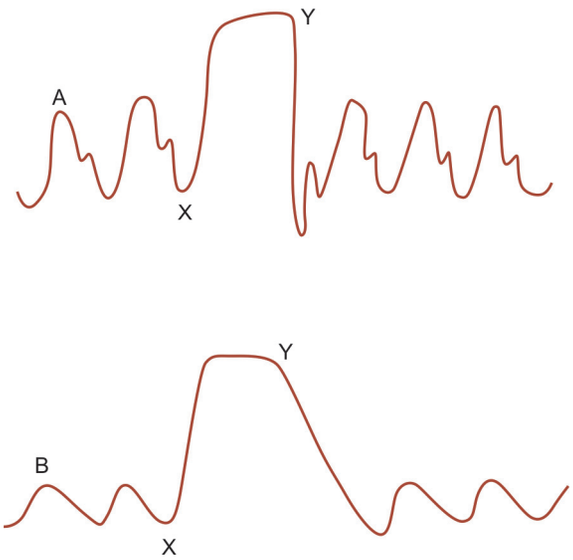

Fig. 3: Eliciting a waveform response at the bedside
A = normal waveform response
B = dampened waveform response
X = intraflo activated by pulling the pigtail
Y = release of pigtail

it suggests some sort of occlusion in the tubing or catheter, which needs to be looked into.

Common Problems Related to Monitoring Systems

Distortion of the waveform, questionable pressure readouts, and artifacts are three common problems encountered whilst dealing with pressure monitoring systems, irrespective of venous or arterial catheterizations. Table 2 enumerates the causes, and gives guidelines for solving most of these problems. Some general precautions, which need to be taken for smooth and uncomplicated monitoring are listed in Box 2.

ARTERIAL PRESSURE MONITORING[5]

The techniques and complications of arterial cannulation are described in the Chapter Procedures in the Intensive Care Unit.

Arterial pressure monitoring is initiated in all patients with compromised hemodynamic status. In these cases, the cuff

Table 2: Trouble-shooting guide for pressure monitoring systems

Problems	*Check and correct*
Waveform related problems—	
No Waveform	Power supply, calibration and balancing, loose connections, clots in the tubings, stopcock direction, broken catheter, catheter tip abutting against the vessel wall
Over-dampened waveforms	Air bubbles in the pressure lines, kinks or clots in the tubings, catheter tip abutting against the vessel wall
Questionable pressure readings	Balancing and calibration, reference level of transducer, loose connections in the pressure lines, faulty intraflo
Artefacts	Patient movements, respiratory movements, electrical interference, catheter whip artifact

Box 2: General precautions and care of pressure lines during monitoring

- Employ aseptic technique at all times
- Select uncomplicated monitoring kits (avoid long pressure lines or too many interconnecting tubes, in order to eliminate kinks, leaks and air bubbles)
- Once system is in use, avoid disconnecting the line for any reason
- Avoid blood collection and administration of IV drugs through these catheters
- Avoid use of sharp instruments when removing dressings around the catheter site
- Do zero referencing at the beginning of the procedure, and each time following interruption of continuous monitoring, whatever the reason. In any case, it is recommended that zero referencing be done 3–4 times a day

method of recording blood pressure is likely to be inaccurate as Korotkoff's sounds are less audible at low flow rates. It is also indicated in severely vasoconstricted patients, and in patients being treated with vasoactive or antihypertensive drugs, which require careful titration of dosage to avoid precipitous changes in arterial blood pressure.

The radial artery is usually the preferred site for placement of an arterial catheter, provided that the adequacy of collaterals to the ulnar artery has been assessed and determined to be sufficient by the Allen's test (see Chapter Procedures in the Intensive Care Unit). In addition to the fact that the hand receives a generous collateral circulation, the radial artery is superficial, compressible and easily accessible. Cannulation of the artery involves little or no risk to neighboring anatomical structures, and above all the surrounding skin area can be easily kept clean. The only drawback of the radial artery is its relatively small size which may limit the success of cannulation. For proper monitoring the placement catheter should be inserted right up to the hub to avoid kinking, and the wrist should be maintained in a neutral position.

The brachial, axillary and femoral arteries are other possible sites for cannulation, but they should never be the first choice for arterial catheterization as they have many disadvantages, and more serious complications may ensue.

During intra-arterial monitoring, the catheter should be properly secured to avoid accidental disconnection resulting in significant blood loss. Silent bleeds or oozing within the tissue spaces, which are most common following femoral punctures, may lead to huge hematomas. Aseptic measures should be strictly followed during catheterization, subsequent manipulation and blood sampling.

The extremity distal to the catheter site should be frequently assessed for adequacy of blood flow, and neurological integrity. The pressure infusor bag should always be pumped to a level higher than the systolic pressure so as to prevent reverse blood flow in the catheter, and prevent embolization at a peripheral site.

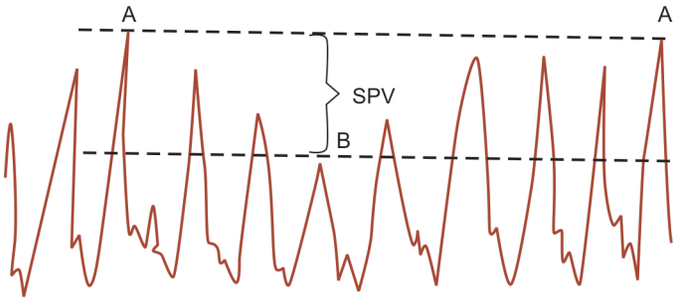

Fig. 4: Systolic pressure variation. **A** is the maximum systolic pressure and **B** is the minimum systolic pressure during one ventilatory cycle (A-A')

Waveform Interpretation and Clinical Applications (Fig. 4)

The normal arterial pressure produces a characteristic waveform, which has two main components. The initial upstroke (anacrotic limb) represents the rapid ejection of blood from the ventricle through the open aortic valve, the peak value representing the systolic pressure. This is followed by the downward trend (dicrotic limb) as the pressure begins to fall. This fall in pressure continues till it reaches a point where the pressure in the ventricle is less than the pressure in the aortic root; the aortic valve closes at this point, producing a characteristic dicrotic notch in the descending limb of the waveform. The closure of the aortic valve signals the onset of diastole, which progresses till it reaches its lowest resting level. The value at this level represents the diastolic pressure.

The configuration of the waveform and the actual pressure measurements vary depending on the catheterization site. Arteries more distal from the aorta show higher systolic and lower diastolic pressures; hence, systolic and diastolic pressures in the peripheral arteries may not be an accurate reflection of the pressure in the aorta. However, the mean pressure remains relatively constant irrespective of the anatomical site of catheterization, and it is this value which is most commonly used to derive various hemodynamic parameters. The mean pressure is measured electronically

Table 3: Advantages and disadvantages of various central venous sites

Site	*Advantages*	*Disadvantages*
Subclavian	• Accessible and secure • Affords unrestricted patient movements • Easy to keep the area sterile and maintain intact dressing • Allows very rapid flow	• Likely complications— – Pneumothorax – Injury to subclavian artery – Hemothorax • Operator skill—advanced • Difficult to compress if bleeding occurs
Internal jugular	• Low risk of pneumothorax • Short and direct pathway to the RA • Unrestricted arm movement • Allows very rapid flow	• Likely complications— – Injury to common carotid artery or trachea – Operator skill—advanced; more difficult in patients with short neck – Restriction of neck movement – Landmarks not very clear
Femoral	• Operator skill-easier techniques with high success rate • Most useful for emergency pacing as it is fastest pathway to the RV apex	• Likely complications— – High infection rate – Ischemia of lower limb • Difficult to maintain a sterile intact dressing
Antecubital site	• No major complications	• Difficult to advance the catheter • Restricted arm movements • Thrombophlebitis

by dividing the area under the arterial waveform by the duration of the cardiac cycle. Mean pressure can also be estimated manually as the diastolic pressure and one-third the pulse pressure, but this estimate is often unreliable, and it is preferable to use the electronically derived measurement.

The size and configuration of the waveform can be altered due to abnormal physiological conditions such as severe hypertension, shock and aortic stenosis. Careful observation of the waveform are useful to the extent that they may roughly indicate changes in the hemodynamic status, depending on changes in an individual's waveforms over a period of time; however, mere interpretation of a waveform at a specific point in time cannot reflect on the patient's cardiovascular status, and may be most misleading. Interestingly, Parel and coworkers[6] had observed in their study in 1987 that significant systolic pressure variation (SPV) occurs during positive pressure ventilation which is discussed later in this chapter.

CENTRAL VENOUS PRESSURE MONITORING[7]

Central venous catheterization (see Chapter Procedures in the Intensive Care Unit) provides venous access to one of the central veins, and can be used to monitor the CVP. Various anatomical sites may be used to insert the catheter into the central vein. The advantages and disadvantages of the more commonly used sites are listed in Table 3. We find that the internal jugular and subclavian sites are ideally suited for long-term monitoring.

The actual measurement can be done by using a simple water manometer or attaching the central line to a transducer. *Water manometer technique* is a simple bedside procedure, which does not require any sophisticated equipment. The central venous catheter is connected to a three-way stopcock via an extension tubing which in turn is connected to a pre-calibrated manometer placed on a stand. The level of CVP is read by observing the descent of the fluid column in the manometer, which is in direct continuity with the blood in the central veins. The descent eventually stabilizes and the reading at this level is the CVP measurement (in cm of H_2O). Marked respiratory fluctuations in the fluid level are expected, and in fact, the patient is at times encouraged to cough or breathe deeply to confirm the catheter placement in a central vein. However, most ICUs today use a *transducer monitoring technique* whereby the proximal end of the CVP line is connected directly to a pressure transducer and a continuous digital recording and a waveform of RA pressure is obtained on the monitor.

Clinical Application

The mean pressure in the right atrium is 0–6 mm Hg (using a transducer monitoring system), and 3–8 cm of H_2O (when using a simple water manometer), the conversion being 1 mm Hg = 1.36 cm of H_2O. The CVP catheter may be placed in the superior vena cava instead of the RA because it accurately reflects the right atrial pressure and waveforms. Placing the catheter tip in the right atrial cavity may inadvertently cause the tip to negotiate the tricuspid valve and momentarily record the higher RV pressure; this may also result in ventricular premature contractions (VPCs). However, in the case of a pulmonary artery catheter (PAC), the proximal port would automatically lie in the RA.

The CVP or RA pressure reflects the right ventricular end-diastolic pressure (RVEDP). Ordinarily in healthy individuals the RVEDP and the left ventricular end-diastolic pressure (LVEDP) correlate rather well. Therefore, in a young person with normal cardiac function, the CVP correlates well with the LV filling pressure, and can be used as a guideline for

monitoring the LV preload during fluid therapy. However, in clinical practice, it is fallacious to assume that the CVP is a good guide to LV filling pressure in all cases; in fact, there may be a disparity between the right and left ventricular function in critically ill patients, for more than one reason. This disparity can occur in patients with isolated right ventricular dysfunction caused by tricuspid or pulmonary valve defects, right ventricular infarcts or pulmonary hypertension. In all these conditions, the CVP will be high, and will not correctly reflect the LV preload. It can also occur in patients with isolated LV dysfunction in which case the CVP will remain within normal limits and will not reflect the high LVEDP. Because of this frequent disparity between right and left ventricular functions in critically ill patients, CVP readings should be interpreted with circumspection.[8]

A CVP reading can be most misleading if it is interpreted as an isolated reading. In order to obtain maximum benefits, serial measurements over a period of time should be studied and correlated with the patient's clinical state. This is most important when considering fluid replacement in elderly patients suspected of having cardiac dysfunction. In such patients, small amounts of fluid challenge should be given whilst closely monitoring the rise in CVP. If there is a sharp rise, further fluid challenge should be withheld, or given very cautiously. Also, in such patients, a CVP value even in the lower limit of normal should be accepted as the endpoint, provided there is a significant clinical improvement in perfusion. If this is practised meticulously, CVP monitoring can be a safe alternative in the absence of a PAC.

There are several other limitations to the use of CVP, for instance, if the venous tone is increased in severe hypovolemia, the CVP may not fall in proportion to the fluid loss. Similarly patients on mechanical ventilator support may show falsely elevated CVP values due to raised intrathoracic pressure. Falsely raised CVP values may also occur with external compression of the vena cava because of a tumor mass, or due to increased intra-abdominal pressure.

PULMONARY ARTERY (PA) PRESSURE MONITORING[9-11]

As the LV is primarily responsible for the forward flow of blood perfusing the vital organs, it is logical to assume that an accurate means of measuring the LV function would be the most essential part of critical care monitoring. Though clinical findings such as tachypnea, moist lung sounds, or gallop rhythm are common manifestations of LV failure, unfortunately they are not sensitive indicators of rapidly deteriorating LV function. They may appear late in the natural history of the disease, and vital time may be lost before the hemodynamic disturbance is corrected.[10] Measurement of the LV filling pressure (or LVEDP) without actually entering the left side of the heart was first made possible by the discovery of a flow-directed PAC by Swan and Ganz in 1970. Here the catheter tip with an inflated balloon just proximal to it was floated far into one of the branches of the pulmonary artery and wedged, so that the catheter tip was in direct continuity with the LA via the pulmonary veins, and hence reflected the LA pressure which was the same as LVEDP, provided there was no LV inflow obstruction. In addition, the PAC could measure the RA pressure through its proximal lumen, and the CO could also be measured by the thermo-dilution technique. Further, mixed venous blood could be collected from the distal lumen of the catheter for assessment of $P\bar{v}O_2$ and saturation of mixed venous oxygen ($S\bar{v}O_2$).

Indications[11-13]

Though bedside monitoring with a balloon tip PAC has been in use since the last 30 years, controversy still persists regarding its value. However, in conditions such as septic shock or acute lung injury (ARDS), manipulation of certain hemodynamic parameters and of oxygen transport, have definitely changed the approach to therapy, with an improved outcome. There is also no dispute over the fact that constant monitoring of LV preload is mandatory whilst infusing large volumes of fluids or giving massive transfusions, especially in the elderly or in those with suspected cardiovascular dysfunction. Similarly, pulmonary wedge pressure measurements are helpful in differentiating between cardiogenic pulmonary edema and non-cardiogenic pulmonary edema.[14]

It is clear that PAC provides data that can be used to make therapeutic decisions as above. However, the critical question is whether these therapeutic decisions improve outcomes. Some studies have suggested that the use of PAC actually worsens outcome.[15] This rekindled the strong debate regarding the efficacy and safety of PAC. Dalen and Bone, in their editorial accompanying this study[16] recommended that the US (FDA) should issue a moratorium on the use of PAC till a designed randomized clinical trial of use of the PAC in critically ill patients is undertaken. However, a joint statement by the American College of Chest Physicians (ACCP) and the American Thoracic Society (ATS)[17] stated that there was no indication for the moratorium on the use of the PAC at that time, but released the following recommendations—

- Further prospective randomized controlled trials of the PA catheter.
- The decision to insert a PAC and its potential benefits should be weighed against the risks involved.
- Informed consent should be obtained whenever possible.
- Only physicians knowledgeable about the technique of proper placement, potential complications and interpretation of the data generated should use the PAC and proper documentation should be mandatory.

Recent studies have consistently shown that PAC monitoring has not demonstrated improved survival or reduced ICU or hospital length of stay compared with control groups. However, it remains plausible that there is a subgroup of patient population for whom PAC as a guide to hemodynamic management may be helpful. Though, in the final analysis, it is worth stressing that diagnostic tests and monitoring devices do not alter clinical outcome, but treatment does. If

Box 3: Indications for pulmonary artery pressure monitoring

- In critically ill, hemodynamically unstable patients—
  - Shock (of any etiology)
  - Burns, sepsis, peritonitis, acute renal failure, acute lung injury, fulminant tetanus, etc.
- In patients where the diagnosis is uncertain—
  - Cardiogenic versus non-cardiogenic pulmonary edema
  - Acute respiratory failure with uncertain cardiac status
  - Acute myocardial infarction with a new loud murmur indicating acute rupture of the interventricular septum, or of a papillary muscle
  - Suspected pulmonary embolism
  - In patients with acute myocardial infarction and shock, in whom hypovolemia has to be differentiated from pump failure
- As a therapeutic guideline under the following conditions—
  - Massive fluid replacement in patients with severe fluid loss, especially in elderly patients, or in those with a history of ischemic heart disease
  - Fluid management in patients with non-cardiogenic pulmonary edema (ARDS)
  - In acute hemorrhage necessitating massive transfusions, particularly in patients with associated cardiac or renal problems
  - Management of patients with shock, or other critically ill patients on inotropic and/or vasodilator drugs
  - In patients with pump failure who respond unsatisfactorily to initial therapy
- Patients at risk of hemodynamic decompensation—
  - Preoperative monitoring in all seriously ill patients (cardiac or non-cardiac surgery)
  - Patients with underlying cardiac disease on mechanical ventilator support with PEEP or continuous positive pressure

PAC does not alter treatment decisions, it can have no positive effect on the clinical outcome but may unnecessarily add to potential complications. Hence, to benefit patients, the PAC must provide information that is not otherwise available and the information so provided should be useful in selecting a treatment plan that has proven clinical benefit.[18] It should also be realized time is of essence; there are studies, which show significant improvement in outcomes, when therapy guided by PAC was given early, within 8–12 hours postoperatively.[19,20]

The general indications for PAP monitoring are listed in Box 3. These are only guidelines and there is no compulsion to adhere to them to the letter. Each individual patient should be carefully considered, and the anticipated benefits must clearly outweigh the possible risks.[21] By and large this procedure should not be used too liberally in developing countries, and its use should be restricted to centers having the proper set-up, expertise and an assured aseptic environment.

Catheter Design

A wide range of catheters (from the adult to the pediatric size) are available for various clinical applications. They range from

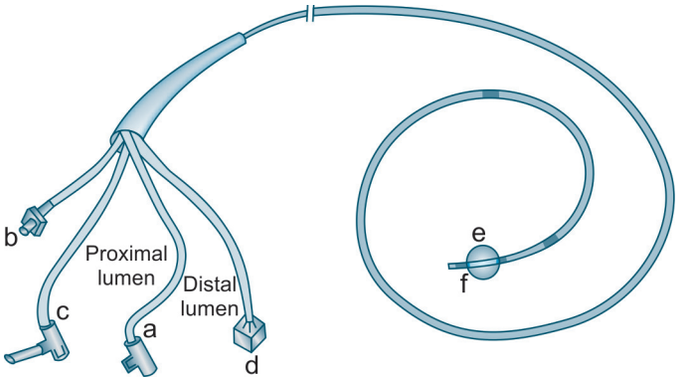

Fig. 5: Triple lumen pulmonary catheter. a = distal PA port, b = balloon inflation port, c = proximal RA port, d = thermistor hub, e = balloon, f = thermistor

60–110 cm in length, 4–7.5 Fr in caliber, with balloon inflation volumes ranging from 0.5–1.5 mL. The catheter material is polyvinyl chloride which is pliable at room temperature, and softens further at body temperature. The simplest type of catheter contains only two lumens, one to transmit PAPs, and the other for balloon inflation; however, the most commonly used one is the sophisticated triple-lumen thermodilution catheter. In fact, there are various types of catheters available and their use depends on the clinician's choice.

The *triple lumen 7.5 Fr thermodilution PA catheter* (Fig. 5) is 110 cm in length. The lumen of the distal PA port (a) runs through the length of the catheter to terminate at the tip, and is used to measure the PAP, and the pulmonary capillary wedge pressure (PCWP); mixed venous blood can also be drawn from this lumen. Drugs and hyperosmotic solutions should never be administered from the distal lumen as they may induce a local vascular or tissue reaction in a small pulmonary artery segment. The balloon inflation port (b) opens to a lumen that terminates within the balloon (e), which is situated just proximal to the catheter tip. The proximal RA port (c) opens to a lumen that terminates 30 cm from the tip of the catheter and lies in the right atrium (RA), when the tip of the catheter is in the PA. The RA port is used for monitoring RA pressure and also for administration of fluids. The RA port is also used to inject ice-cold saline during CO measurement, (d) represents the thermistor hub which is connected by wires to a small thermistor (f) located 3.5-4 cm proximal to the catheter tip. The thermistor records changes in the temperature over change in time during CO measurement; this is then relayed to an outside computer via the thermistor hub.

Further innovations to the three-lumen standard thermodilution PA catheter are also available. These include the *four-lumen thermodilution catheter* and its modified versions referred to as *position monitoring catheter,* which prevents distal migration of the catheter into the small branches of pulmonary arteries by signaling the need to withdraw the catheter.[22,23]

The newer *S-tip* catheters are designed for femoral vein insertion; similarly stiffer catheters (Swan-Ganz Hi-Shore from Baxter) are available, and may be used when more torque

control and maneuverability are needed, particularly during a femoral approach. Some new catheters available today are treated with antimicrobials and coated with heparin.

A *fibreoptic thermodilution PA catheter* is also available for continuous monitoring of mixed venous oxygen ($M\bar{v}O_2$); this has an additional channel that contains two fibreoptic bundles for light transmission. The light transmitted from outside is reflected back from the hemoglobin in the blood to a photodetector, which calculates the fraction of Hb saturated with oxygen, and displays it continuously on a bedside monitor.

Insertion Technique

Balloon catheters float easily from the vena cava to the pulmonary wedge pressure position, and knowledge of the various intracardiac waveforms is generally sufficient to be able to insert the catheter. Bedside fluoroscopy is not mandatory, and fluoroscopic equipment can be very cumbersome in an already small and cluttered ICU room. Besides, each patient's bed needs to be especially designed for imaging purposes, thereby adding to the overall cost. However, in cases with abnormal intracardiac flow patterns due to raised right ventricular pressures, the flow direction of the catheter may become very difficult and fluoroscopic guidance becomes necessary.

Percutaneously, a Seldinger technique is usually employed, which leaves an introducer catheter *in situ* through which the PA catheter is easily passed. These procedures have been described in detail in the Chapter Procedures in the Intensive Care Unit. There is no ideal site for PAC insertion, and this choice depends entirely on the operator's preference and expertise. In our unit, we prefer the subclavian or jugular site; femoral site is not commonly used except when subclavian or jugular sites are not accessible for various reasons. Many operators prefer to use the left subclavian vein as this approach offers the easiest route from the site of insertion to the RV due to its unidirectional bend.

Before insertion of the PAC, the pressure monitoring system should be set-up and kept ready as discussed earlier in this chapter. The catheter tip should be jiggled before insertion, and this produces sharp oscillations on the monitor. If no oscillations occur, there is probably an equipment malfunction, which should be corrected. The balloon should be tested by inflating with air as per the manufacturer's recommendations. After ascertaining the integrity of the balloon, the catheter is flushed with a sterile solution to ensure its patency and to remove all air.

Now with the balloon deflated, introduce the catheter through the introducer sheath into a central vein. Before advancing the catheter further, it is advisable to follow the markings on the catheter, as this gives a fair idea of the distance the catheter has traveled from the insertion point. In a normal adult to reach the RA, the catheter has to be advanced 10–15 cm from the subclavian vein, 15–20 cm from the right jugular vein, and 30–40 cm from the femoral vein. Under continuous pressure, monitoring with or without fluoroscopy, gently advance the catheter into the RA. Entry

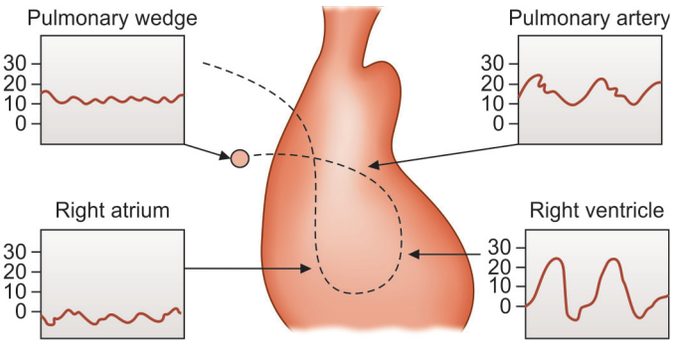

Fig. 6: Pressure waveform configuration as seen during the passage of the pulmonary artery catheter through the various chambers of the heart and in wedge position. The position of the catheter shown here is as seen on fluoroscopy

of the catheter tip into the thorax is signaled by increased respiratory fluctuations of the waveform. Once in the RA, inflate the balloon with air or CO_2 to the recommended volume (printed on the catheter). Never use fluids to inflate the balloon. In the presence of intracardiac shunts, CO_2 should be used instead of air for inflation of the balloon, in order to avoid systemic air embolization in case of accidental balloon rupture. Further, passage of the catheter from the RA to the pulmonary wedge position should normally not take longer than 30–40 seconds, provided there is no abnormal flow pattern in the heart or markedly elevated RV pressures. The shapes of the waveform and RV, PA and PCWP readings are used as a guide in advancing the catheter (Fig. 6). On entering the RV, the waveform is characterized by a steep upstroke, which is normally 3–4 times higher than the RA pressure. The sharp downstroke without a dicrotic notch dips to near zero, and then rises to reach a baseline plateau, which directly records the RVEDP, and is equal to the mean RA pressure. On advancing the catheter further into the pulmonary artery, another change in pressure waveform is noted, and this can be immediately differentiated from the RV waveform by the sudden elevation of the diastolic pressure and the appearance of the dicrotic notch. In the pulmonary vasculature, the inflated balloon acts as a sail, and continues with the flowing stream into the more peripheral branch of the pulmonary circulation where it will wedge. The catheter tip will now record a pulmonary wedge pressure tracing, which is very similar to the RA waveform (Fig. 6).

Correct Wedging Procedure

The balloon should not be allowed to remain inflated in the occluded position beyond 10–15 seconds. Inflation beyond this period can lead to pulmonary infarction. In addition, artifactually elevated pressures may result due to prolonged wedging. Upon deflating the balloon, the catheter recoils back toward the hilum into the main branch of the PA, and the PA waveform reappears. If the wedge tracings continue even after the balloon is deflated, the catheter should be carefully withdrawn to a point where PA waveforms reappear. The pulmonary wedge tracing should be obtained on reinflating

Table 4: Complications directly attributable to PAC

Complications	*Action/Prevention*
Arrhythmias	• Decrease insertion time • Use fluoroscopic guidance in high risk groups so that less maneuvering of catheter is necessary • Promptly remove catheter if arrhythmias persist
Infection	• Meticulous, sterile technique with all aseptic precautions during insertion and after care • Avoid repeated manipulations • Catheter to be removed at the earliest
Balloon rupture	• Inflation of balloon is typically associated with a feeling of resistance, the absence of resistance and failure to wedge suggest balloon rupture
Knotting	• Knots may be resolved by insertion of suitable guidewires and manipulation under fluoroscopy • If knot does not include any intracardiac structure, apply gentle traction to tighten the knot and then withdraw slowly • Only in worst cases, a thoracotomy and cardiotomy may be required
Clotting and thromboembolic complications in RA or systemic veins	• Intermittent flushing of catheters with heparinized saline • Avoid long standing catheter placements • Heparin coated catheters may reduce catheter thrombogenecity
Pulmonary infarction and PA rupture	• Avoid prolonged or over inflation of the balloon in the wedge position • Avoid repeated inflation of balloon for PCWP measurements; instead use PADP for continuous monitoring as PADP equals PCWP • Avoid inserting the catheter too far peripherally into a branch of PA. If catheter is seen beyond the hilum there is increased chance of infarction or rupture

the balloon to the recommended inflation volume; if the inflation volume is significantly lower than that recommended to produce a wedge trace, it implies that the catheter tip is still placed too far peripherally.

It is vital to remember that the mean pulmonary artery wedge pressure, which is normally equal to pulmonary artery diastolic pressure (PADP) may be lower in certain conditions associated with increased pulmonary vascular resistance (PVR). However, the PCWP is never higher than the PADP, and if so, it represents an artifact.

Lastly, the blood sample withdrawn from the catheter which is truly wedged, should represent and be equal to the oxygen saturation of arterial blood, whereas blood drawn from the pulmonary artery with the balloon deflated, gives the oxygen saturation of mixed venous blood, averaging 75%.

Normally, if there is a good correlation between PADP and PCWP, the PADP should be used to estimate the left atrial pressures instead of rewedging the catheter frequently. This reduces the risk of pulmonary vascular damage and pulmonary infarction, and also prolongs the balloon life.

Complications of Pulmonary Artery Catheterization[24]

All complications associated with a cutdown procedure or a percutaneous central venous catheterization can occur during PA catheterization. These complications have been discussed separately under the appropriate techniques in the Chapter Procedures in the Intensive Care Unit. Complications directly attributable to pulmonary artery catheterization and their prevention are discussed in Table 5.

Briefly, arrhythmias and possibility of infection are the most common complications. The occurrence of *arrhythmias*, and of ventricular ectopics in particular, are common during insertion of the catheter. The incidence is higher in patients with ischemic heart disease, ventricular failure, hypoxemia, digitalis toxicity, metabolic and electrolyte imbalance, and in patients with shock. Further, critically ill patients are commonly immunocompromised, and are frequently at a higher risk for *catheter-induced infections*.

Some less common causes are balloon rupture, knotting of the catheter, pulmonary thromboembolic complications and pulmonary artery rupture. Though *balloon rupture* by itself is not a dreaded complication, a remote possibility of embolization of balloon fragments to distal pulmonary circulation remains. Small caliber catheters are more likely to *knot* within the cardiac chambers and around other intravascular catheters. *Clots* occluding catheter lumen or the tip can result in inaccurate measurements; *thrombotic occlusion* can also occur in systemic veins or in the RA due to longstanding catheter placements. Persistent or repeated wedging of PAC or inadvertent migration of the catheter tip into smaller branches of pulmonary artery or prolonged balloon inflation can lead to *pulmonary infarction*. *PA rupture* though rare is the most dreaded of all complications with a high mortality rate. It may clinically result as mild hemoptysis to begin with but if ignored may progress to massive hemorrhage. In Table 4, details of problem solving and steps taken to prevent complications secondary to pulmonary artery catheterization have been discussed.

Pitfalls in Pulmonary Artery Pressure Measurement[25]

Several practical factors may be crucial in obtaining meaningful information whilst performing hemodynamic studies.

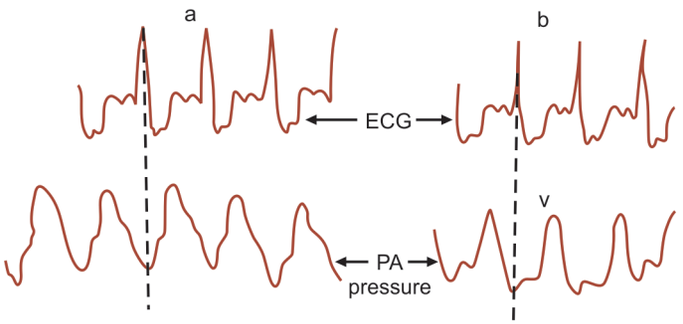

Fig. 7: Identification of v wave by superimposing the ECG on the pressure tracings. (a) PA tracing with the balloon deflated; the upstroke of the PA systolic wave starts near to the end of the QRS. (b) Balloon-inflated wedge tracing with superimposed v wave which is delayed by 200–300 msec after the QRS (see text)

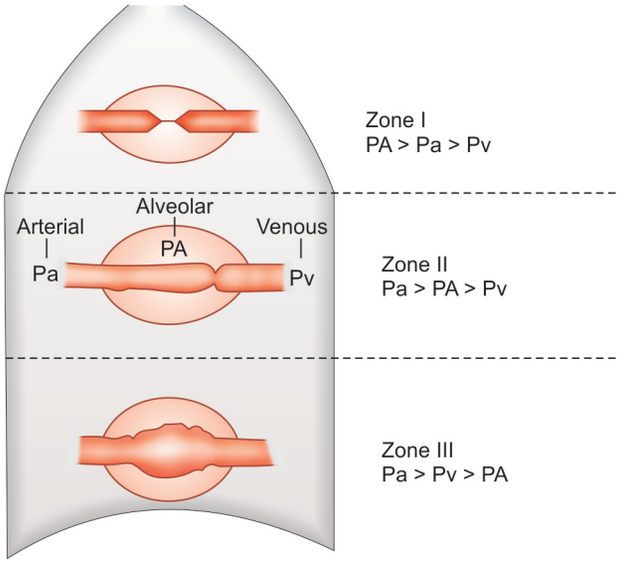

Fig. 8: Interrelationship between the alveolar and vascular pressures in the three West Zones. PA = alveolar pressure; Pa = pulmonary artery pressure; Pv = pulmonary venous pressure (see text for details)

Problems related to pressure lines, transducers and monitors, which commonly manifest as overdamped or underdamped waveforms, are common to both arterial and venous catheterizations. Similarly improper zero leveling and whip artifacts may be seen. All these problems have been discussed earlier in the Subsection on Pressure Monitoring System (Table 2). In addition to all these problems, PA waveforms in particular, are affected by cardiac dysfunction and by changes in intrathoracic pressures.

Cardiac dysfunction The PCWP waveforms consist of two distinct peaks: (1) the a and (2) the v waves. The more problematic, however, is the v wave which occurs in the presence of mitral insufficiency or significant mitral valve prolapse. This is a large v wave transmitted retrogradely from the LV, which is superimposed on the PCWP wave, thereby exaggerating its size; this may be wrongly interpreted as a pulmonary waveform even though the catheter is in the fully wedged position.

The v wave should be suspected if no PCWP waveform is seen despite the catheter being properly positioned in the wedge position. This can be confirmed by superimposing an ECG strip on both the balloon-inflated and balloon-deflated pressure tracings (Fig. 7). The v wave of the wedge waveform in the balloon-inflated tracing will be delayed by 200–300 msec after the QRS, whereas the upstroke of the PA systolic wave starts near the end of the QRS as shown in Figure 7.

Clinically, identification of v waves is important from two points of view. Firstly, once it is identified as a true PCWP waveform, and not a pulmonary artery waveform, the catheter need not be advanced any further into the peripheral pulmonary artery branch. Secondly, the correct pulmonary artery occlusion pressure should be read just prior to the upstroke of the v wave.

Artifacts due to ventilatory effects during spontaneous breathing During normal quiet breathing, inspiration or chest expansion requires a slightly negative intrapleural pressure (subatmospheric), whilst expiration requires a slightly positive intrapleural pressure (near atmospheric). These cyclic changes in the intrathoracic pressure are transmitted to the intravascular pressure tracings, creating a minimally wandering baseline, with expiration producing positive deflections, and inspiration producing negative deflections. These pressure changes are insignificant, and minimally affect the mean PCWP. However, in case of marked labored breathing, as in patients with acute lung injury or COPD, greater swings in pleural pressures are required to move air in and out of the lungs. As a result there is a wide fluctuation in the pressure waveform baseline. This leads to inconsistent and inaccurate recordings. In such a situation, it is best to disregard the digital display and record a long tracing of the PAP or PCWP waveforms, and read that portion of the waveform that corresponds with end-expiration. It should however be noted that in patients on mechanical ventilation, the end-expiration is reflected by the negative deflection of the wandering pressure baseline.

Artifacts due to influence of gravity[25] Pulmonary artery pressures increase progressively down the lung, as the blood flow increases in the lower parts of the lung due to the influence of gravity. However, the alveolar pressures remain equal throughout. West divided the lung model conceptually into three zones, called the West Zones (Fig. 8), which illustrated the interrelationship between the alveolar and vascular pressures and the effect of gravity.

Zone 1 is the uppermost portion of the lung or apex in an upright person. This is an area with potentially low vascular pressure, hence, alveolar pressures here exceed both the PAP and the pulmonary venous pressure (PVP) (Alveolar pressure > PAP > PVP). If a wedged catheter tip is placed in this position, it will not reflect the LA pressure as the continuous conduit between the catheter tip and the LA is occluded by the higher alveolar pressure, but will reflect only the alveolar pressure.

Zone 2 is represented by the middle portion of the lung and here too the alveolar pressure is greater than PVP, but

less than PAP. However, during end-expiration and inspiration the alveolar pressure is at its lowest, and does not occlude the pulmonary veins, thus allowing the wedged catheter tip to accurately reflect the LA pressure; however, during end-inspiration and early expiration, the elevated alveolar pressure will pinch the pulmonary veins, and the wedged catheter once again shows an erroneously high PCWP.

Zone 3 is at the bottom of the lung, where there is increased blood flow due to gravity, and vascular pressures are greatest. Hence, both the PAP and the PVP far exceed the pulmonary alveolar pressure, producing a constant open vascular conduit from the catheter tip to the LA, which allows the PCWP to accurately reflect the LA pressure in all phases of respiration.

To confirm the Zone 3 catheter position one should constantly be able to identify the wedge waveform. A damp tracing in absence of other problems suggests a Zone 1 or Zone 2 position. A lateral chest X-ray can also ascertain the proper catheter position; a Zone 3 position can be confirmed if the catheter tip is seen to lie at, or below the left atrial level. Lastly, in patients on positive end-expiratory pressure (PEEP), the PCWP should not be influenced by sudden increase or decrease in PEEP levels if the catheter is properly positioned in Zone 3.[26]

The three zones described above hold true for an individual in an erect position, and as measurements are so often made with the patient upright or semi-inclined, it is important to place the catheter tip at or below the left atrial level, confirming the Zone 3 condition. However, in the supine position, most of the alveolar capillary units fall in the gravity-dependent area of the lung having the characteristics of Zone 3 condition, and as most of the blood flows in this area, the PA catheter invariably floats into Zone 3.

Artifacts due to effects of mechanical ventilation and PEEP

Positive changes in the airway pressures produced by mechanical ventilation reflect on the heart and vascular structures of the thorax. This can lead to inaccurate measurements and wrong interpretation of hemodynamic parameters for three reasons.

1. Measured PAP and PCWP will increase during the delivery of each mechanical breath. However, the pressure at end-expiration should be the same as with spontaneous breathing, and therefore it is important that the measurements are recorded at end-expiration.
2. Mechanical ventilation has the potential to decrease CO by increasing the intrathoracic pressure and thus reducing the venous return to the heart. In addition, the positive pressure surrounding the heart may produce a tamponade effect, further interfering with the diastolic filling. Though the CO may fall, the CVP, PAP and PCWP may rise because of perivascular compression distorting the volume-pressure relationship. In other words, pressures that appear to be normal may be insufficient to ensure adequate preload and CO.
3. Positive alveolar pressure may increase the Zone 1 and 2 conditions, so that a considerable anatomical area of Zone 3 now takes on the characteristics of Zones 1 and 2, especially if the PAP is low. This will lead to inaccurate measurements as PCWP will no longer reflect the LA pressure correctly, even though the catheter tip seems to lie in Zone 3 on X-ray.

All these above-mentioned effects of mechanical ventilation will be exaggerated in patients on either PEEP, or continuous positive airway pressure (CPAP). Generally, PEEP levels less than 10 cm of H_2O do not compromise the measurements of PCWP or CO very significantly. However, PEEP levels greater than 10–15 cm H_2O certainly increase the disparity between the PCWP and LA pressure relationship, and also compromise cardiovascular function.

In order to obtain more accurate LA pressure measurements by measuring PCWP in patients on high levels of PEEP, one has to assume that approximately 50% of the PEEP is transmitted to the LA. As PEEP is measured in centimeter of water, and PCWP in mm Hg, a simple calculation would be to subtract 1.5 mm Hg pressure from PCWP for every 5 cm of H_2O of PEEP administered (as 1 mm Hg = 1.36 cm H_2O). For example, if a PCWP of 28 mm Hg is recorded in a patient on PEEP of 20 cm H_2O, the patient's corrected LA pressure should read 6 mm Hg less, i.e. 22 mm Hg.

Many clinicians prefer to disconnect the patient from the mechanical ventilator during PCWP measurements; this practice should however be discouraged. As long as the pressure tracings show the characteristic PCWP waveforms, and one-half of PEEP is approximately subtracted from the PCWP, it seems reasonable to measure the pressures that apply to the patient during therapy, rather than during a brief interval without it. On the other hand, on discontinuing mechanical ventilation or PEEP, a sudden change in hemodynamics occurs because of an increase in venous return, and the measured parameters may be different from those that exist when the patient is on ventilator support.

CARDIAC OUTPUT MEASUREMENT BY THE THERMODILUTION TECHNIQUE[27,28]

The Fick oxygen consumption method described by Adolph Fick in 1870 is usually considered to be the gold standard to which other methods are compared because of its extreme accuracy in measuring the CO. However, this method is not practical for day-to-day use in the ICU as it is time consuming, and requires the patient to be in a steady metabolic state.

The indicator dye dilution technique is another method of measuring CO, but this too is not a practical bedside procedure.

The thermodilution technique is currently the most widely used method in clinical practice. Though first introduced by Fegler in 1954, its first reported use in humans was published by Margaret Branthwaite and Ronald Bradley in 1968.[29] The basic principle underlying this method is the detection of the change in temperature of blood over a period of time; this can be accomplished by injecting cold saline in the RA from a proximal port of the PA catheter, whilst the thermistor on the catheter tip detects the temperature change in the PA. This change is inversely proportional to the blood flow.

Procedure

The main equipment required for CO monitoring is the CO computer and a thermodilution PAC. Also needed are five to six 10 mL sterile plastic syringes, an injectate solution (usually ice cold normal saline), an injectate temperature probe and catheter connecting cables. It goes without saying that aseptic precautions should be observed throughout the procedure. The patient should be preferably supine, but a semi-reclined position (<20°) should not alter the CO. A more erect position, particularly in critically ill patients on potent vasodilators, can produce orthostatic hypotension; hence in such patients relative changes in position during serial measurements can affect the reliability of the CO readings.

Prior to injection, the position of the thermodilution catheter should be ascertained. The catheter tip must lie in the pulmonary artery and should not be in the wedged position. The balloon must be deflated prior to injection and the thermistor hub should be connected to the CO monitor via the catheter connecting cable. The injectate probe should be connected to the CO computer, with the sterile probe dipped into the injectate solution.

About 10 mL of 0.9% saline or 5% dextrose (ice cold solution or solution at room temperature, depending on the method used), is injected within 4 seconds as a bolus through the proximal port of the PA catheter. Lesser volumes, or prolonged injection times can give unreliable measurements. The cold solution mixes with the blood in the right heart chamber lowering the blood temperature, the cooled blood flows into the PA, and the thermistor at the catheter tip records the temperature change and relays this information to the CO monitor. The CO computer calculates the temperature difference between the injectate solution and the blood, and displays the temperature-time curve. The area under the curve is inversely proportional to the flow rate in the PA, which is representative of the CO.

The injectate used need not be an ice cold solution, as solutions at room temperature also produce reliable results. It is also important that serial measurements should be obtained, after discarding the first trial which is often unreliable. The average value of three measurements is taken as the CO, provided that they do not differ from each other by more than 15%. The injections should be always timed during end-expiration to avoid unacceptable variations in CO, which may occur during different phases of the respiratory cycle. This is particularly important for patients on mechanical ventilator support. However, it may be impossible to start and complete injection precisely during one phase of the respiratory cycle. To overcome this practical difficulty, it is reasonable to time the starting of the injection at the onset of inspiration; it may take 2–4 seconds to reach the thermistor, and this should produce the thermodilution curve close to the end of expiration.

Pitfalls in CO Monitoring

Erroneous CO readings may be produced by conditions such as tricuspid regurgitation, or by a clot partially blocking the catheter lumen, or due to intracardiac shunts. In case of right to left shunts, the CO is falsely high because part of the cold injectate crosses the shunt and the temperature difference sensed by the thermistor in the PA is less; in left to right shunts, falsely elevated readings are obtained as the blood volume in the right side of the heart is increased, and the injectate is diluted, once again decreasing the temperature difference in the PA, and producing a curve with a reduced height.

Besides other technical points, the temperature and volume of the injectate solution must be precisely determined to avoid errors in CO measurements. A larger volume will produce a greater temperature change in the pulmonary circulation, which is interpreted by the monitor as a low CO. Conversely, a lesser volume will produce a smaller temperature change, which will be interpreted as a high CO.

If the injectate solution is at room temperature, producing very minor temperature changes, the serial CO readings will be less reproducible. This is therefore the practical disadvantage of using a room temperature injectate instead of an ice cold solution. Similarly, the reproducibility of the measurements may be affected despite using iced injectate, if there is a significant temperature change between the time the solution is drawn and the time it is injected. However, several systems are available today that measure the injectate temperature at the time it enters the proximal port of the PAC. This minimizes injectate temperature errors, and improves the reproducibility of the measurements.

Continuous CO Monitoring

Continuous CO measurements using thermodilution techniques are also available. Instead of cold water, a small heating filament at the end of the catheter warms pulmonary blood and a downstream sensor records changes in temperature. These measurements are found to lag behind by a few minutes, but they are reliable and able to provide near real-time COs. Most minimally invasive and noninvasive methods including continuous monitoring of mixed venous oxygen saturation ($S\bar{v}O_2$) or its surrogate central venous oxygen saturation ($Sc\dot{V}O_2$) described next also enable continuous CO monitoring.

MIXED VENOUS O_2 SATURATION ($S\bar{v}O_2$) AND CENTRAL VENOUS O_2 SATURATION ($Sc\dot{V}O_2$)[30]

Saturation of mixed venous oxygen ($S\bar{v}O_2$) is the saturation of mixed venous blood drawn from the pulmonary artery through a PAC. It is usually though not always, a good indicator of the adequacy of tissue oxygenation and it reflects the balance between oxygen demand and supply to the tissues (Table 5).

The oxygen saturation of blood in the pulmonary artery, which represents the $S\bar{v}O_2$ can be monitored continuously by using special fiberoptic thermodilution catheters, or intermittently by obtaining serial samples of blood drawn from the distal lumen of the PAC. The technology for measuring $S\bar{v}O_2$ is based on reflection spectrometry. This involves

Table 5: Conditions affecting $S\bar{v}O_2$

Decrease in $S\bar{v}O_2$	*Increase in $S\bar{v}O_2$*
Poor O_2 supply— • Decreased CO • Anemia • Hypoxic hypoxia	Impaired O_2 utilization— • Sepsis • Cyanide poisoning
Excessive O_2 demand— • Fever • Seizures • Increased metabolic rate • Increased physical activity	Decrease in O_2 demand— • Hypothermia • Prolonged anesthesia

sending light of selected wavelengths down one fiberoptic filament in the catheter body to blood flowing past the catheter tip. The reflected light is then transmitted back through the second fiberoptic filament to a photodetector located in the optical module. Hemoglobin and Oxyhemoglobin absorb light at different wavelengths, and the reflected light is analyzed to obtain the $S\bar{v}O_2$.

In a normal individual, $S\bar{v}O_2$ ranges from 60% to 80%. It is generally accepted that $S\bar{v}O_2$ should be considered clinically significant if the value is outside the normal range or if a change in $S\bar{v}O_2$ of 5–10% from the baseline value persists for greater than 3–5 minutes, even if the value is in the normal range. A marked fall in $S\bar{v}O_2$ generally indicates inadequate tissue oxygenation, and the fall is attributed to a decrease in SaO_2, Hb concentration, or the CO or to a marked increase in $\dot{V}O_2$. When thermodilution techniques are not available, serial measurements of $S\bar{v}O_2$ are frequently used to monitor changes in the CO, provided that the Hb concentration remains constant, and the PaO_2 does not fluctuate significantly.

In non-shock conditions, there is a good correlation between $S\bar{v}O_2$ and oxygen saturation obtained from a central vein ($Sc\dot{V}O_2$) but not so in case of circulatory shock. However, changes in both parameters run parallel so that changes in $S\bar{v}O_2$ indicating a hemodynamic derangement are mirrored by appropriate changes in $Sc\dot{V}O_2$. Similarly, changes in $S\bar{v}O_2$ due to therapeutic interventions are well reflected by changes in $Sc\dot{V}O_2$ even in patients with severe shock. Hence, in day to day clinical practice it is simpler and less invasive to measure $Sc\dot{V}O_2$ from a CVP line as a surrogate of $S\bar{v}O_2$.[31]

MINIMALLY INVASIVE CARDIAC OUTPUT MONITORING[32,33]

It should be emphasized that introducing new technologies for non/minimally invasive monitoring systems will not necessarily influence outcomes; unless it is demonstrated, that the measured parameters are absolutely reliable and can be translated easily into therapeutic interventions, with a high degree of confidence. This is why we still believe that PAC in a selective group of patients is a valuable monitoring tool especially when used by adequately trained physicians to correctly interpret and apply the data provided.[34] Currently available minimally invasive CO measuring devices are based on the following principles (Table 1)—

- ❑ Pulse pressure analysis.
- ❑ Doppler.
- ❑ Applied Fick principle of dye dilution.
- ❑ Bioimpedance.
- ❑ Plethysmographic indices.

Pulse Pressure Analysis

By this method, SV can be estimated continuously by analyzing arterial pulse waveform, which is derived from an indwelling arterial line. Briefly, this method involves the calculation of the area under the systolic portion of the arterial pressure waveform, which when divided by the aortic impedance allows estimation of the LVSV. Basically, these devices are of two kinds: (1) those requiring calibration and (2) those which are self-calibrated.

Systems requiring calibration The pulse induced contour cardiac output (PiCCO)[35] is based on the above principle but requires calibration by transpulmonary thermodilution to obtain accurate CO measurements. It therefore requires a central venous line placement with a temperature sensor on the distal lumen and a thermodilution sensor at the arterial catheter end. Calibration is required to measure the aortic impedance and needs to be repeated at least every 8 hours in a hemodynamically stable patient and at shorter intervals under certain conditions. This is necessary in order to calculate the SV from a pressure trace because the algorithm used by these devices has to compensate for the overall impedance of the system, based on both the compliance and resistance of the cardiac vasculature.

Once calibrated, the system computes LVSV by measuring the area under the systolic part of the arterial waveform from end diastole to the end of the ejection phase and then dividing this area by the aortic impedance; the SV is thereby continuously monitored.

Further, information, such as intrathoracic blood volume (ITBV), extravascular lung water (EVLW) and stroke volume variation (SVV), is derived by application of appropriate inbuilt formulae. ITBV is a volumetric measure of cardiac preload (LVEDV) and changes in ITBV correlate with changes in CO and can be used as a surrogate for a patient's fluid status. EVLW on the other hand serves as an early warning during fluid resuscitation by estimating the water content extravasated in the lung tissue as in ARDS or cardiac failure. Studies have shown that resolution of pulmonary edema may be more rapid when EVLW is used as a guideline and prognostically there was higher risk of mortality when EVLW was greater than 14 mL/kg.[36]

Similar to the PiCCO system is the newly introduced EV 1,000 per volume view system, which also requires calibration and though the manufacturer's claim it to be comparable to PiCCO in tracking CO, it needs further studies for clinical validation. For both these systems, the company manual should be referred for procedural and calibration details.

Alternatively a new technique is the LiDCO plus system[37] which is also a PPA device requiring a central venous access

and calibration for vascular compliance. However, it uses a pulse power analysis in contrast to PiCCO, which uses a pulse contour device, but this is only a modification in a technical sense to circumvent certain theoretical problems of the pulse contour analysis. LiDCO is an abbreviation for lithium dilution CO. Here, calibration is done by using lithium chloride injected via a central line and collecting the blood that flows past a lithium sensor attached to the patient's existing arterial line, thereby it is not affected by thermal influences. The main limitation of this device is that if a muscle relaxant has been used on the patient, it can cross react with the lithium sensor resulting in unreliable readings. Hence, the calibration should be done prior to the use of muscle relaxants.

Self-calibrated devices Methods, like PiCCO described earlier, require regular manual calibration from time to time as they cannot automatically correct the patient's changing vascular tone. Therefore, the accuracy of these techniques is highly dependent on the delay between two normal calibrations and on the hemodynamic stability of the patient. A self-calibrated method (Flo Trac/Vigileo,[38] Edwards Lifesciences) has been in use since 2005, and the latest 3rd generation version is able to update the self-calibrated CO every 20 seconds. This is an improvement over the earlier generation softwares.

Briefly, in this method the CO is computed from the following equation—

$$CO = \text{Pulse rate} \times APsd \times K$$

where, APsd is the standard deviation of the arterial pressure and K is an autocalibration factor derived from a proprietary multivariate equation, which includes biometric variables (e.g. age and sex) that are known to affect the arterial compliance. This 3rd generation software is based on a large human database containing memory recordings from septic and liver transplant patients who are often vasodilated. This makes the 3rd generation software far more accurate (even in presence of a low SVR) than the earlier softwares based on a limited database.

The monitoring device consists of a transducer (Flo Trac) that is connected to a standard radial or femoral arterial catheter and to a Vigileo monitor. It is important to keep the Flo Trac sensor level to the phlebostatic axis at all times to ensure accuracy of CO. The step-by-step methodology for Flo Trac sensor set up, Vigileo monitor set up and zeroing techniques are well described in the Edwards Quick guide to cardiopulmonary care available from Edwards Lifesciences.

Other self-calibrated devices available in the market are shown in Table 1.

NONINVASIVE MONITORING DEVICES

Noninvasive Pulse Pressure Analysis[39]

These devices monitor continuous CO noninvasively without an arterial line, using instead a finger cuff to reconstruct a brachial artery pressure waveform. One of the available monitors (Nexfin) calculates the CO on a beat to beat basis by dividing the integrated pulse systolic area by the aortic impedance which in turn is derived from a predetermined model incorporating patient specific aortic mechanical properties. So far only limited clinical validation studies are available; however, it has shown acceptable CO values when compared with thermodilution performed by PAC. Such noninvasive monitors have a great potential in critical care setting where tracking the CO for early hemodynamic intervention is required and where invasive modalities are not readily available.

Transesophageal Doppler Monitoring Devices[40]

Doppler ultrasound can provide a relatively noninvasive and continuous real time quantification of CO. It involves inserting a flexible probe into the mid-thoracic esophagus where it lies in close proximity to the aorta without any signal interference from other anatomical structures. A pulse wave Doppler transducer placed in the probe tip calculates the changes in blood flow velocity in the descending aorta. Aortic diameter is estimated by using a normogram after entering age, gender, height and weight of the patient. The aortic diameter can also be assessed by M mode echocardiography, which allows for the actual measurement of the aortic diameter, eliminating the possible error associated with normogram based estimates. Once the cross-sectional area of the aorta is known, SV can be derived from the blood flow velocity (i.e. multiplying cross-sectional area of the aorta by blood flow velocity). As the measurements are made in the descending aorta it represents only 70% of the total CO since coronary and brachiocephalic flows are not measured, creating a partition between caudal and cephalic blood supply areas. Clinical validation studies initially had shown conflicting results; however, a recent meta-analysis reviewing all validation studies confirms reliability of CO measurement in clinical practice.

Transesophageal Echocardiography (TOE)[41]

In this method, one uses a combined 2D Echo and Doppler approach to measure the CO. The 2D Echo measures the diameter of the aortic annulus in mid-systole, which allows the calculation of the flow cross-sectional area; this when multiplied by the velocity of blood flow across the aortic valve measured by the aid of Doppler gives the CO. It is necessary to ensure that blood flow is parallel to the path of the pulse wave Doppler ultrasound. In experienced hands, TOE can give valuable hemodynamic information and in addition can identify presence of vegetations in infective endocarditis or the presence of pericardial effusion. The 2D Echo measurement of aortic valve diameter is clinically well established and of proven accuracy; however, it is challenging time-consuming and requires training and skill. For instance, a wrongly measured diameter can be magnified when squared (as required in the equation), or if the angle between the Doppler beam and blood flow is not exact, it will lead to an underestimation of velocity.

Table 6: Normal hemodynamic values

Variables	*Abbreviations*	*Units*	*Normal range*
Right atrial pressure	RAP	mm Hg	0–6
Mean pulmonary artery pressure	MPAP	mm Hg	11–15
Pulmonary capillary wedge pressure	PCWP	mm Hg	3–15
Cardiac index	CI	L/min-m^2	2.8–3.6
Left ventricular stroke work index	LVSWI	g-m/m^2	44–68
Right ventricular stroke work index	RVSWI	g-m/m^2	4–8
Systemic vascular resistance index	SVRI	dynes-sec/cm^5-m^2	1700–2600
Pulmonary vascular resistance index	PVRI	dynes-sec/cm^5-m^2	100–225
Oxygen delivery index	DO_2I	mL/min-m^2	500–650
Oxygen consumption index	VO_2I	mL/min-m^2	110–150

There are many other minimally invasive monitoring devices available in the market which are still not very widely used in clinical practice. *Applied Fick Principle*[42] based on partial CO_2 rebreathing method (NICO System) is one such method. *Bioimpedance* and *Bioreactance (NICOM)* are some of the other available methods. Thoracic electrical bioimpedance is a technique, which is based on correlating changes in aortic flow throughout the cardiac cycle with changes in electrical impedance of the thoracic cavity. In contrast, bioreactance mode of monitoring CO involves delivery of an oscillating current and the variation in the frequency spectra that occurs when the current traverses the thoracic cavity; it relies only on the analysis of the changes occurring in the signal amplitude. Validation studies for all these three techniques though showing occasional discordances were in most instances comparable with thermodilution and other techniques.[33,43]

HEMODYNAMIC VARIABLES AND THEIR CLINICAL APPLICATION[44-46]

Determinants of Ventricular Performance

Pulmonary artery monitoring allows us to obtain various hemodynamic variables, which are either directly measured or derived by using specific calculations (Table 6). These help us to understand the determinants of cardiac performance, and factors influencing oxygen transport, thereby providing a better perception of cardiovascular hemodynamics at the bedside.

The *stroke volume* (SVI) is the volume of blood ejected by the heart during each contraction, and is a very important indicator of ventricular performance. It is calculated by dividing the CO by the heart rate, and when indexed to the body surface area (BSA), the normal stroke volume index (SI) is arrived at (normal range is 35–45 mL/m^2). The three most important physiological determinants of SV are: (1) preload, (2) afterload and (3) myocardial contractility.

Preload refers to the length of the cardiac muscle fibers at the start of ventricular contraction; this is equal to the left ventricular end-diastolic volume (LVEDV), and is clinically measured as LVEDP. The PCWP, which is directly measured by a well-positioned PAC, in the absence of left ventricular inflow obstruction, gives an indication of the relative changes in the preload. However, this is true only if the ventricular compliance is static; in a diseased heart the LVEDP and the LVEDV may not correlate, as the ventricular compliance is altered. For instance, in dilated cardiomyopathy, the ventricular compliance increases, and a large increase in the ventricular filling volume is accompanied by only a small change in the filling pressure. On the other hand, in a stiff non-compliant ventricle seen in ischemic heart disease, the ventricular filling pressure increases disproportionately to the ventricular filling volume. Hence, the clinical importance of maintaining a slightly higher LVEDP in cases of acute myocardial infarction, in order to achieve an adequate CO, cannot be overstressed.

Afterload is defined as the impedance to blood flow from the ventricle. Whilst preload determines the force of the ventricular contraction, afterload denotes the tension developed by the cardiac muscle during systole as a result of systemic vascular resistance (SVR). Resistance is typically calculated as a pressure gradient divided by mean flow. Hence, the resistances to the two ventricles (indexed to the BSA) are derived by the following equations—

$$\text{SVRI} = \frac{\text{Mean arterial blood pressure} - \text{CVP}}{\text{Cardiac Index}} \times 80$$

$$\text{PVRI} = \frac{\text{Mean pulmonary artery pressure} - \text{PCWP}}{\text{Cardiac Index}} \times 80$$

The normal range of values is given in Table 7.

The SVRI is usually raised in cardiogenic and hypovolemic shock, in systemic hypertension and with the use of vasoconstrictor drugs. It is characteristically low in septic shock, thyrotoxicosis, anemia, cirrhosis and with vasodilator therapy. The PVRI is primarily raised in pulmonary edema, following pulmonary embolism, and in some valvular or congenital heart diseases. It is also raised in hypoxemia, due to pulmonary vasoconstriction.

Table 7: Hemodynamic changes caused by some commonly used IV drugs

Drugs	*HR*	*MAP*	*PCWP*	*CO*	*SVR*
Nitroprusside	↑	↓	NC or ↓	↑	↓
Nitroglycerin	↑	↓	↓	↑	↓
Norepinephrine	NC or ↑	↑	↑↓	↑, NC	
Dopamine	NC or ↑	NC or ↑	NC or ↑	↑	↑
Dobutamine	NC or ↑	NC or ↑	NC	↑	NC
Amrinone	NC	↓	↓	↑	↓

Key: NC = No change; * Dose related; ↑ = increased; ↓ = decreased.

Contractility is the inotropic state of the cardiac muscle, and may be expressed as the velocity of muscle fiber shortening during systole. It is important to realize that contractility is independent of preload or afterload, and at present we have no bedside method of monitoring cardiac contractility. However, if two of the three fundamental factors determining SV (viz. preload and afterload) can be kept constant, then obviously the changes in stroke work performed by the ventricle become the determinant of ventricular function, and give a good idea of the inotropic state of the heart. The stroke work for the two ventricles (indexed to the BSA) is calculated as follows—

$$\text{LVSWI} = \text{SI} \times (\text{MAP} - \text{PCWP}) \times 0.0136 \text{ g.m/m}^2$$
$$\text{RVSWI} = \text{SI} \times (\text{MPAP} - \text{CVP}) \times 0.0136 \text{ g.m/m}^2$$

The normal range of values is given in Table 7.

The basic relationship between preload, afterload and contractility is best described by Starling's pressure curves, which are plotted by obtaining responses of LV filling pressure (PCWP) and SV to fluid challenge. LV performance can be judged by plotting such a curve; however, one cannot be sure if a good or poor response is due to increased or decreased contractility, or is secondary to an alteration in the afterload.

Hemodynamic parameters can be greatly influenced by drug therapy, which may rapidly change the hemodynamic status of a critically ill patient. Hence, it is important to know the pharmacological influence of the drugs commonly used in the ICU, on the hemodynamic variables (Table 7).

DETERMINANTS OF OVERALL CIRCULATORY FUNCTION AND TISSUE PERFUSION

The importance of arterial oxygen content, the oxygen delivered to the tissues, oxygen consumption by tissues has been dealt with in the Chapter Basic Cardiorespiratory Physiology in the Intensive Care Unit to which the reader is referred. These are important parameters that help the intensivist to assess the overall hemodynamic state.

ASSESSMENT OF TISSUE PERFUSION[47]

Variables that may assist tissue perfusion are shown in Table 8. Tissue hypoperfusion can be present even in patients with a normal blood pressure and an adequate CO and is commonly referred to as cryptic shock or microcirculatory failure. Microcirculatory failure has been discussed in the Section Clinical Shock Syndromes.

Table 8: Variables that may assist with tissue perfusion

Global	*Organ or Regional*
Hypotension, tachycardia mottled skin, delayed capillary refill, altered mental status	Raised serum bilirubin and/or liver transaminases Elevated cardiac enzymes
Hyperlactemia	Side-stream dark-field video microscopy
Low cardiac output (but not necessarily so)	Gastric tonometry
Low mixed venous oxygen saturation	Sublingual capnometry
Low central venous oxygen saturation	Near infra-red spectroscopy

At the bedside tissue perfusion should be judged clinically—cold peripheries, sweating, poor capillary refill, mental obtundation, fall in urine output. There may be tachycardia, bradycardia or the heart rate may be normal. Hypotension is usually present but not necessarily so. Overall poor tissue perfusion is associated with a rise in blood lactate levels.[48,49] A progressive rise in lactate levels is associated with worsening prognosis.[50] Also a rapid fall in the lactate level following resuscitation denotes a better prognosis.[51,52]

These are features that characterize global tissue hypoperfusion. A lot of research is today being conducted on methods to determine regional tissue perfusion. *None of these methods which are referred to below have been shown to provide information that ultimately benefits patient outcome.*

Methods to determine regional tissue perfusion are gastric tonometery,[53-56] which by measuring the local PCO_2 within the stomach lumen assesses the perfusion status of the gastric mucosa; side-stream dark field videomicroscopy; sublingual capnometry and near infrared spectroscopy (see Section Clinical Shock Syndromes).

MEASUREMENT OF STROKE VOLUME VARIATION AND ARTERIAL PULSE PRESSURE VARIATION

Stroke volume variation (SVV) and arterial pulse pressure variation (PPV) are dynamic measurements that help to better assess the likely responsiveness of the ventricles to a fluid challenge as compared to the measurements of the CVP and the PCWP. Here, fluid responsiveness correlates with the preload responsiveness part of the Frank Starling Curve (Fig. 9).

Stroke Volume Measurement (SVV)

Studies have shown that SVV in patients on MV is highly predictive of preload responsiveness. However, dynamic

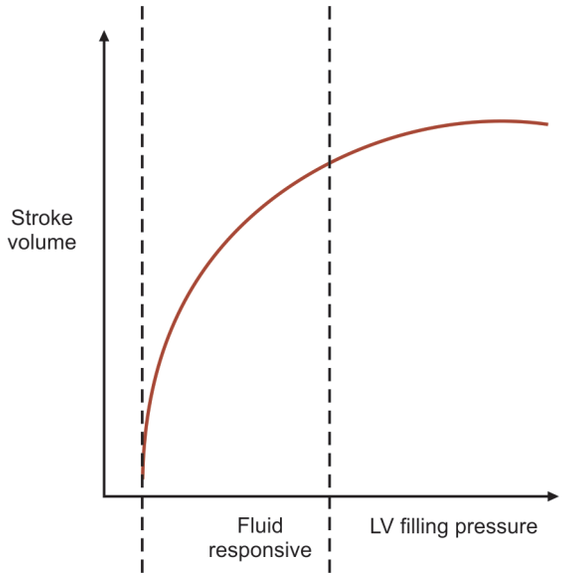

Fig. 9: Cardiac performance

indicators lose their validity during spontaneous non-uniform breathing. Hence, monitoring of SVV requires the patient to be on MV and properly sedated to attain uniform ventilation. Similarly, these parameters will lose their predictive value in presence of irregular R-R intervals as in atrial fibrillation. SVV greater than or equal to 10% predicts an increase in CO of greater than or equal to 15% for a bolus of 500 mL of fluid. SVV can be assessed directly by the esophageal Doppler or by pulse pressure analysis using devices, such as PiCCO, LiDCO or FloTrac systems, described earlier in this chapter.

Arterial Pulse Pressure Variation

Pulse pressure variation is a fairly reliable alternative being more practical and showing reasonable accuracy. Arterial pulse pressure defined as the difference between systolic and diastolic pressures is directly proportional to LV stroke volume and inversely related to arterial compliance. Hence, the respiratory variations in the pulse pressures reflect the changes in LV stroke volume and become a marker for preload dependence. PPV is calculated as a percentage, i.e. PPV % = (Ppmax – Ppmin)/[(Ppmax – Ppmim)/2] × 100 where Ppmax is the difference between maximum systolic and maximum diastolic pressures and Ppmin is the difference between the minimum systolic and minimum diastolic pressures. A PPV of greater than 13% implies 85% probability that the patient will benefit by fluid administration. Once again here, the parameters will lose their predictive value and accuracy under conditions of varying RR intervals (atrial fibrillation) or varying tidal volume; hence the patient has to be sedated and on MV during the measurements.

Entirely noninvasive methods that predict the response of the ventricles to fluid-loading are the measurement of the inferior vena cava (IVC) diameter during respiratory variation by an M mode echocardiography and estimation of the Massimo Continuous noninvasive Pleth Variability Index (PVI).[57,58] Both these methods are only applicable to patients who are sedated and on ventilator support.

Many of these methods used for dynamic measurements may not be available readily in most ICUs in our country. It is doubtful if these methods have shown as yet any improvement in outcome in patients with shock. *The clinical response of the patient to a volume challenge, even today, is the sheet anchor to gauge the presence or absence of ventricular responsiveness to an increase in preload.*

SUMMARY OF HEMODYNAMIC MONITORING

1. The main indication of hemodynamic monitoring, and more specifically of PA catheterization, will always depend on the risk-benefit ratio as judged by the clinician. However, it is invaluable in monitoring fluid administration, inotropes, vasopressor and vasodilator therapy in critically ill patients with shock, acute lung injury or multiple organ dysfunction.
2. The accuracy and reliability of all invasive hemodynamic measurements depend mainly on the correct method of assembling and calibrating the pressure monitoring equipment.
3. In most centers in India, CVP monitoring is common, and may be considered to be quite reliable, provided its limitations (as discussed earlier) are fully appreciated.
4. The following criteria should be fulfilled if PA pressure monitoring is to be used as a measure of left ventricular preload: (a) a normal ventricular compliance, where the LV pressure-volume relationship can be predicted; (b) absence of LV inflow obstruction; (c) unobstructed vasculature in the pulmonary capillary bed.
5. It is not advisable to disconnect the mechanical ventilator or remove PEEP during PCWP measurements. On the contrary, the measurement of pressures during therapy (with appropriate correction for PEEP) is more relevant and meaningful.
6. Catheter-induced sepsis is the commonest of the long-term complications of pulmonary artery catheterization in our part of the world, and hence, strict asepsis should be observed. Pulmonary artery rupture, though rare, is the most dreaded complication, and carries the highest mortality.
7. It is important to understand and differentiate the various determinants of cardiac and circulatory functions and measurements of tissue perfusion. It would be inappropriate to treat perfusion failure entirely with the concepts and therapy designed for cardiac failure. Hence, for overall management, it is important to understand the failure of each circulatory component.
8. The goal of noninvasive monitoring is not just attaining comparable information vis-à-vis invasive monitoring,

but the information attained should be continuous and in real time. Another important advantage of noninvasive monitoring would be to provide information early, possibly in pre-ICU locations such as in the casualty room. Once the hardware and software innovations of these monitoring devices attain acceptable accuracy, reliability and cost-effectiveness, it may change the standards of management of acutely ill patients with early hemodynamic impairment.

9. Tissue hypoperfusion, when present in patients with normal blood pressure and CO, is commonly referred as microcirculatory failure.
10. Measurement of SVV and arterial PPV are comparatively new technologies that help to assess the likely increase in ventricular responsiveness to volume load.

CHAPTER 8

Respiratory Monitoring in Adults

GENERAL CONSIDERATIONS

Respiratory monitoring is merely one facet in the overall monitoring of a critically ill patient.[1-3] The degree of respiratory monitoring and the number of parameters monitored, depend on the nature of the critical illness. Close monitoring of the respiratory system is particularly essential in respiratory emergencies and in acute respiratory failure, problems so frequently encountered in busy intensive care units. Since the heart and lung function as a single interrelated unit, hemodynamic monitoring is often equally essential in these patients. Acute respiratory failure particularly when due to acute lung injury [acute respiratory distress syndrome (ARDS)] is often complicated by renal dysfunction. Monitoring renal function in these patients is essential for diagnosis and management.

Respiratory monitoring helps: (1) in assessment of respiratory function; (2) in detecting complications involving the respiratory system in the course of any critical illness and (3) in detecting complications of mechanical ventilation. The information provided by this monitoring improves decision-making ability, and hopefully should improve patient outcome. Monitoring techniques can also help to assess progression or regression of pulmonary disease, and the response to various therapeutic interventions. It is however important to bear in mind that decision making in the management of patients with acute respiratory problems should not rest solely on monitoring of the respiratory parameters. Decision making should also depend on overall patient assessment, particularly of the hemodynamic state and of renal function.

MONITORING TECHNIQUES

Monitoring techniques particularly in poor developing countries should always invoke cost-benefit considerations. The potential risk and hazard of invasive monitoring procedures together with the added cost and added patient discomfort should be balanced against the possible benefit of improved diagnosis and better management.

The simplest, most basic and perhaps the most valuable aspect of patient monitoring is the close observation of the patient by the medical and nursing staff. Physical examination and radiological examination from day-to-day are of critical importance and provide a wealth of information. Sophisticated units unfortunately tend to neglect these basic, irreplaceable tenets of critical respiratory care. *All other monitoring techniques should supplement these basic tenets; they should never supplant them.*

An overall complete *physical examination* is of paramount importance. Special emphasis is placed on the heart rate, blood pressure, respiratory rate, examination of the chest and heart. A *radiological examination* of the chest is really a necessary appendage of the physical examination and merits equal importance. *Other basic monitoring techniques* include an arterial pH and blood gas analysis, electrocardiogram (ECG) monitoring, monitoring of hemoglobin and hematocrit, monitoring of urine output and of basic renal function parameters.

Other specific respiratory and hemodynamic parameters may need to be monitored at the bedside depending on the nature of the problem. These include tidal volume (V_T), minute ventilation (V_E), maximum inspiratory force, the

Box 1: Bedside measurements in patients with acute respiratory failure

- Physical examination—heart rate, blood pressure, respiratory rate, clinical examination of the heart and chest
- Radiological examination and ultrasonography of the chest
- Electrocardiogram (ECG) monitoring
- Monitoring of arterial pH, arterial blood gas analysis, oxygenation indices
- Pulse oximetry
- Airway CO_2 monitoring
- Monitoring of renal function
- Monitoring of hemoglobin and hematocrit
- Monitoring of respiratory parameters—tidal volume (V_T), respiratory rate, minute ventilation, maximum inspiratory force, physiological dead space (V_D), V_D/V_T ratio
- Bedside measurement of lung mechanics—dynamic and static compliances, airways resistance
- Monitoring waveform and loop analysis in mechanically ventilated patients
- Measurement of physiologic shunt, oxygen delivery or transport, oxygen consumption
- Monitoring of mixed venous oxygen tension and mixed venous oxygen saturation
- Hemodynamic monitoring in selected cases

physiological dead space (V_D) and the V_D/V_T ratio. Patients on mechanical ventilation may need bedside measurements of lung mechanics—this includes measurements of dynamic compliance, static compliance and resistance to airflow. Physiological shunt (Q_S/Q_T) may also need to be measured together with measurements of oxygen (O_2) delivery or transport (DO_2), and O_2 consumption ($\dot{V}O_2$). Hemodynamic monitoring is essential in some patients; it provides a measure of the cardiac index, filling pressures of the right and left heart, the vascular resistances in the pulmonary and systemic circulation. It also enables measurements of the mixed venous oxygen tension (PvO_2) and saturation, and enables the computing of the shunt equation and of DO_2 and the $\dot{V}O_2$. Finally, an analysis of expired gas, particularly with reference to carbon dioxide (CO_2), may provide useful information in a few patients. Box 1 lists bedside measurements, which are useful in patients with acute respiratory failure.

Not all measurements are necessary in every patient. The clinician should selectively monitor those parameters which are of help either in diagnosis, in management, or in both, bearing in mind the cost-benefit ratio of each monitoring technique in a given patient.

Physical Examination[4,5]

Tachycardia or bradycardia should be assessed in relation to the overall clinical situation. Both can occur in relation to increasing hypoxia.

Changes in arterial blood pressure may be due to several factors. These include hypoxia, hypercapnia, changes in effective circulating blood volume, and changes in cardiac contractility and in systemic vascular resistance due to various causes. Methods of measurement of arterial blood pressure have already been discussed in the earlier Chapter Cardiac Monitoring in Adults.

Respiratory Rate

A careful count and monitoring of the respiratory rate is of crucial importance. The normal range is from 10 to 16 per minute. A rate above 20 per minute always demands a satisfactory explanation. Rates greater than 30 per minute signify respiratory distress and may cause significant hypocapnia.

An increase in the respiratory rate is an early feature of a fall in PaO_2 or a rise in $PaCO_2$. Pulmonary problems producing tachypnea include atelectasis, pneumonia and pulmonary edema. Pleural effusion and pneumothorax should also be carefully excluded. In a critical care setting, sudden tachypnea may also be an early sign of sepsis, of increasing liver cell dysfunction or of pulmonary embolism. Metabolic acidosis initially produces an increase in the depth of breathing followed by an increase in the rate. Increase in respiratory rate and V_E are observed in patients on total parenteral nutrition who receive large carbohydrate loads. A large carbohydrate intake increases CO_2 production (VCO_2) so that a higher V_E is required to excrete the excess CO_2. In a critically ill patient, this constitutes a significant stress demanding increased respiratory muscle work. Respiratory muscle fatigue can result, particularly in patients who already have chronic airways obstruction. Overfeeding with carbohydrates may make weaning (in a patient on mechanical ventilation) impossible, and this is manifested by tachypnea and dyspnea on a T-tube. Decreasing total caloric intake and increasing the ratio of fat: carbohydrate intake decreases the VCO_2 and remedies the situation.

Clinical Examination of the Chest

The degree of chest movements during breathing often enables an astute observer to assess the adequacy of ventilation. Movements may however be deceptive in that adequate chest movement on clinical examination, may still be associated with alveolar hypoventilation, particularly when the physiological V_D is increased.

Asymmetrical movements with diminished breath sounds over the poorly moving side indicate pneumothorax, pleural effusion, pneumonia, atelectasis or uneven ventilation due to right main stem bronchial intubation.

Clinical examination should include a search for signs of respiratory muscle fatigue (see Chapter Acute Respiratory Failure in Adults). A stony dull note over the base of the chest may confirm a doubtful radiological opacity to be related to fluid, rather than to a parenchymal lung lesion.

Auscultation should determine the intensity of breath sounds, character of breath sounds and the presence of wheezes or crackles. Auscultation over the trachea may help in the detection of an inadequately inflated cuff of an endotracheal or tracheostomy tube.

Clinical Examination of the Cardiovascular System

This should be meticulous. Myocardial dysfunction may manifest with a diastolic gallop. A low cardiac output causing a low PaO_2 may be related to pump dysfunction or to mechanical problems like a valvular defect, or a ruptured septum or ruptured papillary muscle.

Radiological Examination

This as mentioned earlier is an appendage or a continuation of a physical examination. A radiological examination helps: (1) to check the position of various tubes, lines, catheters; (2) to detect early pulmonary edema, atelectasis, pneumonia, pleural effusion; (3) to diagnose a pneumothorax, which has been missed, or is undetectable on clinical examination; (4) to detect localized hyperinflation of a portion of the lung due to uneven lung compliance in patients on mechanical ventilation and positive end-expiratory pressure (PEEP); (5) to detect other features of barotrauma and (6) to detect abnormalities in the cardiac silhouette.

Pneumothorax may be difficult to diagnose when only supine films are available for interpretation. Features which may help in diagnosis in such situations include: (1) a sharp curvilinear change in density over the upper quadrant of the abdomen, which becomes significantly radiolucent and (2) a deep lateral costophrenic angle on the affected side.[6,7] A cross-table lateral or decubitus film in the above circumstance should be able to confirm the diagnosis of a pneumothorax.

A bedside ultrasound examination of the chest is extremely useful to confirm or detect fluid within the pleural space.

ECG Monitoring

Arrhythmias are frequent in patients with acute respiratory failure. Supraventricular tachycardia, chaotic atrial tachycardia, atrial flutter/fibrillation all occur. Ventricular rhythm disturbances including ventricular tachycardia may be observed with increasing hypoxia particularly in patients with ischemic heart disease.[8] ECG monitoring techniques have been discussed in an earlier chapter.

Arterial pH and Arterial Blood Gas Analysis

A close monitoring of arterial pH and arterial blood gases is indispensable in the management of acute respiratory failure, as also in the management of any critically ill individual with multiple organ system dysfunction. The PaO_2 is an index of arterial oxygenation, and the $PaCO_2$ is an index of alveolar ventilation. The significance of a low PaO_2 and of changes in $PaCO_2$ have been discussed in the Chapter of Basic Cardiorespiratory Physiology in the Intensive Care Unit, as also in the Chapters Acute Respiratory Failure in Adults and Mechanical Ventilation in the Critically Ill.

It is however extremely important to restress that a fall in PaO_2 in a critically ill patient could be due to either deteriorating pulmonary function or to nonpulmonary causes—in particular to deteriorating cardiovascular function.

The PaO_2/fractional inspired oxygen (FiO_2) ratio is a good overall index of gas exchange.[9] In a similar fashion, the arterial O_2 tension divided by the alveolar O_2 tension (the a/A ratio) remains stable with a varying FiO_2 and is a reliable index of factors governing gas exchange.[9] The normal a/A ratio is greater than 0.75. The ratio can predict the new PaO_2 that should result from a change in O_2 concentration.[10] It is therefore a good pointer to a change in lung function when the FiO_2 administered to the patient is changed.

Pulse Oximetry

In critically ill patients, the PaO_2 might fluctuate significantly, and a sharp fall in the PaO_2 may be missed during suctioning, during change in posture and following the administration of drugs. Continuous monitoring of PaO_2 by special electrodes in the radial, brachial and femoral arteries, as also of mixed venous blood (PvO_2) in the pulmonary artery can be done.[11] These are invasive, expensive techniques and it is doubtful if they help to significantly decrease the morbidity and mortality of very ill patients. However, a universally accepted noninvasive method of measuring arterial O_2 saturation is by the use of the pulse oximeter.[12,13] A beam of light of appropriate wavelength is made to shine through a finger or earlobe. The change in light absorption as blood traverses the vascular bed from beat-to-beat is dependent on the oxyhemoglobin saturation, and this saturation is continuously displayed on the monitor. The sensor, however, needs to be in continuous contact with the finger or the earlobe to which it is clipped. Monitoring O_2 saturation through pulse oximetry is today universally practiced in all critical care units, emergency departments and operation theaters. Pulse oximetry is also used during all minor procedures. A sharp fall in O_2 saturation should alert the physician or surgeon to potential disaster. There are however certain issues which need to be considered in this monitoring technique. Pulse oximetry is fairly accurate in the range of mild to moderate hypoxia. When hypoxemia is severe, as with a fall in O_2 saturation below 75%, its accuracy is suspect. In severe hypoxemia, the difference between measured O_2 saturation and the O_2 saturation obtained through pulse oximetry ranges from 5% to 12%.

Pulse oximetry is also unreliable in patients with severe hypotension and in patients with poor perfusion of the peripheries either from shock due to any etiology or from the use of vasopressors causing severe vasoconstriction. These factors impair blood flow to the site of the sensor of the oximeter and cause a variation in the contour and intensity of the pulse beats used to calculate O_2 saturation. Most oximeters are devised and programmed to stop recording O_2 saturation in states of low perfusion or when a poor pulse

signal is being measured. However, some oximeters continue to display O_2 saturation in spite of marked hypoperfusion and hypotension. These results are inaccurate, and the O_2 saturation readings under the above circumstances are misleadingly high.

Pulse oximetry though of great use in critical care medicine cannot and should not replace measurement of arterial blood gases. The measurement of PaO_2, pH remains of vital importance. The PaO_2 cannot always be accurately predicted from the O_2 saturation readings of the oximeter. When the O_2 saturation is between 95% and 100%, the exact measure of the PaO_2 can only be made by an accurate blood gas (PaO_2) estimation.

Clinical Uses

- Monitoring O_2 saturation in all procedures—major and minor. Minor procedures would include bronchoscopy, endoscopies, hemodialysis, cardioversion, injection of dyes and contrasts for imaging purposes.
- Keeping track on patients who are hypoxemic.
- Helping in ventilator support, as it enables (1) adjustment of FiO_2 as per the O_2 saturation readings and (2) detection of effects on arterial oxygenation with different modes of ventilator support and with use of PEEP.
- Aiding the weaning process, as it tracks the O_2 saturation when the patient is off ventilator support.

It is to be noted that the pulse oximeter cannot measure carboxyhemoglobin nor measure oxyhemoglobin in the presence of carboxyhemoglobin. Unreliable readings are also observed in methemoglobinemia.

Transcutaneous blood gas analysis is an important non-invasive method of monitoring infants with acute respiratory failure, and has been described in the Chapter Respiratory and Hemodynamic Monitoring in Children.

Airway CO_2 Monitoring

Airway CO_2 monitoring is done noninvasively, either with a quickly responding infrared CO_2 analyzer or a mass spectrometer, which measures CO_2 directly at the end of the endotracheal tube. Breath-by-breath analysis of the end-tidal PCO_2 ($PETCO_2$) can thus be obtained from an endotracheal tube during mechanical ventilation. Nonintubated patients can have the $PETCO_2$ sampled by a catheter placed through the nares in the posterior nasopharynx. Continuous waveforms can be recorded by capnography and the expired CO_2 is thereby monitored. The end-tidal pressure of CO_2 is related to partial pressure of alveolar CO_2 ($PACO_2$), which in turn is a measure of the $PaCO_2$. Thus, when expired CO_2 waveforms are continuously monitored, an estimate of the $PETCO_2$ would amount to a noninvasive measurement of the $PaCO_2$. The $PETCO_2$ will be increased if there is alveolar hypoventilation, or an increase in the VCO_2; it will be decreased if there is alveolar hyperventilation.

Analysis of the $PETCO_2$ thus helps in assessing the adequacy of alveolar ventilation, and guides ventilator adjustments to ensure that this is achieved. However, the close correlation between $PETCO_2$ and $PaCO_2$ observed in normal subjects does not always hold in patients with marked ventilation/perfusion (V/Q) abnormalities. In such patients, there is a divergence between $PETCO_2$ and $PaCO_2$ values. The expired gas in the presence of a V/Q abnormality is more influenced by lung units with high V/Q ratios and increased V_D, whereas the arterial blood is more weighted by lung units with low V/Q ratios and increased shunt. The $PETCO_2$ is thus an unreliable estimate of the $PaCO_2$ in these circumstances, though monitoring of changing trends may still be of use.

Capnography and $PETCO_2$ monitoring have been useful in the following other clinical situations—

- To provide a noninvasive method determining correct endotracheal tube placement. The capnograph should display an increased CO_2 concentration during expiration and the $PETCO_2$ reading should be plausible.
- To assess the efficacy of cardiopulmonary resuscitation. A very low $PETCO_2$ during cardiopulmonary resuscitation points to a very poor return of venous blood to the right heart and central circulation.

Monitoring Renal Function

Renal function needs to be monitored in every critically ill individual. *Close monitoring is especially important in acute respiratory failure, as renal dysfunction is a frequent complication and this significantly adds to the mortality*. Sweet et al.[14] in a study of 400 critically ill patients noted a mortality of 32% in respiratory failure alone, 44% in renal failure alone and 65% in combined respiratory and renal failure. Hypoxemia, acidosis, mechanical ventilation and use of PEEP may all disturb renal hemodynamics and tubular functions. Sepsis, hypovolemia and the use of nephrotoxic drugs can also significantly add to renal dysfunction.

Urine output, blood creatinine, blood urea nitrogen and serum electrolytes require close monitoring. A urine sodium level less than 10–20 mEq/L or a urine osmolality greater than 600 mOsmol/L suggests hypovolemia.

Renal function can also be monitored by measuring the urine osmolality, the plasma osmolality and the osmolar clearance (COsm). The urine osmolality divided by the plasma osmolality is calculated; if greater than 1.7 the concentrating ability of the kidney is good.

The COsm is calculated as follows—

$$\text{Osmolar clearance} = \frac{\text{Urine osmolality}}{\text{Plasma osmolality}} \times \text{Urine output}$$

The normal COsm is 120 mL/hour; it is decreased in renal dysfunction.

The normal calculated serum osmolality is between 275 mOsmol/L and 295 mOsmol/L (see Chapter Fluid and Electrolyte Disturbances in the Critically Ill). The calculated osmolality is 5–8 mOsmol less than the measured osmolality, the difference being related to anions like phosphate and

lactate. The greater this difference between measured and calculated osmolality in a critically ill patient with acute respiratory failure, and the greater the increase in serum lactic acid, the poorer the prognosis.

Monitoring Hemoglobin and Hematocrit

Monitoring hemoglobin concentration is essential as O_2 content of the blood depends significantly on this parameter. It is best to keep the hemoglobin concentration around 11 g/dL. The hematocrit is affected by a loss or gain in the red blood cells or in plasma volume. Sudden blood loss will not immediately change either hemoglobin or hematocrit. The hematocrit falls gradually as a result of shift of fluid from the interstitial compartment into the vascular compartment. This is a compensatory mechanism, which helps to maintain an effective circulating volume. Blood loss of 500 mL is replaced by fluid from the interstitial compartment initially at a rate of 1 mL/min.[15] The hematocrit needs to be monitored periodically; following hemorrhage, it needs to be monitored every 4–6 hours.

Monitoring Specific Respiratory and Hemodynamic Parameters

Tidal Volume, Respiratory Rate, Minute Ventilation and Maximal Inspiratory Force

Bedside spirometers, as also dry gas meters, are easily available to measure exhaled volumes. V_T, respiratory frequency (f) and V_E often need to be monitored, particularly in ventilatory failure and in patients who are to be weaned off ventilator support. As mentioned earlier, an increase in respiratory rate (f) may be the first sign of respiratory distress, and the degree of rise is proportional to the severity of underlying lung disease. Rapid shallow breathing is commonly observed in those who fail to be weaned from ventilator support. This can be quantitated by the ratio of f/V_T; if the value is above 100 breaths per minute per liter weaning is generally unsuccessful.[16]

A rapid respiratory rate with a low V_T may cause a fall in alveolar ventilation, particularly if the V_D is increased. A marked increase in V_E should lead to hypocapnia; if the $PaCO_2$ is within normal limits, it points to a marked increase in V_D. A V_T greater than 5 mL/kg and a vital capacity (VC) greater than 10 mL/kg suggest a good chance of weaning the patient from ventilator support. A V_E greater than or equal to 10 mL makes weaning difficult and unlikely. A maximum inspiratory force less than –20 cm H_2O generally necessitates the use of mechanical ventilatory support (see Chapter Mechanical Ventilation in the Critically Ill).

Physiological Dead Space

As explained in the Chapter Basic Cardiorespiratory Physiology in the Intensive Care Unit, an increase in physiological V_D points to wasted ventilation. Mechanical ventilation by itself leads to an increase in V_D. In respiratory failure and in many pulmonary pathologies, an increase in V_D is due to increased ventilation of alveoli, which are poorly perfused or unperfused.

$$\frac{V_D}{V_T} = \frac{PaCO_2 - P_ECO_2}{PaCO_2}$$

where P_ECO_2 in the mixed expired CO_2 tension.

If the $PETCO_2$ is substituted for $PaCO_2$, anatomical V_D can be calculated by analysis of the expired gas. An increase in V_D or in the V_D/V_T ratio in acute respiratory failure due to severe lung injury (ARDS) correlates with an increase in mortality. The higher the V_D, the greater the mortality.[17]

Bedside Measurement of Lung Mechanics

It is important to monitor lung mechanics in patients on ventilator support. The volume delivered by the ventilator divided by the peak airway pressure, constitutes the dynamic compliance. It includes the components of resistance to airflow and resistance related to the elastic properties of the lung.

$$\text{Dynamic compliance} = \frac{\text{Tidal volume}}{\text{Peak pressure}}$$

If PEEP is being used or if auto-PEEP is present, then

$$\text{Dynamic compliance} = \frac{\text{Tidal volume}}{\text{Peak pressure} - \text{PEEP (if present)}}$$

Dynamic compliance correlates with changes in airway resistance.

If we occlude the outflow of the ventilator momentarily (by turning the knob to inspiratory hold or to pause), the pressure dial will show a momentary drop at which no airflow occurs. This pressure is the plateau pressure.

$$\text{Static compliance} = \frac{\text{Tidal volume}}{\text{Plateau pressure} - \text{PEEP (if present)}}$$

Static compliance correlates with changes in elastic recoil.

The normal static compliance of the lung and the chest wall in mechanically ventilated patients is 70 mL/cm H_2O. When the static compliance of the lung and the chest wall is less than 20 mL/cm H_2O, the lungs are very stiff, and the degree of respiratory failure is invariably severe. In very severe acute lung injury, the static compliance may be as low as 10 mL/cm H_2O.

Periodic monitoring of the peak inflation pressure and plateau pressure for a fixed V_T, thus gives a good indication of lung mechanics. High plateau and peak pressures, and in particular progressively increasing plateau and peak pressures, are indicative of increasingly stiff lungs. This occurs in pulmonary edema, atelectasis, pneumonia, acute lung injury and pneumothorax. It is also observed when for some reason the patient strongly clashes with the machine.

Normally the peak pressure exceeds the plateau pressure by less than 5 cm H_2O. If the plateau pressure is significantly

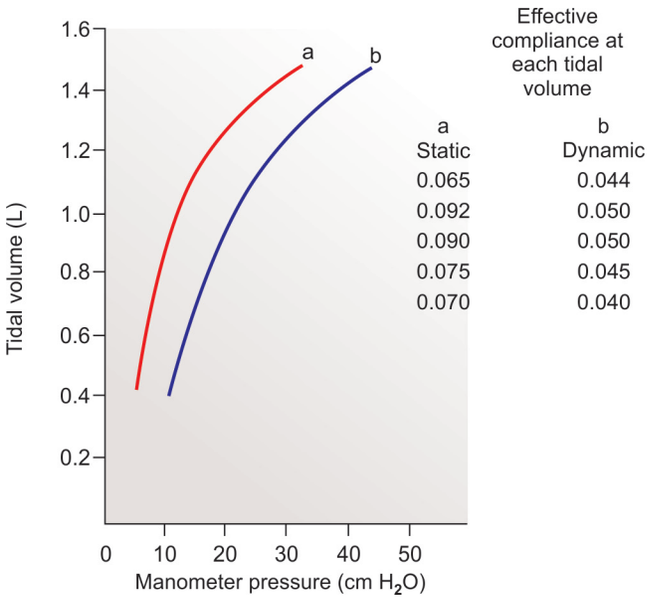

Fig. 1: Effective static and dynamic compliance curves calculated at varying tidal volumes: (a) effective static compliance curve; (b) effective dynamic compliance curve. Figures show effective (a) static and (b) dynamic compliance at each tidal volume

Source: Modified from Bone RC. Adult Respiratory Distress Medicine. New York: Thieme Medical Publishers; 1981.

lower than the peak pressure, it indicates an increase in airways resistance (Raw). A normal plateau pressure with a markedly increased peak pressure points to a marked increase in Raw. This can be due to a blocked endotracheal or tracheostomy tube, to secretions within the bronchial tubes or to bronchospasm (see Chapter Mechanical Ventilation in the Critically Ill). If airflow is measured, Raw can be calculated as follows—

$$\text{Raw} = \frac{P_P - P_{ST}}{V}$$

where P_P is the peak pressure, P_{ST} is the static or plateau pressure, V is the volume of airflow measured at end-inspiration at the time of peak pressure. In normal subjects, Raw is between 2 cm H_2O/L/sec and 3 cm H_2O/L/sec. In severe airways obstruction, Raw may be more than 10 times the normal value.

It is sometimes important to chart on a graph the dynamic and static compliance of the lungs, by ventilating the lungs at different V_{Ts} and recording the peak and plateau pressures for each volume. The dynamic compliance curve correlates with Raw and the static compliance curve with lung stiffness. The method of charting compliance is as follows—

- Select different V_{Ts}—400, 600, 800, 1,000, 1,200 mL.
- For each volume record spirometer volume, peak pressure, plateau pressure (ensure that the tracheostomy cuff is adequately inflated and that there is no air leak).
- Calculate dynamic compliance and static compliance as explained earlier.
- This procedure is repeated for each volume setting.
- If at any volume setting, the peak pressure shows a marked increase, a further increase in V_T setting should not be done as barotrauma may result.
- The data is charted on a graph so that dynamic and static compliance curves are obtained for varying V_{Ts} (Fig. 1).

Peak and plateau pressures (with graphs of dynamic and static compliance) can also be charted at a constant V_T with a gradual increase in PEEP. At high V_{Ts} or with higher PEEP levels, decreasing static compliance signals hyperinflation and care must be taken to avoid barotrauma. The incidence of the latter increases with high V_{Ts} or high levels of PEEP, which causes overdistension of the alveoli.

A careful examination of the static and dynamic compliance curves provides further information on lung mechanics (Figs 2A to C). Conditions causing an increase in Raw, shift the dynamic compliance curve to the right and flatten it. Conditions causing increasingly stiff lungs or causing chest wall stiffness, shift both the static and dynamic compliance curves to the right and flatten both.[18] If the patient has a low PaO_2 and both compliance curves are unchanged, the possibility of pulmonary embolism should be entertained.[15]

The charting of compliance graphs is subject to two possible errors.[15] If the patient clashes with and resists the ventilator, the pressure required to inflate the lungs will be greater than when he is relaxed. Also, if the patient actively assists the ventilator in inspiration, the pressure shown on the ventilator dial will be less than the total pressure required.

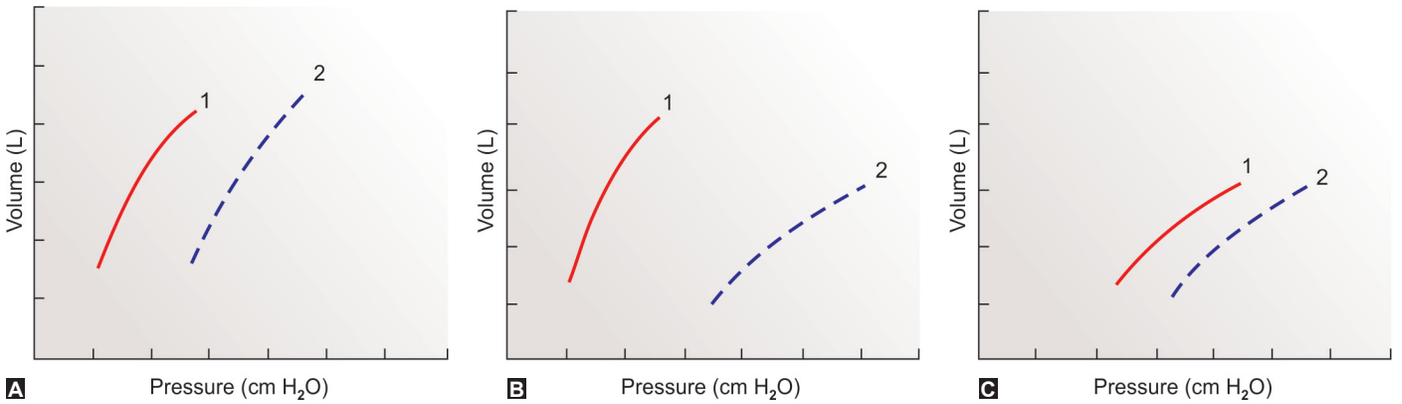
Ordinarily compliance curve charts are rarely necessary, and mere monitoring of peak and plateau pressures in relation to V_T settings provides adequate information on lung mechanics in patients on ventilator support.

Intrinsic Positive End-Expiratory Pressure

Intrinsic PEEP (auto-PEEP) is dealt with at length in the Chapter Mechanical Ventilation in the Critically Ill. Intrinsic PEEP is measured in relaxed patients on ventilator support by using the expiratory hold maneuver at the end of expiration. Intrinsic PEEP imposes an increase in the respiratory threshold load; this needs to be overcome by an increased inspiratory muscle effort so that a sufficient negative pressure is created in the central airways to trigger the ventilator. The inspiratory effort needed to trigger the machine must overcome the set sensitivity plus the intrinsic PEEP. Monitoring intrinsic PEEP is important not only in ventilated patients who have airways obstruction, but also in patients with other lung pathologies such as acute lung injury.

Waveform and Loop Analysis in Mechanically Ventilated Patients

Modern ventilators are provided with gadgetry capable of displaying breath-by-breath waveforms, pressure volume loops and also flow volume loops. The waveforms provided are the pressure-time waveform, the volume-time waveform and the flow-time waveform. Analysis of waveforms and loops enables the clinician to determine changes in resistance



Figs 2A to C: (A) Static compliance curve (1) and dynamic compliance curve (2) in normal individuals. These curves remain unchanged in patients who are hypoxic due to pulmonary embolism. (B) Static (1) and dynamic (2) compliance curves in patients with increased airway resistance. Note flattening and shift of the dynamic compliance curve (2) to the right. (C) Static (1) and dynamic (2) compliance curves in patients with increased stiffness of the lungs. Note that both the static and dynamic compliance curves are flattened and shifted to the right

and compliance of the patient's lungs while on ventilator support. A correct interpretation of waveforms and loops allows the intensivist to make a correct clinical decision on patient-ventilator relationship. It is our considered opinion that the display of waveforms and loops is of help; yet patient management can be as good and as effective with good clinical observation coupled with basic monitoring of respiratory mechanics discussed earlier.[19]

Physiological Shunt

The true venous admixture is an index of the quantity of cardiac output perfusing unventilated alveoli. This has already been explained in the Chapter Basic Cardiorespiratory Physiology in the Intensive Care Unit.

$$\frac{Q_S}{Q_T} = \frac{CcO_2 - CaO_2}{CcO_2 - CvO_2}$$

where Q_S is the shunt, Q_T is the total blood flow to the lungs, and CcO_2, CaO_2 and CvO_2 refer respectively to the O_2 content of pulmonary capillary, arterial and mixed venous blood.

Shunt is measured while breathing 100% O_2 for 20 minutes. If inadequate time is given to wash out all nitrogen from poorly ventilating alveoli, the degree of shunt will be overestimated. On the other hand, prolonged breathing of 100% O_2 promotes atelectasis and increases the Q_S/Q_T value.

If the shunt is measured on an FiO_2 of less than 1, ventilation-perfusion inequalities will contribute to the shunt. It needs to be stressed that a change in the degree of shunt may reflect either a change in pulmonary function influencing gas exchange or may be related to a change in cardiac output. A decrease in the cardiac output in acute lung injury can decrease the shunt within the lungs and thereby cause a rise in the PaO_2. A decrease in cardiac output, on the other hand, could lower the PvO_2 and thereby further decrease the PaO_2. The final effect on the PaO_2 depends on which of the above two hemodynamic changes predominates.

Oxygen Delivery

The importance of DO_2 has been dealt with in a number of chapters.

$$\text{Oxygen delivery} = \text{Cardiac output} \times CaO_2$$

where CaO_2 is the content of arterial O_2 (see Chapter Basic Cardiorespiratory Physiology in the Critical Care Unit).

Monitoring Mixed Venous Oxygen Tension and Mixed Venous Oxygen Saturation

The $P\bar{v}O_2$ and mixed venous oxygen saturation ($S\bar{v}O_2$) are often used as indices of tissue oxygenation and of cardiac output. This can only be possible if a pulmonary artery catheter is in use. Fiberoptic catheters are available for continuous monitoring of $S\bar{v}O_2$. A $P\bar{v}O_2$ less than 30 mm Hg invariably signifies severe hypoxia due to poor tissue perfusion. It is generally accepted that though the $P\bar{v}O_2$ accurately reflects tissue oxygenation in hemorrhagic and hypoxic shock, it often does not do so in septic shock and in patients with acute lung injury (ARDS). Misleadingly high $P\bar{v}O_2$ values may be obtained in these situations even when there is marked tissue hypoxia and lactic acid acidosis. This is probably related to a number of factors, chiefly perhaps to inability of the tissue cells to utilize O_2.[20]

Measuring $P\bar{v}O_2$ and $S\bar{v}O_2$ requires invasive hemodynamic monitoring. In most instances, O_2 saturation in the superior vena cava ($Sc\bar{v}O_2$) is measured in place of $P\bar{v}O_2$ and $S\bar{v}O_2$.

The $Sc\bar{v}O_2$ normally measures 65–70% and is 3–5% higher than $S\bar{v}O_2$. The $Sc\bar{v}O_2$ is measured through a catheter in the superior vena cava; the catheter is so designed as to give a continuous display of the $Sc\bar{v}O_2$.

Monitoring Serum Lactate Levels

The normal lactic acid levels in blood are less than or equal to 2 mm/L. Increase in serum lactic acid levels indicates tissue hypoxia. A normal or even an increased DO_2 may however at times be associated with increase in lactic acid levels. This either indicates that the O_2 needs of the tissues are still relatively greater than the O_2 delivered to the tissues or that the tissues are unable to effectively utilize O_2 (see Section Clinical Shock Syndromes).

Hemodynamic Monitoring

This is indicated in select cases of acute respiratory failure. A stable cardiovascular function is essential for good respiratory function, the heart and lungs being inseparably linked in function. Hemodynamic monitoring is invasive, and should be done with circumspection after due consideration of potential risks versus the possible benefits. It is particularly helpful in acute lung injury as it enables the clinician to manipulate filling pressures and adjust inotropic support so that DO_2 to tissues is adequately maintained.

Computer Monitoring[21]

We have no experience with the mass spectrometer and of online simultaneous measurements of gas exchange and lung mechanics. The cost-effectiveness of this technology is doubtful, perhaps confusing, and at times unreliable. The data obtained does not substantially add to patient management and may well detract from it. More time may be spent in looking at computer data rather than in observing the patient. This is not to decry the use of computers; it is a plea to use them in a proper perspective particularly in poor countries.

CHAPTER 9

Introduction

Anirudh Kohli *MD, DNB, DMRD. Head of Department of Radiology, Breach Candy Hospital, Mumbai, Maharashtra, India*

Imaging procedures are extremely useful in the diagnosis and management of acute illnesses in the critical care unit. Therapeutic interventions using image guidance are being increasingly practised in selected problems, thereby considerably reducing both morbidity and mortality. Numerous imaging modalities are now available for diagnostic and therapeutic help. These include radiology, ultrasonography, echocardiography, computed tomography (CT scanning), magnetic resonance imaging (MRI), nuclear scintigraphy, Doppler study of blood flow through the arteries and veins, angiography and digital subtraction angiography (DSA). It is important for the critical care physician to be aware of the advantages, disadvantages, benefits, risks and complications of each of these modalities. The mode or modes selected in a particular patient should thus increase the diagnostic and therapeutic yield at minimal cost. Cost is indeed an extremely important factor to be considered in our country. CT scans and MRI are expensive imaging procedures. To repeat them unnecessarily in a critically ill individual is bad medicine.

Management of critically ill patients requires a close liaison and communication between the radiologist and the critical care physician. Good management would also entail early availability of results of imaging procedures. This entails rapid processing of images, immediate interpretation by the radiologist, and prompt availability of the films to the clinician. A daily discussion between the radiologist and the intensive care unit physician of all X-rays and other imaging procedures is mandatory for the smooth, efficient functioning of a critical care unit.

Some imaging procedures like X-rays of the chest and abdomen, ultrasonography, echocardiography, and Doppler studies, can be performed at the bedside. Other investigations like CT scan, MRI, angiography, nuclear scintigraphy, unfortunately require the patient to be transported to the imaging department within the hospital. The risk of transfer of a critically ill individual to other departments, even if within the hospital, should be carefully assessed. All necessary safeguards and precautions must be ensured, and the risk-benefit ratio carefully considered before transfer.

The next chapter deals with imaging of the chest, followed by imaging of the abdomen and of the central nervous system. The imaging modalities considered are radiology, ultrasonography, CT and MRI. Echocardiography, Doppler studies, angiographic studies and nuclear scintigraphy are briefly discussed in relation to the relevant clinical problems in different chapters of this book. Nuclear scintigraphy is the one modality, which has been infrequently used by our unit. This is because of logistic reasons: we do not have a nuclear medicine department, and the use of nuclear medicine would necessitate transfer of seriously ill patients to centers outside the hospital. Nuclear scintigraphy does however have important uses in the critically ill individual. These include: myocardial perfusion scanning in cardiac disease, evaluation of an occult gastrointestinal bleed, establishing the diagnosis of acute cholecystitis, and the localization of an occult infection.

It needs to be stressed that imaging procedures for diagnosis and management in a critically ill individual, should supplement and never supplant a good clinical examination.

A machine, particularly an expensive one, does not have to be used just because it is available. It should be used only when its use confers a clear benefit to the patient, and not merely to the institution which houses it.

CHAPTER 10

Imaging Techniques in the Chest

Anirudh Kohli *MD, DNB, DMRD. Head of Department of Radiology, Breach Candy Hospital, Mumbai, Maharashtra, India*

GENERAL CONSIDERATIONS

Radiology plays a key role in the successful management of critically ill patients. The chest radiograph, especially when performed at the bedside is an invaluable examination in identifying and evaluating pulmonary and cardiac problems.

It is often debated whether there is a need for daily chest radiographs or only stat films. Many studies have shown that daily portable chest X-rays are very effective in diagnosing unexpected problems resulting in treatment alterations, which in turn affect the final outcome of the patient.[1-3] The quality of portable chest X-rays however is a factor of major concern. The limited power output and longer exposure time required for portable chest X-rays results in poorer quality than departmental films. There are other factors, which also contribute to non-consistent quality. In a large hospital with numerous radiographers, many different film screen combinations and multiple portable X-ray machines, the quality of portable films is bound to be inconsistent as each radiographer uses technical factors, which he feels are appropriate. Similarly, film screen combinations and portable machines require different settings. The ideal situation is for a single radiographer to use a single film screen combination and a single portable machine to take all the radiographs in the intensive care unit (ICU), as this would eliminate the variations. Often in a large hospital, this is not possible. For this reason, it is advocated that the radiographer should note the radiographic factors used, the distance, the film screen combination and the portable machine used, on the film. As films are taken on a daily basis, the radiographer taking the next X-ray can view the previous day's films, note the factors and other technical details and repeat the same, so that there is no change in the consistency of the radiographs. In addition, if the previous day's films were overexposed or underexposed, then the factors can be adjusted to achieve optimal quality.

The recent introduction of digital radiography has resulted in a dramatic improvement in image quality of radiographs in the critically ill patient especially at the bedside. Not only is there a marked improvement in image quality, but also there is no need for retakes. The images being digital can be adjusted to correct any under or overexposure, thus helping to remove any variability. There are two means to go to digital. One is to have purely digital portable X-ray machines, these are very expensive, and the other is to use a portable digital detector with routine portable X-ray machines. Rather than recording the image on a film, the image is recorded on a digital detector as pixels. There are two types of detectors available: computed radiography and digital. The computed radiography detector needs to be brought back to the imaging department to be read and erased. In case of digital detector, the image is available instantly at the bedside. This is a significant advantage in addition to better image quality over the computed radiography detectors.

Most of the X-rays taken in the ICU are an AP view with the patient upright. In this view, there is cardiac magnification, and it is very difficult to comment on the cardiac size. It should also be kept in mind that in supine chest X-rays the lung volume appears smaller. Another point, which is often overlooked, is the difficulty encountered in getting a critically ill patient to sit upright. Pathology in the lung bases can easily be missed in an X-ray chest taken when a patient is not totally upright. Every effort should therefore be made to position the patient correctly.

Computed tomography (CT) scan has evolved over the last two decades and is now an integral part of the radiological work-up. Its cross-sectional display eliminates superimposition

of structures, improves contrast, resolution and tissue characterization, thus allowing better diagnosis of diseases. The only disadvantage is the need to transport the patient to the CT scanner suite and back. This can be time consuming and occasionally risky with the patient away from the ICU. However, the useful information offered by CT far outweighs the risks. In one study, evaluation of thoracic CT in critically ill patients provided useful additional information, which was not available on plain chest X-rays in 70% of the cases.[4,5]

PULMONARY EDEMA

This is one of the most important pathologies affecting the cardiovascular system and a very frequent cause of respiratory distress in the critically ill patient. There are three main causes for pulmonary edema: (1) cardiogenic edema; (2) overhydration edema due to over-infusion of fluids or renal failure; and (3) increased capillary permeability due to various insults to the capillary membrane. The initial treatment for pulmonary edema is the same irrespective of the etiology. Management however requires accurate assessment and correction of the underlying cause. The chest radiograph should therefore be evaluated not only for signs of pulmonary edema, but also to identify the underlying etiology.

The radiographic features of pulmonary edema can be considered in three categories—

1. Pulmonary venous hypertension.
2. Interstitial edema.
3. Alveolar edema.

On an upright chest radiograph of a normal subject, the lower lobe vessels are more prominent than the upper lobe vessels. With elevation of pulmonary venous pressures, the blood flow is redirected to the mid and upper zones. In addition, non-perfused blood vessels in the upper zones are opened up, and there is reflex vasoconstriction of the lower zone vessels, resulting in a vascular redistribution on the chest radiograph. The appearances can be classified into three types: (1) normal or caudalization of blood flow, i.e. normal flow patterns; (2) balanced, essentially equal blood flow to apices and bases; (3) inverted or cephalization of blood flow when the upper lobe vessels are larger than the lower lobe vessels. These findings will only be observed on upright X-rays; recumbent or supine X-rays may show no evidence of vascular redistribution.

When the pulmonary capillary wedge pressure (PCWP) increases to 18–25 mm Hg, there is transudation of fluid into the interstitium; when the PCWP is greater than 25 mm Hg, transudation of fluid occurs into the alveoli. Interstitial edema is recognized by the presence of Kerley lines, perivascular cuffing, peribronchial cuffing and perihilar haze. The Kerley lines are of three types: (1) Kerley A lines; (2) Kerley B lines, and (3) Kerley C lines. Kerley A lines are 2–6 cm in length and about 1 mm in thickness. These lines radiate from the hilum to the periphery of the lung and are best seen in the upper zones. Kerley B lines are 1–2 cm long and about 1 mm in diameter. These lines are seen in the subpleural regions of the lower zones adjacent to the costophrenic angles. Kerley B lines are more frequently seen than the Kerley A lines. Kerley C lines are considered as an overlap between Kerley A and B lines. These are not important as they are seldom detected on a chest radiograph. With transudation of the fluid into the interstitium around the vessels and bronchi, the sharp margin of these structures becomes indistinct, and this is known as perivascular and peribronchial cuffing. Similarly, exudation into the interstitium about the hilum results in a perihilar haze.

Alveolar edema occurs with transudation of fluid into the alveoli and is characterized by fluffy ill-defined opacities in the lung, especially in the central zones giving rise to a bat's wing or butterfly appearance. Often an air bronchogram pattern may be seen within these ill-defined fluffy shadows.

Unilateral pulmonary edema is not an uncommon finding and poses a diagnostic dilemma, as the radiological appearances may be similar to those seen with an inflammatory pathology. Pulmonary edema may occur in one lung or lobe, either due to a disease process within that lung (e.g. patients lying on one side for prolonged periods, or unilateral veno-occlusive disease), or may be related to some pathology in the opposite lung, which prevents pulmonary edema from developing on the same side (e.g. cases with unilateral pulmonary emboli or the Swyer-James syndrome). The distribution of unilateral pulmonary edema may be patchy, with some areas of the lung being more affected than others. This is usually due to underlying emphysema, scarring, or radiation injury. It is difficult to differentiate focal pulmonary edema from focal inflammation radiologically, and a clinical correlation together with serial follow-up X-rays is often needed to confirm the diagnosis.

DIFFERENTIATION BETWEEN CARDIOGENIC EDEMA, OVERHYDRATION EDEMA AND CAPILLARY EDEMA

Milne and coworkers[6] have reported that these could be differentiated on the basis of three principal features: (1) distribution of pulmonary blood flow; (2) distribution of pulmonary edema and (3) width of the vascular pedicle. Systemic blood volume is accurately depicted by the vascular pedicle, which is the portion of the superior mediastinum containing the great vessels. As these vessels are distensible, they respond to changes in the circulating blood volume.[7]

It has been found that the vascular pedicle was enlarged in 60% of patients with cardiac edema, and 85% of patients with renal failure or overhydration; in contrast, 70% of patients with capillary permeability edema had a vascular pedicle of normal width.[6] As regards the distribution of pulmonary flow, patients with overhydration edema had balanced or cephalization of blood flow, while patients with capillary permeability edema had normal or balanced flow. The distribution of edema was symmetric, perihilar in patients with cardiac or overhydration edema, whereas capillary permeability edema appeared patchy and peripheral.

ACUTE LUNG INJURY (ACUTE RESPIRATORY DISTRESS SYNDROME)

Acute lung injury [acute respiratory distress syndrome (ARDS)] is a consequence of acute lung injury resulting in damage to the alveolar epithelium and pulmonary vasculature with resultant capillary permeability edema. Three stages have been described in ARDS.[8]

Stage I is the earliest and occurs within a few hours after the insult. Pathologically, there is a pulmonary capillary congestion, endothelial cell swelling and extensive microatelectasis. As the fluid leakage into the interstitium is minimal, the radiograph at this stage shows relatively clear lungs, though the lung volumes may appear small due to diminished compliance. If the acute lung injury is due to primary lung pathology such as aspiration or pneumonia, then pulmonary opacities related to this condition will also be seen.

Stage II occurs about 2–5 days after the injury. The pathological features are of fibrin deposition, hemorrhagic fluid leakage and hyaline membrane formation. These are seen on the radiograph as diffuse ill-defined bilaterally symmetrical patchy areas of consolidation, which may have an air bronchogram pattern present in them. Asymmetrical shadowing can also occur. Rarely, there may be associated pleural effusions, but these are usually small.

Stage III is characterized by collagen deposition, proliferation of fibroblasts and epithelial cells. Radiologically, the appearance is of progressive lung destruction with a transition from alveolar to interstitial opacities. The treatment of ARDS includes positive pressure ventilation, which may result in barotrauma, manifested by pneumothorax, pneumatocele, pneumomediastinum or pulmonary interstitial emphysema. With the use of positive end-expiratory pressure (PEEP), there may be areas of overinflation or barotrauma in the lung parenchyma that give rise to the appearance of disappearing opacities. However, this is not accompanied by evidence of clinical or physiological improvement. After recovery, there may be residual fibrosis and focal emphysema, but often the X-ray returns to normal.

Pneumothorax and pneumomediastinum are easily identified on radiographs. However, CT helps in detecting the early features of barotrauma, e.g. interstitial pulmonary emphysema and pneumatoceles. Interstitial pulmonary emphysema is seen as thin streaks of air in the interstitium and should be differentiated from an air bronchogram. There is sharp delineation of the bronchovascular bundle in interstitial pulmonary emphysema. A CT examination can detect a large pneumatocele formed by the coalescing of small thin walled peripheral cysts.

In stage II ARDS, the X-ray may resemble that of cardiogenic pulmonary edema, and needs to be differentiated from it. In contrast to cardiogenic, uremic and hypervolemic pulmonary edema, the alveolar edema of ARDS is not associated with widening of the vascular pedicle, cardiomegaly or altered pulmonary blood flow distribution. The pulmonary vessels visualized are usually constricted because capillary leak occurs directly into the alveolar spaces and septal lines are absent.

PNEUMONIA

Aspiration Pneumonia

Aspiration pneumonia occurs as a result of endotracheal aspiration of oropharyngeal or gastric secretions. Tracheal and esophageal intubation, depressed cough reflex, impaired mucociliary function, increased secretions, cardiopulmonary resuscitation events and the supine posture are factors that predispose the critically ill patient to aspirate. Radiologically, the demonstration of suddenly appearing new focal pulmonary lesions should raise the suspicion of aspiration. The areas of involvement are mainly in the dependent portion of the lung—superior segments of the lower lobes, or posterior segments of the upper and lower lobes when the patient is supine. If the patient has been in the lateral decubitus position, aspiration causes collapse consolidation of multiple segments of one lung, while the other lung is spared. Patients who are prone in roto beds show involvement of the anterior segments of the upper and lower lobes, the middle lobe and the lingual.[9] Aspiration pneumonia may be complicated by a necrotizing lung abscess. Aspiration of gastric contents results in an acute pulmonary reaction with pulmonary edema causing chemical pneumonitis. This type of pneumonitis may eventually progress to ARDS or secondary bacterial pneumonia.

Nosocomial Pneumonia

Nosocomial pneumonia is defined as a lower respiratory tract infection occurring after 72 hours of hospital admission and is an important cause of death in hospitalized patients. A large study showed that 31% of patients admitted to an ICU were at risk of developing pneumonia following intubation.[10] Radiologically, nosocomial pneumonia is seen as new or worsening multifocal parenchymal opacities. Nosocomial pneumonias are often complicated by a lung abscess or empyema. These complications help to differentiate nosocomial pneumonia from other conditions like atelectasis or pulmonary edema that may present in critically ill individuals as new opacities on a chest radiograph.

Community-Acquired Pneumonia

The appearances can be divided into three types: (1) lobar pneumonia; (2) bronchopneumonia and (3) interstitial pneumonia. In lobar pneumonia, there is usually alveolar inflammation resulting in a diffuse opacity with the presence of an air bronchogram pattern. The opacity usually involves a segment or a portion of a lobe; rarely, it may involve the entire lobe. It is generally impossible on radiographic appearance to differentiate the various bacteriological organisms that cause pneumonia. However, when there is evidence of increased lung volume in the affected portion of the lung, then the possibility of *Klebsiella* or pneumococcal pneumonia should

be considered. It is important to localize the consolidation to a specific lobe, as this is helpful to the bronchoscopist. The silhouette sign is used to determine the site of the consolidation. Whenever the consolidation is adjacent to a soft tissue structure, it causes obliteration of the margin of that structure. When the consolidation is adjacent to the right border of the heart, it is localized to the right middle lobe; when the consolidation is in the left lingula, it obliterates the left heart border. Lower lobe pneumonias may cause loss of the diaphragmatic contour.

Bronchopneumonia results from inflammation of the terminal end-respiratory bronchioles. Radiologically, this is seen as patchy, infiltrates involving multiple segments. There may be evidence of volume loss, but air bronchograms are usually not visualized.

Interstitial pneumonias are usually caused by viruses or *Mycoplasma pneumoniae*. Radiologically, they appear as diffuse reticular opacities in both lung fields with peribronchial thickening. These changes may however progress to an alveolar inflammation thereby simulating a lobar pneumonia.

Parapneumonic fluid collections may accompany pneumonias. These are usually well seen on radiographs, though occasionally they may be difficult to separate from a consolidation. In such situations, a sonography or CT examination accurately picks up fluid within the pleural space, and enables the interventional radiologist to perform a guided aspiration of the fluid. Examination of the fluid confirms the diagnosis of empyema. Mediastinal adenopathy is not usually present with bacterial pneumonias, but may be seen with tuberculosis, fungal and viral pneumonias. Pneumonia may be complicated by the formation of lung abscess or empyema. The diagnostic feature of a lung abscess is the presence of an air-fluid level. For this to be demonstrated, the patient has to be in the erect position. Occasionally, the abscess may have no significant fluid level and appears as a cavitatory lesion. This needs to be differentiated from a bulla, pneumatocele, or a cavitatory neoplasm. Bullae and pneumatoceles have thin walls whereas lung abscesses have relatively thick walls. A cavitatory neoplasm usually does not have any perilesional inflammation, as is usually seen with a lung abscess. It has been reported that lung abscesses may not be detected radiologically in 18% of cases.[11] A CT scan in these patients becomes mandatory. CT scan clearly demonstrates the air-fluid level in an abscess. CT is also very useful in differentiating between pleural and parenchymal components, which may be superimposed on a plain X-ray, and thus be difficult to differentiate.

ATELECTASIS

Atelectasis is one of the commonest findings on chest X-ray taken in the ICU. The left lower lobe is the most frequent location of atelectasis, especially in the post-bypass patient. The atelectatic portion of the lung has variable radiological appearances. It may be seen as plate-like or linear opacities known as plate atelectasis. Loss of volume is evidenced by shift of the fissures, hilum, diaphragm, trachea and heart. A bronchogram pattern may be seen within the opacity. This is an important finding because patients with an air bronchogram pattern within an atelectatic segment may not improve with bronchoscopy. If no air bronchogram is seen, the patient is likely to improve with bronchoscopic aspiration.[12, 13]

PULMONARY EMBOLISM

The X-ray findings and spiral CT angiography (CTA) scan abnormalities seen in critically ill patients with pulmonary embolism, have been discussed in the Chapter Pulmonary Embolism.

Pleural Effusions

Free pleural effusions tend to gravitate to the most dependent portions of the pleural cavity. On erect chest X-rays, these are seen as homogenous densities in the lower zone with a typical concave or upward-sloping contour, the lateral margin being higher than the medial margin. The posterior costophrenic (CP) sulcus is the deepest portion of the pleura. This is the site where the fluid first tends to accumulate. Radiologically, this is seen as blunting of the costophrenic angle on the lateral view.

At least 200 mL of fluid is required to cause obliteration of the CP angle on a posteroanterior view of the chest, though in some cases, there is no blunting of the angle even when 500 mL of fluid is present. The lateral decubitus view is the most sensitive X-ray to demonstrate free fluid. Fluid is seen layering in the dependent part of the chest wall as a thin uniform opacity. This view however may be technically difficult to obtain in a patient who is critically ill. In patients who are too critically ill to sit erect, a diagnosis of pleural effusion has to be made on a supine X-ray chest. The findings in moderate sized or large effusions are a homogenous opacity of the affected hemithorax with absence of the vascular markings. This is because the fluid is layering posteriorly along the chest wall. Fluid also tends to accumulate along the apex, like an apical pleural cap, and in the base, as these are the most dependent areas on a supine film. Small pleural effusions can be easily missed on a supine radiograph. In fact, only 67% sensitivity and 70% specificity have been reported for the detection of a pleural effusion on supine chest X-ray as opposed to a lateral decubitus view.[14]

In critically ill patients who cannot be positioned for a lateral decubitus view, or if a supine radiograph shows equivocal or negative findings, sonography is an excellent means for demonstrating pleural fluid. This imaging modality is portable and can be easily performed at the bedside. Pleural fluid is seen as an anechoic area separating the echogenic line of the diaphragm and the echogenic inferior margin of the lung. Sonography is also useful in differentiating a pleural effusion from atelectasis/consolidation, which may simulate an effusion on the chest X-ray. Further, it is an excellent guide for thoracocentesis markedly reducing the incidence of iatrogenic pneumothorax.

Occasionally, free pleural fluid may accumulate in a subpulmonic location between the lung and diaphragm, with the lung floating on the fluid. The upper margin of the fluid may then take the appearance of the diaphragm. Left sided subpulmonic effusions may be detected by noting the wide distance between the stomach air bubble and diaphragm. On the right side, differentiation from an enlarged liver pushing the diaphragm upward may be difficult. In these cases, either a lateral decubitus view or sonography is useful to clinch the diagnosis. A loculated effusion may occur when there are adhesions between the visceral and parietal pleura, as a result of which the fluid does not shift with change of the patient's position. Empyema and hemothorax may appear as loculated effusions.

Computed tomography scan is extremely sensitive in detecting even small pleural fluid collections. With the patient supine, free fluid accumulates posteriorly as a hypodense layer conforming to the contour of the chest wall. The presence of septae in the pleural fluid (denoting a likely exudate) is however brought out by a sonographic study rather than by a CT scan. Acute hemorrhage in the pleural space can be well identified by the hyperdensity of blood. CT is also useful in the assessment of the site, extent and wall thickening of the loculated effusions, and for loculated interlobar effusions. These may simulate a mass lesion on plain X-ray but can easily be differentiated on CT. CT with intravenous contrast medium is very useful in differentiating parenchymal from pleural lesions, especially when a plain radiograph has not helped. CT is also an effective guide for thoracocentesis except when the effusion is small and layering posteriorly in the dependent portion of the chest. In these conditions, sonography is far superior to CT.

EMPYEMA

On a chest radiograph, an empyema is usually seen as a loculated fluid collection. It tends to be lenticular in shape as compared to a lung abscess that is rounded. Further, an empyema usually forms an obtuse angle with the chest wall while a lung abscess forms an acute angle. CT is very useful in the diagnosis and management of empyema. On CT scan, an empyema appears as a well-defined fluid collection with enhancing parietal and visceral pleura. This sign of separation of the pleura is known as the split pleura sign. CT scan is far superior to any other imaging modality in differentiating lung abscess from empyema, though occasionally the differentiation may be difficult. On CT scan, a lung abscess is usually rounded whereas an empyema is lenticular in shape. Also, the lung margin is very sharp in relation to an empyema; whereas in a lung abscess, there is usually peripheral consolidation around the abscess.

Traditionally, empyemas have been treated with insertion of chest tubes. The success rate with chest tube drainage is 35–71%.[15] However, 35% of all patients treated with conventional chest tubes are found to subsequently require either open chest tube drainage or decortication. Several studies estimated the success rate of fluoroscopy, sonography and CT scan in image-guided percutaneous insertion of chest tubes to be between 70% and 90%. Under imaging, the catheter can be placed accurately in the fluid collection. In fact, image-guided percutaneous drainage of empyemas is advocated as the primary method of treating empyemas. Patients, who show inadequate drainage or progressive persistent pleural thickening, may finally require decortication.

PNEUMOTHORAX

This is a relatively common complication seen in the ICU and should be very carefully looked for on every chest radiograph of a critically ill patient, especially following procedures such as thoracocentesis, central venous line insertions, endotracheal intubation, tracheostomy and in patients on positive pressure ventilation. Air in the pleural cavity is seen in the most nondependent portion of the chest. On the erect chest X-ray, it is therefore seen in the apical region. There are numerous radiographic signs to recognize a pneumothorax, the most important being demonstration of the visceral pleura as a thin opaque line. Other signs observed are hypertranslucency between the chest wall and the collapsed lung, this region being devoid of vascular markings.

The degree of atelectasis of the underlying lung is variable and depends upon the size of the pneumothorax. The underlying lung shows a mild increase in density but appears opaque only when total collapse has occurred. The size of the pneumothorax may be measured but is usually depicted as small (<25%), moderate (25–50%) and large (greater than 50%). Routine X-rays obtained in the ICU are usually inspiratory films and in these films, a small pneumothorax may be missed. If there is a high index of suspicion, then an expiratory film should be taken to demonstrate a small pneumothorax. Another important point to bear in mind is that a pneumothorax following a procedure may take up to 4 hours to develop; thus, the ideal X-ray to determine a postprocedure pneumothorax is a delayed (4 hours) expiratory film.

Often patients are critically ill and cannot be radiographed in the upright position. The appearance of a pneumothorax on a supine film is different. As air collects in the most nondependent portion (this being the anteroinferior portion on a supine film), this is seen as a hypertranslucency over the upper quadrant with a deep costophrenic sulcus. If these signs are doubtful a cross-table lateral view is obtained, which clearly shows the collection of air.

Occasionally, tubes and skin folds may mimic a pneumothorax; these can however be differentiated by visualizing lung markings beyond these structures. Also skin folds are usually in pairs, bilateral, do not have a sharp margin like the visceral pleura and often extend outside the thorax.

Two unusual types of pneumothorax need to be considered. The more important one is a tension pneumothorax, which is an absolute emergency and, if untreated, will result in death. A tension pneumothorax occurs when air enters during inspiration but cannot exit during expiration due to a check

valve mechanism. On a chest X-ray, the entire hemithorax is hypertranslucent, the mediastinum is shifted to the opposite side and the ipsilateral lung is compressed. In addition, the diaphragm on the affected side may be deeply inverted. The second unusual type of pneumothorax is when there is collapse or lobar atelectasis. There is diffusion of gas into the pleural space due to volume loss. In this scenario, the pneumothorax is essentially an ex vaco occurrence, and resolves spontaneously as the affected portion of lung is better aerated by suctioning or bronchoscopy.[16]

PNEUMOMEDIASTINUM

This may occur following esophageal rupture, tracheobronchial injuries or alveolar rupture with air tracking into the hilum via the interstitium. Air in the mediastinum is seen as a lucency about the mediastinal structures, bounded laterally by an echogenic line—the mediastinal pleura—which is now visualized as it has air on both sides. Air tracking inferiorly in a pneumomediastinum, permits visualization of the infracardiac surface giving rise to the continuous diaphragm sign. In children, the mediastinal air elevates the thymus and outlines it, producing a triangular opacity along the lateral mediastinal border, known as the spinnaker sail sign.

PULMONARY INTERSTITIAL EMPHYSEMA

Pulmonary interstitial emphysema occurs due to elevated intra-alveolar pressure causing rupture of the alveoli, with consequent leak of air into the interstitium. This air then dissects along the bronchovascular bundle that is the path of least resistance. This may extend to the mediastinum, or peripherally to the visceral pleura, resulting in pneumomediastinum or pneumothorax. It may also track superiorly into the neck as subcutaneous emphysema, or rarely decompress into the retroperitoneum as a pneumoperitoneum.

On X-ray, pulmonary interstitial emphysema is difficult to detect and can be seen only when it is superimposed on an area of air space consolidation. It is then seen as thin streaky and bubbly radiolucencies. In fact, when visualized and compared with previous X-rays, it may falsely suggest an improvement in an air space consolidation, as the density of the consolidation becomes less due to the superimposed radiolucencies. This is one paradoxical situation where the patient clinically deteriorates and yet the radiograph shows an apparent improvement. When there is no air space consolidation and the lung is normally aerated, these radiolucencies are not visualized, as they are contrasted against a dark lung. In these cases, a CT scan is very helpful as it demonstrates the linear and cystic areas of air trapping.

TUBES AND SUPPORTING DEVICES

There are numerous tubes and devices used in the ICU for monitoring and support of the critically ill patient. It is important to monitor the position, possible malpositions and complications of these tubes and devices. Portable chest bedside X-rays usually provide adequate information on these devices/tubes.

Airway Tubes

Endotracheal and tracheostomy tube position should be checked immediately after placement and periodically thereafter to ensure proper positioning, as airway tubes if malpositioned may cause serious complications. These tubes usually have a radiopaque line running along their entire length or may be totally opaque. The correct site for the tip of an endotracheal tube is 5–7 cm above the carina with the head in the neutral position.[17] If the carina is not easily delineated, then it is assumed that the carina is between T5 and T7 and the endotracheal tube should end 5–6 cm above the T4/T5 disc space, i.e. between T2 and T4. Changes in head position can alter the site of the tip of the endotracheal tube seen on the radiograph as the tube is usually fixed to the nose or mouth. The tube shifts approximately by 2 cm in flexion or extension. It is, therefore, important to determine the position of the head on the radiograph first. If the tube is too inferior in position, it may be seen to extend into the main bronchus especially the right main bronchus resulting in a bronchial intubation. This results in overinflation of the intubated lung which is therefore at increased risk of barotrauma and pneumothorax. The opposite lung may show changes of atelectasis and collapse. Conversely, an endotracheal tube not inserted inferior enough may extubate or cause vocal cord damage. To prevent vocal cord damage the tip should be at least 3 cm below the vocal cords. Esophageal intubation may rarely occur. This is detected by visualizing the tube outside the tracheal lumen and the presence of gross overdistension of the stomach. Occasionally, it is difficult to determine if the tube is outside the trachea on the frontal radiograph as the esophagus lies behind the trachea. In these cases, a right posterior oblique view with the patient's head turned to the right allows separation of the esophagus and trachea.

A tracheostomy tube tip is ideally situated between half and two-thirds the distance from the stoma to the carina, and the width of the tube should be approximately two-thirds the tracheal width. Tracheal intubation may result in injury to the trachea and consequent tracheal stenosis. Endotracheal intubation may result in subglottic stenosis or stenosis at the cuff site. Anteroposterior and lateral radiographs of the neck and trachea may demonstrate the site and level of stenosis. CT scan is very useful in the demonstration of subglottic and tracheal stenosis, depicting the level, extent and degree of narrowing. Magnetic resonance imaging (MRI) demonstrates the larynx and trachea well and may also be used to demonstrate the site, extent and degree of narrowing.

Nasogastric Tubes

These tubes usually have small rounded radiopaque balls at their lower end denoting the inferior extent of the tube. The ideal location of the tube is in the duodenum as this prevents

gastroesophageal reflux; it also should be kept in mind that the last 10 cm of the tube has side holes; therefore, at least 10 cm should be below the esophageal hiatus. After introduction of a nasogastric tube a radiograph should be taken to determine its location. Occasionally, tubes may be coiled in the pharynx or esophagus, or worse still, they may be in the tracheobronchial tree, which may by result in pneumonia, lung abscess, pneumothorax or a hydropneumothorax. Inadvertent tracheobronchial insertion of a nasogastric tube may occur in patients with endotracheal intubation especially in those with low pressure, high volume balloons, as these do not prevent passage of a feeding tube into the tracheobronchial tree. If inadvertent placement of the tube has occurred into the tracheobronchial tree as seen on X-ray, then the tube is withdrawn and repositioned. A rare malposition has been a perforation of the nasopharynx and base of the skull with an intracranial placement of the nasogastric tube. Rarely, esophageal perforation may result in pneumomediastinum, mediastinal hematoma or pleural effusion. This may occur with a Sengstaken-Blakemore tube when the gastric balloon is inadvertently inflated in the esophagus.

Thoracotomy Tubes

These tubes are frequently used to evacuate air/fluid from the pleural cavity. This is a clear plastic tube with a radiopaque line along its length, which is interrupted by the proximal-most side hole. When used to drain air, it is ideally placed in the second intercostal space anterosuperiorly and directed to the apex. To drain fluid, it is ideally located in the 6th, 7th or 8th intercostal space in the midaxillary line and directed posteriorly. Ideally, the tubes take a gentle curve within the thorax at the site of penetration of the pleura. The tube may be malpositioned in the lung parenchyma or fissures. Malposition in the lung parenchyma usually leads to the formation of a hematoma, bronchopulmonary fistula or parenchymal laceration. Placement of the tube in a fissure results in poor drainage. The malposition may not be appreciated on a frontal radiograph but is usually well seen on a lateral radiograph, as the tube is seen to turn sharply medially when in a minor fissure, and obliquely when in a major fissure. Occasionally, the tube may be malpositioned within the extrapleural soft tissue resulting in inadequate drainage and subcutaneous emphysema. Rapid decompression of the pleural space by the tube may result in a unilateral re-expansion pulmonary edema. A pulmonary infarct may occur if lung tissue is sucked into the tube. Fibrous adhesions may occur around an indwelling tube, so that when the tube is removed, a track persists and may be confused with a pneumothorax. Fluid may accumulate in this tract and appears as an abscess on a chest X-ray. These tracks usually decrease in size over a few days and then finally disappear.

Central Venous Pressure Catheters

Central venous catheters are commonly used in ICU patients to monitor central venous pressure (CVP) and provide a venous access. These catheters are seen as thin radiopaque tubes extending peripherally from the subclavian, internal jugular or femoral vein into the superior vena cava (SVC). The ideal location of the tip of a CVP tube is in the SVC. This is because the tip should be outside the right atrium and beyond the most proximal venous valves, which are usually situated in the subclavian and internal jugular veins.

The CVP catheter may be malpositioned in the internal jugular, opposite subclavian, azygos, brachiocephalic, axillary, hepatic veins or in the right atrium/ventricle. Rarely, there may be a possibility of intra-arterial introduction of a CVP catheter. This may be seen in a hypoxic/hypotensive patient in whom the arterial blood is non-pulsatile and dark, simulating venous blood. As the SVC is a right-sided structure, visualization of the catheter on the left side or in the midline should raise the possibility of an intra-arterial placement.

The main complication of CVP catheter insertion is a pneumothorax. This may occur immediately, or may be delayed for a few hours or even days after insertion due to the slow accumulation of pleural air.[18,19] Therefore radiographs immediately after placement of CVP catheters may not totally exclude a pneumothorax, and delayed films are required. Hemothorax, perforation of the vessel, mediastinal hemorrhage and ectopic infusion of intravenous fluids may occur resulting in radiographic appearances of fluid accumulation at these sites. Venous air embolism is another uncommon complication, which may be visualized on a chest X-ray as air in the main pulmonary artery, with associated signs of pulmonary embolism. Other complications, which may occur, and which are diagnosed on an X-ray are catheter knotting, catheter fragmentation and the catheter pinch-off syndrome. Catheter knotting and fragmentation are serious complications. To visualize the catheter fragments, both frontal and lateral views are required as some fragments may be overlapped on the frontal view. The catheter pinch-off syndrome occurs due to kinking of the catheter between the clavicle, and the first rib resulting in poor catheter function and increased incidence of catheter fracture. This is seen on the radiograph as a focal narrowing of the catheter at the site of kinking.

Pulmonary Artery Catheter

The pulmonary artery catheter is a thin radiopaque tube with a balloon at its terminal end. When in situ it is seen to pass from either the internal jugular vein or subclavian vein into the SVC, right atrium, right ventricle and into the pulmonary outflow tract. The tip of this catheter should lie beyond the pulmonic valve in the right or left pulmonary artery. The catheter tip however should not be more than 2 cm lateral to the pulmonary hilum on the frontal chest radiograph. When the balloon is inflated to measure pulmonary wedge pressure, it is seen as a rounded radiolucency at the tip of the catheter.

Complications, which may occur due to the catheter, are pulmonary infarction if the catheter is placed too distally

and the balloon inflated, thereby occluding a pulmonary vessel. Intracardiac placement of the catheter can result in arrhythmias or perforation. A rare complication is the formation of a pulmonary artery pseudoaneurysm, which is seen on a chest X-ray as a rounded well-defined opacity in relation to the pulmonary artery. This can be easily confirmed with dynamic CT or MRI.

Intra-Aortic Counterpulsation Balloon

The distal tip of this catheter is visualized as a small radiopaque rectangle. The ideal location for this balloon is at the proximal portion of the descending aorta just distal to the left subclavian artery. If the catheter is advanced too far, it may obstruct the left subclavian artery or carotid artery leading to ischemic changes. An abdominal location of the catheter may occur in extensively atherosclerotic or tortuous aortas, resulting in occlusion of the intra-abdominal vessels and consequent renal/mesenteric ischemia. Rarely, this catheter may cause aortic dissection.

Cardiac Pacemakers

These are used in the treatment of bradyarrhythmias and various degrees of heart block. They are usually implanted by either epicardial placement or transvenous placement, the latter technique being more commonly used. On frontal radiographs, the right ventricular electrode of a pacing catheter should point just to the left of the midline, and on the lateral view the catheter projects anteriorly and inferiorly with the electrode seen behind the sternum.

The electrode may be malpositioned in the right atrium, pulmonary outflow tract, inferior vena cava or coronary sinus. This may occur in 3–14% of cases.[20] Most of the above sites of malposition are well-identified on frontal radiographs. A pacing catheter malpositioned in the coronary sinus is difficult to appreciate on a frontal radiograph. A lateral radiograph, however, shows the catheter directed to the posterior aspect of the heart rather than the anterior.

THORACIC AORTIC ANEURYSM

Spiral CT angiography is the modality of choice in the evaluation of thoracic aortic aneurysms. Spiral CTA demonstrates the exact extent of the aneurysm in multiple planes. Further, the mural thrombus and true lumen are well visualized. Though angiography has been considered the gold standard in evaluation of thoracic aortic aneurysms, it only demonstrates the true lumen of the aneurysm. The mural thrombus and aortic wall are not demonstrated on angiography. Spiral CTA also visualizes the arch vessels and defines the relationship of the arch vessels with the aneurysm, the effect of the aneurysm on adjacent structures, and in case of aortic rupture demonstrates a periaortic hematoma. Spiral CTA provides information regarding lumen/wall/structures outside the wall, rules out other clinical conditions, which may simulate dissection.

AORTIC DISSECTION

Spiral CTA is the ideal technique to evaluate aortic dissection. The definitive diagnosis of aortic dissection requires the identification of the intimal flap, which is seen as a linear density within the lumen of the aorta separating the true and false lumens. In chronic dissection, CTA can also demonstrate thrombosis within the false lumen. MRI also demonstrates whether the aortic branches arise from the true or false lumen, and also identifies the most serious complication of dissection, viz. aortic rupture.

A diagnostic problem, which affects CT, MRI and angiography, is the differentiation between a completely thrombus-filled false channel, and a thoracic aortic aneurysm with a mural thrombus. If the patent lumen is eccentric and appears to be compressed, if the thrombus extends for greater than 7 cm, and if the thrombus changes position within the aorta at different levels, then it is more likely to be related to dissection.

CHAPTER 11

Imaging Techniques in the Abdomen

Anirudh Kohli *MD, DNB, DMRD. Head of Department of Radiology, Breach Candy Hospital, Mumbai, Maharashtra, India*

GENERAL CONSIDERATIONS

The radiologist is now well-armed with a full complement of diagnostic modalities to evaluate the abdomen in a critical care setting. These modalities are also an excellent guide for therapeutic procedures. A plain X-ray of the abdomen (erect and supine) is usually the first investigation ordered. These films are very useful in diagnosing perforation, bowel obstruction, bowel ischemia and other bowel pathologies. Calcification, calculi, foreign bodies and information regarding the position and placement of tubes, are easily detected on plain X-rays.

A chest X-ray is also mandatory as this is the best view to demonstrate a pneumoperitoneum with gas under the diaphragm. A number of chest pathologies may present clinically as an acute abdomen, e.g. pneumonia, congestive heart failure, myocardial infarction, dissecting aortic aneurysm, pulmonary infarction and pericarditis. Acute abdominal conditions can also cause respiratory complications, chiefly pleural effusion, atelectasis and aspiration pneumonia. Finally, an X-ray of the chest on admission provides a good baseline study. Postoperative complications like a subphrenic abscess may cause subtle changes on an X-ray, which may be evident only on comparison with a baseline X-ray.

Sonography is indispensable in the evaluation of the abdomen and pelvis in critically ill patients with acute abdominal problems, as it can be performed at the bedside. In fact, it is the modality of choice for evaluation of the gallbladder, free fluid, genitourinary system, and compares well with computed tomography (CT) in evaluation of the liver. Unfortunately, bowel gas, obesity, wound dressings, and abdominal scars interfere with sonographic evaluation.

A CT scan is the modality of choice as it can image the entire abdomen and pelvis, and factors which interfere with sonographic evaluation do not hamper a CT scan. The only disadvantage is the need to transport the patient to the CT scanner suite. However, the information that is gained far outweighs the risk of transportation of the patient.

Spiral CT angiography is an excellent noninvasive modality to visualize the abdominal vasculature especially aortic aneurysms.

Magnetic resonance imaging (MRI) of the abdomen and pelvis has shown significant improvement over the last few years. Unfortunately, it is a lengthy procedure; however, it is useful in vascular pathologies where spiral CT angiography is contraindicated such as when serum creatinine is elevated or there is known allergy to contrast media. Angiography is now mainly used as a combined diagnostic and therapeutic procedure for the treatment of GI hemorrhage.

ACUTE CHOLECYSTITIS

Sonography is the modality of choice in evaluating acute cholecystitis. The hallmark of acute cholecystitis is the presence of gallstones with a positive sonographic Murphy's sign. These features are present in 92% of cases of acute cholecystitis.[1] The sonographic Murphy's sign is similar to the clinical Murphy's sign. The only difference being that pressure is applied by the sonography transducer instead of the clinician's hand. This sign is more sensitive than the clinical sign as the transducer is applied exactly over the site of the gallbladder. Gallstones are seen as echogenic (bright) dependent shadows, which are accompanied by acoustic shadowing below the calculi due to the reflection of the sound waves by the calculi. The calculi are usually mobile and move

with change in the patient's position; occasionally they may be impacted at the neck of the gallbladder and in these situations do not move with change of position. Other sonographic findings are gallbladder wall thickening, presence of sludge and pericholecystic fluid. These signs are not specific as they are seen in a variety of other conditions. The gallbladder wall is considered to be thickened when it exceeds 3 mm in diameter. Sludge in the gallbladder may be seen as echogenic material layering the dependent portion of the gallbladder with no shadowing. Pericholecystic fluid is seen as a thin halo around the gallbladder.

Complications of acute cholecystitis are gangrenous cholecystitis, emphysematous cholecystitis and perforation. Gangrenous changes are reported to occur in 2–38% of cases of acute cholecystitis.[2] On sonography, this appears as marked asymmetry of the gallbladder wall evidenced by focal wall thickening and irregularity of the wall. These changes are due to mucosal edema, necrosis, ulcers, intramural hemorrhage and microabscesses in the gallbladder wall. There may also be intraluminal echoes due to sloughing of the gallbladder mucosa and fibrous or mucosal debris. An important sonographic sign in gangrenous cholecystitis is the conversion of a positive sonographic Murphy's sign to a negative sonographic Murphy's sign due to denervation of the gallbladder. This is usually accompanied by diffuse abdominal pain. Emphysematous cholecystitis is a severe variant of acute cholecystitis, which occurs due to gas-forming bacteria invading and devitalizing the gallbladder wall. More than one-third of patients with emphysematous cholecystitis are diabetics; gangrene and perforation of the gallbladder are important complications. The sonographic findings depend upon the demonstration of gas which is released by the bacteria into the lumen or the wall of the gallbladder. Air in the lumen is seen as an echogenic (bright) nondependent area, whereas air in the gallbladder wall is seen as a curvilinear or arc-like echogenic area.

Perforations occur in 5–10% of cases with acute cholecystitis.[3] It can present in three forms: (1) an acute form which results in generalized peritonitis; (2) a subacute form which results in the formation of a pericholecystic abscess and (3) a chronic form which results in an internal biliary fistula. Most cases are of the subacute variety resulting in abscess formation at the fundus of the gallbladder. It is important to differentiate an intraperitoneal abscess from a gallbladder bed or intramural abscess, as the former requires surgery and the latter can be managed conservatively. Abscesses are seen as ill-defined hypoechoic to echogenic collections in relation to the gallbladder. CT is considered superior to sonography in the evaluation of gangrenous changes as well as pericholecystic abscesses. Gangrenous changes are demonstrated on CT as an irregularity of the inner gallbladder surface due to sloughing of the mucosa or as frank disruptions in the continuity of the gallbladder wall. Pericholecystic abscesses are seen as contrast-enhanced CT reveals a thick-walled irregular enhancing lesion with a necrotic core, adjacent to the gallbladder. MRI demonstrates similar features.

ACALCULOUS CHOLECYSTITIS

In 5–10% of cases of acute cholecystitis, no calculi can be demonstrated in the gallbladder.[4] This form of cholecystitis has a higher mortality and morbidity rate, and is seen particularly in patients following trauma, surgery, sepsis, and burns; it is also observed in critically ill patients with shock and poor perfusion, in patients with diabetes mellitus, and in hyperalimentation. Gangrene and perforation are common complications. The sonographic signs are limited by the absence of calculi and diagnosis rests on demonstration of the sonographic Murphy's sign, gallbladder wall thickening, presence of sludge and pericholecystic fluid. When there is a high index of suspicion on clinical grounds but imaging findings are negative, an imaging-guided aspiration of the gallbladder contents may be performed and the fluid sent for bacteriology and leukocyte count. In patients who are too ill to undergo surgery, a percutaneous cholecystostomy may be performed by the introduction of a catheter into the gallbladder under imaging guidance. Using sonography a 97.5% success rate has been reported for cannulating the gallbladder.[5] Complications that may occur with this procedure are biliary peritonitis, bilioma, hemobilia, and vagal reaction. However, the reported complication rate in elderly patients is 10% which is far better than the surgical complication rate for cholecystectomy which is 24%.[5] Therefore, in a critically ill patient, percutaneous cholecystostomy can be used as a temporizing procedure till such time as the patient is ready for cholecystectomy.

PANCREATITIS

Computed tomography is the imaging modality of choice for evaluation of acute pancreatitis. It is not limited by gaseous shadows in the intestinal loops, by abdominal bandages, or by an obese abdominal wall; it also evaluates the retroperitoneum extremely well.

Sonography has limited use in the evaluation of acute pancreatitis. It is useful for detecting biliary calculi as a cause of pancreatitis and helps in the follow-up of pancreatic fluid collections. It is also useful as a guide for aspiration of fluid collections. The inflamed pancreas may be visualized on sonography as an enlarged gland with a decrease in its echogenicity due to edema of the gland. However, as necrotic areas are not evaluated well by sonography, CT becomes mandatory.

Magnetic resonance cholangiopancreatography (MRCP) is particularly useful in the evaluation of the etiological cause of acute pancreatitis. It has a sensitivity of close to 100% in detecting calculi as small as 2 mm. It is also useful to detect pancreas divisum.

There are two distinct forms of pancreatitis: (1) acute edematous pancreatitis and (2) acute necrotizing pancreatitis. In acute edematous pancreatitis, there is only mild swelling of the pancreas with loss of normal lobulations and a diffuse decrease in attenuation of the pancreas. This form of

pancreatitis runs a mild course and rarely progresses to acute necrotizing pancreatitis with its associated complications.

Acute necrotizing pancreatitis is a fulminant form of pancreatitis in which there is necrosis of the pancreas. These areas of necrosis may be diffuse or focal, consisting of nonviable pancreatic parenchyma which varies in size, location and extent. A dynamic contrast-enhanced CT accurately defines the extent of pancreatic necrosis; this has been found to correlate very well with the extent of necrosis found at surgery. Necrosis is seen on CT as areas within the pancreas which exhibit no enhancement. These necrotic areas have a very important bearing on the course of pancreatitis, as they are liable to undergo secondary infection and form pancreatic abscesses. The more extensive the pancreatic necrosis the greater is the morbidity and mortality. Patients with no pancreatic necrosis have been found to have a 0% mortality and a 6% complication rate, whereas patients with pancreatic necrosis have a 23% mortality rate and a 82% complication rate.[6]

Patients with acute necrotizing pancreatitis usually have accompanying peripancreatic changes in the form of edema, effusions and peripancreatic necrosis. Edematous changes in the peripancreatic region are manifested by a subtle increase in the density of the peripancreatic fat, which on CT has a nonhomogenous appearance with strands and thickened fascial planes. The anterior pararenal fascia is often thickened; this is more evident on the left than on the right side. Effusions or acute fluid collections are enzyme rich pancreatic juice collections seen in about 40% of patients with acute pancreatitis.[7] The fluid collections usually develop around the inflamed gland; they are localized only by the anatomical space in which they collect. Peripancreatic fluid collections are very well-demonstrated by CT scans, and are most commonly seen in the anterior pancreatic region, the lesser sac, the anterior pararenal, perirenal, posterior pararenal regions, and rarely in the mesocolon and the root of the mesentery. These fluid collections are usually limited by the thickened pararenal or Gerota's fascia. The quantity of fluid in these effusions is variable and can range from a small amount to large quantities. Of these collections, 50% resolve spontaneously; the remainder may evolve into pseudocysts.[8]

Sepsis

Sepsis is a major complication of pancreatitis and is accompanied by a high incidence of mortality and a prolonged hospital stay. Pancreatic abscesses occur following secondary infection of parenchymal pancreatic necrosis, peripancreatic necrosis, effusions and pseudocysts. Detection of the development of sepsis in these areas is very difficult even with a CT, the only sure sign being the presence of gas due to secondary infection by coliform bacteria. Gas is seen in the fluid collection as very dark well-defined bubbles. Occasionally, gas may be present due to a gastrointestinal (GI) fistula or previous surgery. It is important to note that a small amount of fat may be seen interspersed with a peripancreatic necrosis as a result of fat necrosis; this should not be confused with air bubbles, which are indicative of abscess formation. The differentiation is easy by CT, the values of fat ranging between –20 Hu and –80 Hu, and of air being more than or equal to –300 Hu. Also air bubbles have well-defined margins and are homogeneously jet black, whereas fat is non-homogeneously gray with ill-defined margins.

Since the presence of air is seen only in a small percent of patients with pancreatic abscesses, the diagnosis of pancreatic sepsis has to be made by CT-guided aspiration. All sites of fluid collection, parenchymal necrosis and peripancreatic phlegmon are subjected to CT-guided aspiration. This is a tedious process and requires a dedicated interventional radiologist as there are often more than 5–6 sites from, which it may be necessary to obtain samples. The sites of aspiration are marked and guided by CT, a fresh needle and syringe being used for each site. Care is taken not to go through the large bowel as the colon has a large number of bacteria, and transgressing it could result in colonic bacteria contaminating the CT-guided aspiration sample, with false positive results. Further, colonic bacteria may be inoculated into the effusion or acute pancreatic fluid collection thereby converting a sterile collection into an infected one. Technical expertise is therefore of utmost importance. Complications of the procedure include pnuemothorax or empyema if the pleura is transgressed, hemorrhage due to trauma to a vessel, and secondary infection.

It is crucial from the management point of view, to differentiate an abscess from infected necrosis. An abscess may be treated by percutaneous drainage, whereas infected necrosis developing in relatively solid tissue can be treated by surgical debridement alone. On CT an abscess is seen as a peripancreatic fluid collection, which is composed of liquid pus, as determined by needle aspiration. Infected necrosis is seen on CT as a non-enhancing solid or partly liquefied soft tissue, which reveals infected material on needle aspiration. As the CT appearances of an abscess and infected necrosis may be similar, needle aspiration is crucial in differentiating between the two conditions.

Pancreatic sepsis is treated by surgical debridement, necrosectomy and drainage through thick tubes. CT is invaluable in surgical planning and in the follow-up of postoperative patients to evaluate any fresh collection and to determine whether the drains are well sited or not. Patients who are too critically ill to undergo surgery for pancreatic sepsis, may benefit from CT-guided introduction of pigtail and surgical drainage tubes. These CT-guided procedures are extremely successful elsewhere in the abdomen; however, in pancreatitis they have met with only limited success. This is due to the fact that the sepsis of pancreatic necrosis and peripancreatic necrosis usually causes infection in solid tissues which requires manual debridement, and attempts to drain this prove futile. Interventional radiology is mainly a temporizing procedure, which helps to tide the patient over a period of time, till the patient is deemed fit for surgery.

PSEUDOCYSTS

Pseudocysts are round or oval encapsulated fluid collections containing necrotic material, proteinaceous debris and enzymatic material. On CT, a pseudocyst appears as a well-defined fluid collection with a thin capsule. The most common location for pseudocysts is the lesser sac, although they may be found anywhere in the mediastinum, abdomen or pelvis as they may dissect along fascial planes, along vessels and through capsules of solid organs. Complicated, enlarging or symptomatic pseudocysts require percutaneous catheter or surgical drainage.

Infected pseudocysts are treated by percutaneous drainage. The management of a noninfected pseudocyst is controversial. Surgical treatment is only undertaken when the wall is mature after several weeks. Large pseudocysts greater than 5 cm in size can easily be drained percutaneously. The cure rates are reported to be 85% with percutaneous drainage, the drainage period averaging about 20 days.[9]

RETROPERITONEAL HEMORRHAGE

Retroperitoneal hemorrhage may occur as a late complication due to vascular injuries produced by the extravasated pancreatic enzymes. These injuries result in the formation of a pseudoaneurysm which may rupture resulting in massive hemorrhage. This is seen on CT as high density fluid in the retroperitoneum, or as a pseudocyst. The commonly involved vessels are the splenic or pancreaticoduodenal arcade. The diagnosis is usually confirmed by angiography and subsequently treated by embolization of the bleeding vessel.

Grading

Computed tomography may be used as a prognostic indicator of the severity of acute pancreatitis. The patients are classified into five grades—

1. Grade A: Normal CT of pancreas.
2. Grade B: Diffuse pancreatic enlargement with or without parenchymal necrosis.
3. Grade C: Pancreatic enlargement with necrosis and peripancreatic edema.
4. Grade D: Pancreatic involvement with a single ill-defined peripancreatic fluid collection or phlegmon.
5. Grade E: Two or more fluid collections and/or the presence of gas.

Most complications of acute pancreatitis occur in Grade D and E patients. A more accurate grading system is the CT Severity Index (CTSI), in which patients are assigned 0–4 points depending upon their grade (from A to E). To this 2, 4 or 6 points are added depending upon the extent of pancreatic necrosis—30% necrosis or less is given 2 points; 30–50% necrosis is given 4 points, and more than 50% necrosis is given 6 points. Thus, the patients are graded on a scale of 0–10. Those with a score of 0–1 showed no mortality or morbidity. Patients with a score of 2 had no mortality and only a 4% morbidity. Patients with a score between 7 and 10 had a 17% mortality and a 92% complication rate.[8]

It is often confusing to the clinician when to order a CT scan in acute pancreatitis. It has been suggested that an initial CT study should be done: (1) in patients in whom the diagnosis is in doubt; (2) in patients with severe pancreatitis accompanied by fever, tenderness and leukocytosis; (3) in patients who do not improve within 72 hours of conservative treatment; (4) in patients with a Ranson score more than 3 or an acute physiology and chronic health evaluation II (APACHE II) score more than 8; (5) in patients who show initial good improvement, but then rapidly deteriorate. A follow-up CT study is done: (1) in patients with CT scan Grade A to C, or CTSI of 0–2, only if there is a clinical suspicion of a complication; (2) in patients with a CT scan Grade D or E, and CTSI of 3–10 after 7–10 days. Further, CT scans of patients with Grade D/E, and CTSI 3–10, are performed only if the clinical status deteriorates or does not improve. A final CT is done in this group of patients at the time of discharge as important complications may develop without clinical symptoms. It must be remembered that the resolution of the CT features of pancreatic or peripancreatic inflammation lag behind clinical improvement.

Appendicitis

This is the most common surgical emergency with a lifetime risk of 6.7% in women and 8.6% in men.[10] A careful history and thorough physical examination are adequate in most cases to make a diagnosis, imaging having no role to play in these cases. However, approximately 20% of cases have an atypical presentation, especially in elderly patients where there may be minimal pain, in children where an accurate history is not available, and in ovulating women who have a misdiagnosis rate of about 40%, due to pathology in the ovaries, Fallopian tubes, uterus or bladder.[11] In these cases, imaging is useful to clinch the diagnosis, or exclude other conditions, which may be mistaken for appendicitis.

The plain film seldom provides much help in the diagnosis; the presence of a distended cecum with an air or fluid level, or terminal ileal ileus is nonspecific and unreliable signs. Appendicoliths are specific findings on a plain film that generally confirm a diagnosis of appendicitis. These are seen as round or oval opacities, 0.5–2 cm in diameter, with a calcified laminated rim. In 10% of cases of acute appendicitis an appendicolith may be seen; however, 50% of these cases are usually associated with perforation.[11] Over the past 5 years improvements in US/CT technology, techniques and interpretations have substantially improved the sensitivity, specificity and accuracy of ultrasound (US) or CT in diagnosing acute appendicitis. Graded compression sonography has shown a sensitivity of 77–89% and a specificity and accuracy in 90%of cases of acute appendicitis.[11-14]

A high resolution (5–7.5 Hz) transducer is placed over the area of maximal tenderness and pressure is applied slowly and gently to minimize pain and discomfort. This procedure

of graded compression sonography displaces bowel loops and gas, reducing the distance between the transducer and the appendix and thereby providing better resolution, as well as information regarding compressibility of the appendix. On sonography an inflamed appendix is seen as a tubular fluid-filled structure more than 6 mm in diameter, devoid of peristalsis and noncompressible.

Computed tomography is superior to sonography with a 98% sensitivity, 83% specificity and 93% accuracy as it directly visualizes the appendix, the pericecal region and other intra-abdominal structures.[15] Sonography is not able to image well in the obese patient and in those with significant tenderness preventing adequate compression. On CT, the inflamed appendix is seen as a tubular fluid-filled structure approximately 0.5–2 cm in diameter with a thickened enhancing wall which is usually 3 mm or more in diameter. Pericecal inflammatory changes may be seen in the form of pericecal fascial thickening, altered density of pericecal fat, ill-defined phlegmonous soft tissue, and occasionally a fluid containing area representing an abscess. The presence of pericecal inflammatory changes alone, without visualization of the inflamed appendix is not diagnostic but makes the diagnosis highly probable. Adnexal cysts, masses, salpingitis, tubo-ovarian abscess, ureteric calculi, lymphadenitis and ileitis may clinically mimic appendicitis, but ultrasonography or CT helps to differentiate between these conditions.

In women of childbearing age an ectopic pregnancy or a ruptured ectopic pregnancy must be kept in mind as a differential diagnosis. Sonography is the modality of choice in evaluating an ectopic pregnancy, and is preferably done by both the transabdominal and transvaginal routes. The surest sign of an ectopic is the presence of an extrauterine gestational sac; this is seen in only 20% of cases. The other important sign is the extrauterine sac sign seen in 70% of cases.[16] A ruptured ectopic is seen as an adnexal hematoma; on the US, this appears as a complex hyperechoic adnexal lesion often accompanied by echogenic free fluid.

Pneumoperitoneum

Demonstration of a pneumoperitoneum is one of the most important signs in medicine, as it generally warrants emergency surgery. The best view to demonstrate a pneumoperitoneum is the erect frontal chest X-ray, which demonstrates gas under the domes of the diaphragm better than an erect abdominal X-ray. This is because the exposure factors used are higher in abdominal X-rays and the X-ray beam is tangential to the diaphragm, resulting in a darker appearance of the diaphragmatic region with consequent difficulty in demonstrating gas under the diaphragm. In nearly 75–80% of perforations of a hollow viscus, free air is demonstrated on a radiograph and 75% of these cases are visible on a frontal chest X-ray. In a small percentage of patients (10%), when the frontal chest radiograph fails to demonstrate free air, a left lateral decubitus view may be used. This view is very useful to demonstrate small quantities of free air. The patient is positioned on his side with the left side down and the right side up. At least 10 minutes must elapse to permit the free air to migrate to a nondependent position, i.e. between the right margin of the liver and the lateral abdominal wall, and a horizontal radiograph is taken with the X-ray cassette behind the patient. Free air is seen as a crescent between the liver and right abdominal wall. This position is difficult as it may be cumbersome for the patient to lie in this position for 10 minutes, and at least 2–3 attendants are needed to position the patient for this view. Therefore, in patients who are critically ill, traumatized or comatose, erect and left lateral decubitus views may be technically difficult. In such patients, only a supine radiograph of the abdomen is possible. However, this view is not very useful and a pneumoperitoneum can be easily missed.

Postoperative pneumoperitoneum may be seen for a few days (generally about 3 days), after which time, the free air is resorbed. Occasionally, free air may be seen for up to 24 days. The resorption rate is said to be much greater in obese individuals than in thin individuals. It is important to detect a fresh postoperative leak of air which is diagnosed by an increase in the amount of air, or with the help of contrast studies or CT scan.

INTESTINAL OBSTRUCTION

Mechanical obstruction of the bowel is produced by occlusion or constriction of the lumen; this may progress to strangulation, interruption of blood supply with subsequent mucosal ulceration, bowel necrosis and perforation. Obstruction may occur in the small or large bowel.

Small Bowel Obstruction

The most common cause of small bowel obstruction is adhesions (occurring in 75% of cases). In fact, 5–20% of patients who have undergone abdominal surgery will develop small bowel obstruction. On an erect abdominal X-ray, dilated small bowel loops with multiple air fluid levels are visualized. Usually, the dilated loops are in the form of an inverted U with fluid levels in both limbs. Occasionally, in a nonobstructed patient, a few air-fluid levels may be seen, but if more than 3 levels are seen, or if they are present in the left hypochondrium, there is a strong possibility of obstruction. When there is a high jejunal obstruction dilated loops may show a typical appearance known as the string of pearls sign. In this sign, the obstructed bowel loops are fluid-filled and small bubbles of air collect on the surface giving rise to the string of pearls sign.

The site of obstruction in the small bowel, whether jejunal or ileal can be differentiated by noting the pattern of the dilated bowel loops. Jejunal loops have a typical appearance in the form of concentric bands extending across the lumen, known as valvule conniventes. Ileal loops have a featureless appearance, appearing like a tube. A barium enema may be used to differentiate a colonic from a distal small bowel obstruction.

Computed tomography is very useful in the evaluation of a small bowel obstruction and has a sensitivity of 94% and specificity of 96%.[17-19] A small bowel diameter of more than 3 cm indicates that the bowel is dilated. CT also demonstrates a transition zone between the dilated proximal loops and the decompressed distal bowel, this sign is diagnostic of small bowel obstruction. As CT is also able to demonstrate the peritoneal surface of the bowel, tumor or inflammatory mass lesions can thereby be detected or excluded. Absence of tumor or inflammatory processes suggests that the cause of obstruction is an adhesion.

A rare form of small bowel obstruction is gallstone ileus. This occurs due to erosion of a gallstone into the duodenum, the gallstone lodging in the ileum and causing ileal obstruction. The radiological features are the presence of a gallstone in the lower abdomen, dilated small bowel loops and air in the biliary tree.

A diagnosis of intussusception can also be made on CT which shows a typical appearance. As the intussusceptum enters the intussuscipiens, there is trapping of the fatty mesentery and a complex composed of the intussusceptum and the intussuscipiens is seen on CT as concentric cylinders with fat density interposed between them.

Large Bowel Obstruction

The most common cause of large bowel obstruction is carcinoma, about 60% of growths being situated in the sigmoid colon. Other causes are diverticular disease and volvulus of the colon. The radiographic signs of large bowel obstruction depend upon the state of the iliocecal valve. If the iliocecal valve is competent (Type I), there is gross distension of the cecum and the large bowel. If the ileocecal valve is incompetent (Type II), there is no distension of the large bowel, and the appearance is that of a small bowel obstruction. The cecum may perforate in a Type I obstruction. A distended colon is evidenced by the presence of its haustral markings which are seen as asymmetric folds. This is an important distinguishing feature from small bowel obstruction.

Paralytic Ileus

Paralytic ileus occurs commonly following surgery, especially where excessive bowel manipulation has been performed, and in peritonitis. Fluid and gas accumulate in the dilated small and large bowel loops as a result of cessation of intestinal peristalsis. On plain radiographs, these features are seen as dilated small and large bowel loops with multiple air-fluid levels. In view of the dilated large bowel loops, it is difficult to differentiate a distal large bowel obstruction from a paralytic ileus. The differentiation is possible if air is demonstrated in the rectum or distal large bowel. If this is not demonstrated on a plain film then a right lateral decubitus and/or prone film may be taken. In the right lateral decubitus view, air rises into the distal colon and in a prone film air migrates into the rectum. If these are not conclusive then a contrast enema may be required to exclude distal obstruction. Alternatively, a CT can be performed to demonstrate air in the rectum or sigmoid; this excludes an obstruction. If there is suspicion of a perforation or if the colonic diameter exceeds 5.5 cm, a water-soluble contrast should be used instead of barium.

Localized ileus is seen adjacent to the site of inflammation, e.g. cholecystitis, pancreatitis, appendicitis, and is visualized as isolated dilated small bowel loops with a few fluid levels. Ogilvie's syndrome is a condition seen in elderly debilitated patients who have a major underlying systemic abnormality such as severe infection, recent surgery or cardiac disease. There is marked dilatation of the colon and occasionally there is associated with small bowel ileus. This condition is also known as pseudo-obstruction. In view of the markedly distended large bowel, these patients are prone to cecal perforation, especially when the cecum is dilated to more than 9 cm for 2–3 days. Colonic and cecal distension can be treated by colonoscopic decompression.

Toxic Megacolon

Toxic megacolon is a fulminant form of colitis in which there is marked dilatation of the colon (diameter >5.5 cm). The radiographic features are most commonly seen in the transverse colon as this is the region where gas accumulates in the supine posture. In addition to marked distension of the colon, there is thickening of the wall or mucosa with numerous nodular areas projecting into the bowel lumen representing mucosal islands (spared mucosa), adjacent to the areas of ulceration. The haustra are effaced and a thumb-printing pattern may be seen. A contrast enema is contraindicated due to the high risk of perforation, but a CT may be useful in demonstrating the wall thickening.

Ischemic Colitis

Ischemic colitis may be caused by primary ischemia due to mesenteric arterial stenosis, thrombosis or venous occlusion. Occasionally, strangulation or obstruction of the bowel may lead to ischemic changes. Any part of the small bowel may be involved, but in the colon, it is usually localized to the distal colon supplied by the inferior mesenteric artery. Segmental ischemia may result in strictures and occasionally transmural infarction may progress to perforation. On radiographs, the characteristic signs are edematous thickened loops with a thumb-printing pattern due to submucosal hemorrhages. There may be air in the bowel loop wall (pneumatosis intestinalis), and air in the portal venous system. Other non-specific findings are small bowel ileus, or an X-ray plate which remains dark through lack of gas within the small gut.

Computed tomography is very useful in the evaluation of ischemic bowel; it may demonstrate the direct signs of mesenteric arterial or venous thrombosis and secondary signs of thickened bowel loop walls, pneumatosis intestinalis and portal venous air. Ascites and bowel distension may also be seen. A nondiagnostic CT or plain film does not exclude ischemic colitis and if there is a strong clinical suspicion, angiography should be performed. Angiography may be both

diagnostic and therapeutic; vasodilators and thrombolytic therapy may be used as therapeutic interventions.

GASTROINTESTINAL HEMORRHAGE

Angiography has a useful role to play in detecting the cause, and the subsequent management of upper and lower GI bleeds. The cause of upper GI bleeds is usually evident on an upper GI endoscopy; if this fails, then angiography is used to determine the site of bleeding. The limitation of angiography is that the rate of blood loss should be at least 5 mL/minute, or if superselective catheters are used at least 1 mL/minute, to be able to detect the site of bleeding. The site of bleeding is identified on angiography as a diffuse blush of extravasating contrast. Once the site is localized vasopressin may be injected through the catheter at the rate of 0.2 units/minute, to help control the bleeding. The duration of the therapy is 20–40 minutes. Occasionally, it may be longer in elderly atherosclerotic individuals.

Epinephrine may also be used in a dosage of 8–30 μg/minute. Infusions into the left gastric artery usually control bleeding from Mallory-Weiss tears, gastritis, and stress ulcers of the upper part of the stomach. An infusion into the common hepatic artery is useful for antral lesions, and gastroduodenal arterial infusions usually control duodenal bleeding.

An infusion of vasopressin into the superior mesenteric artery may be used to control bleeding due to portal hypertension by lowering the venous pressure. Complications of vasopressin therapy are water retention, abdominal cramps, diarrhea, and occasionally cardiotoxicity. Vasopressin effectively controls bleeding from small vessels and capillaries as seen in mucosal tears and stress ulcers. However, bleeding from large arteries, as in duodenal ulcer, may not be controlled and may require embolization of the vessel.

Different materials have been used for embolization—coils, glue, gelatin or fiber, each having its own advantages and disadvantages. Coils and glues are most commonly used. These are injected through the catheter at the site of bleeding in an attempt to occlude the bleeding vessel. As bleeding from large arteries is not effectively controlled by vasopressin, embolization is advocated as the primary procedure. Lower GI bleeds usually occur as a result of bleeding from colonic diverticulitis. These usually respond well to vasopressin therapy.

ABDOMINAL AORTIC ANEURYSMS

Abdominal aortic aneurysms are usually infrarenal in location and may be fusiform or saccular. Sonography usually detects nearly all abdominal aortic aneurysms; however, CT is required for further evaluation to determine the extent of the aneurysm. On CT, abdominal aortic aneurysms are usually more than 3 cm in diameter with calcification of their walls. There is usually an associated mural thrombus, which is seen as a circumferential thrombus along the wall of the aorta. Occasionally, it may be eccentric along the anterolateral wall, and may be difficult to differentiate from a chronic dissection.

Computed tomography is very useful in determining the extent of the aneurysm—whether it is infrarenal, or involves the renal or superior mesenteric arteries, or if there is any inferior extension into the iliac vessels. These points are very important in planning surgical intervention. MRI is a useful modality for evaluating the aorta, its main advantage being its ability to image in multiple planes; also there is no need to inject intravenous contrast medium as flowing blood is seen as a signal void. Angiography has been the age-old modality for evaluating abdominal aortic aneurysms, but with the current imaging modalities available, it is no longer necessary. In fact, angiography is limited to defining only the patent lumen of an aneurysm, as the extraluminal thrombosed component, which is well visualized on US/CT/MRI, is not demonstrated on angiography.

ABDOMINAL AORTIC DISSECTION

Aortic dissection is fortunately a rare complication of aortic aneurysms, and usually occurs as an inferior extension of a dissecting thoracic aneurysm. The CT, MRI, and angiographic imaging characteristics are similar to those of dissecting aneurysms of the thoracic aorta, and have been discussed earlier.

ABDOMINAL AORTIC RUPTURE

This is a catastrophic event requiring emergency surgery. The crux of the diagnosis lies in the demonstration of a retroperitoneal hematoma adjacent to an abdominal aortic aneurysm. In this emergency situation in a critically ill patient with rapidly dropping blood pressure, sonography is invaluable as it is portable and can be performed at the bedside. A retroperitoneal hematoma is seen as an ill-defined mixed echoic lesion adjacent to the aorta. However, sonographic examination is often hampered by bowel gas especially if the patient is obese. CT is an ideal investigative modality and will demonstrate a mildly hyperdense collection in the pararenal regions adjacent to the aorta. Occasionally, a discontinuity of the aortic wall may be seen on CT. MRI similarly is useful in the detection of a retroperitoneal hematoma which is seen as a mixed intensity retroperitoneal lesion. T1-weighted images are only required to detect the hematoma, a breach in the aortic wall may also be seen on MRI. MRI has a disadvantage of being a much longer procedure with difficulty in monitoring the patient, and therefore CT is the modality of choice.

RENAL INFLAMMATORY PROCESSES

Acute pyelonephritis usually follows infection in the bladder which ascends to involve the renal pelvis and renal parenchyma secondarily. Sonography is usually negative although occasionally may demonstrate an enlarged hypoechoic kidney. CT is more sensitive and specific. The affected kidney

is seen to be enlarged; following administration of intravenous contrast medium the nephrogram has a striated and blotchy appearance due to areas of decreased enhancement or non-enhancement, which subsequently on delayed scans show filling in of contrast. In acute bacterial nephritis, the changes are similar but are more marked. Occasionally, the changes seen on CT may be more lobar extending to the hilum.

Acute lobar nephroma (preabscess) usually occurs due to a partially treated infection and appears as a focal area of inflammation with small necrotic areas. On sonography, these changes may appear as a mass like hypoechoic lesion mimicking a neoplasm. On CT, they appear as a hypodense lesion with small necrotic areas within it, of near water density. These may resemble renal infarct or ischemic areas.

Sonography is usually effective in the detection and evaluation of renal abscesses, which are greater than 2 cm in size. They appear as relatively well-defined hypoechoic or mixed echoic lesions, which may be uniloculated or multiloculated. The presence of debris is very suggestive of an abscess. CT has a much better sensitivity and specificity for renal abscesses as it also depicts the perinephric and retroperitoneal inflammatory changes. On CT, these appear well-defined hypodense collections, which may have debris in the form of a fluid level. Perinephric changes may be present in the form of fascial thickening or perinephric or psoas extension of the abscess.

Pyonephrosis occurs when there is infection of an obstructed collecting system. Sonography is an excellent modality for evaluating pyonephrosis and shows evidence of debris layering in the dilated pelvicalyceal system. Sonography can also be used as a guide for aspiration as well as percutaneous nephrostomy.

EMPHYSEMATOUS PYELONEPHRITIS

This is the most severe necrotizing renal infection and mainly occurs in diabetics, immunocompromised patients, or patients with urinary tract obstruction. The hallmark of this condition is the presence of air in the renal parenchyma or renal pelvis. On sonography, air is seen as echogenic areas but may be missed at times. Occasionally, differentiation of echogenic foci from calculi may be difficult. CT is far more sensitive than sonography or plain X-ray in detecting air which is seen as jet black specks. Gas may also be seen in the perinephric regions.

ACUTE RENAL FAILURE

The question to be answered by imaging is whether the urinary system is obstructed or not. Sonography adequately answers this question where dilatation of the pelvicalyceal system is seen as the separation of the renal sinus echo. Occasionally, in acute obstruction, there may be no evidence of dilatation of the pelvicalyceal system. This may be due to the fact that the obstruction is too early to manifest, or the obstruction may have led to a forniceal rupture with leakage of fluid into the perirenal region. Therefore, the presence of perirenal fluid in acute renal failure indicates obstruction. Occasionally, there may be pre-existing dilatation of the pelvicalyceal system due to an old obstruction, and the clinician has to determine whether this dilatation is due to a new obstruction, or is due to an old lesion. In this condition, a duplex Doppler of the intrarenal vessels is very useful. An estimate of the renal vascular resistance known as the resistive index (RI) is obtained by the formula—

$$RI = \frac{\text{(Peak systolic FS – Minimum diastolic FS)}}{\text{(Peak systolic FS)}}$$

(FS stands for frequency shift).

An elevated RI is seen in fresh obstruction.[20]

In acute renal failure, due to nonobstructive causes the sonogram is usually negative or may show alterations in renal size and echogenicity. These changes however are nonspecific and not helpful as regards the etiology. A duplex Doppler sonography is however helpful in differentiating acute tubular necrosis from acute prerenal failure.[21] The RI is elevated in most patients with acute tubular necrosis, but is also raised in a fifth of patients with prerenal failure.

LIVER

Hepatic Abscess

Both CT and sonography are very useful in the evaluation of hepatic abscesses. CT is slightly superior in the detection of small abscesses. Abscesses may be solitary or multiple, small or large. Amebic abscesses have a predilection for the posterosuperior portion of the right lobe of the liver and are seen on sonography as ill-defined hypoechoic areas with a wall of varying thickness. In the early stages of an abscess, the abnormal area may be seen as an isoechoic or mildly echogenic area. Later, the abscess becomes better defined and more hypoechoic. Often there is debris present in the abscess seen as layering of echogenic material. On CT, abscesses are seen as ill-defined hypodense or nonenhancing areas with a wall of varying thickness.

Large abscesses should be subjected to sonographic or CT-guided aspirations. Of particular importance is the approach used in the aspiration of these abscesses. A liver abscess should not be approached posteriorly as the inferior margin of the posterior recess of the pleura is not known, and inadvertently the pleura may be transgressed; seepage of purulent material from the liver abscess could result in an empyema. Abscesses in the posteriosuperior quadrant of the right lobe of the liver are very difficult to tackle, and are best aspirated under CT guidance. Very large abscesses are best treated with catheter drainage as they would otherwise necessitate a long hospital stay and multiple aspirations.

Immunosuppressed patients with acquired immunodeficiency syndrome (AIDS) or those on chemotherapy may have multiple disseminated fungal abscesses—the most

common incriminating organism being *Candida albicans*. These abscesses have a relatively classical appearance on CT—a hyperdense core with peripheral hypodensity (bull's eye lesion). On sonography, the appearances vary: (1) wheel in wheel appearance with a hypoechoic center, a hyperechoic wall and a hypoechoic periphery; (2) bull's eye lesion with hyperechoic center and hypoechoic outer margin. Occasionally, these abscesses may be uniformly hypoechoic or hyperechoic.

Imaging modalities may help in the diagnosis of a number of other intra-abdominal or gastrointestinal problems in immunosuppressed patients, particularly in AIDS. Thus, cytomegalovirus infections, infections with *Mycobacterium avium-intracellulare*, or *Cryptosporidium* infections in patients with AIDS, can cause an ascending cholangitis recognizable on CT by the presence of dilated intrahepatic biliary radicles. Kaposi's sarcoma, non-Hodgkin's lymphoma may involve the gut. Splenomegaly may be related to a lymphoma. AIDS enteritis may involve the jejunum with effacement of the jejunal folds. CT is the ideal imaging modality as it evaluates visceral organs, adenopathies, and bowel loops. A CT-guided biopsy in visceral disease or in lymphadenopathy also helps in arriving at an exact diagnosis.

Liver Trauma

After the spleen and the kidney, the liver is the third most common organ likely to be injured in abdominal trauma. Most cases result from blunt trauma. The lesions can range from a small tear to a large laceration with an intrahepatic hematoma. CT is the imaging modality of choice in abdominal trauma. An acute hematoma is seen as a bright area (brighter than the liver parenchyma) on the unenhanced scan. After administration of intravenous contrast medium, the lesion does not enhance, the lesion thereby appears darker than the liver.

Peritonitis

Diagnosis of peritonitis is nearly always clinical, the role of imaging being merely to demonstrate: (1) free fluid in the peritoneal cavity; (2) intraperitoneal abscess; (3) the etiology of peritonitis. Sonography is usually adequate to detect free fluid. Small amounts of fluid may be seen in the hepatorenal pouch and/or in the pelvic cul de sac. When there is a large amount of fluid, the liver, spleen and bowel loops are pushed to the center of the abdomen, with the fluid being peripheral. The fluid if not grossly infected may be sonolucent. Severely infected fluid is echogenic with loculations or debris.

Intraperitoneal abscesses occur due to a variety of causes. Most occur between the transverse colon and the diaphragm. Nearly 60% of these are on the right side, 15% bilateral and 25% on the left. Abscesses can occur anywhere in the abdomen or pelvis, and are often distant from the site of perforation or primary pathology. Therefore, the whole abdomen and pelvis need to be imaged in detail when looking for intraperitoneal abscesses. Sonography has been found to be superior to CT in evaluating subphrenic abscesses as these tend to be more plaque-like, spreading along the surface of the liver or spleen. Therefore, a coronal form of imaging is useful to demonstrate these plaque-like abscesses, and determine their relation to solid visceral organs. MRI scanning (which gives good coronal images) is also a useful modality in localizing these abscesses. However, the ability of MRI to image the rest of the abdomen is poor. CT is far superior to sonography for detection of abscesses in other portions of the abdomen/pelvis, as well as interloop abscesses, which may be missed on sonography. When a search for an intra-abdominal abscess is undertaken with CT scan, it is very important that a large quantity of oral contrast (1.5–2 L) is given to the patient and this is supplemented with intravenous contrast. This is because dilated fluid-filled bowel loops can mimic abscesses and vice versa. False-negative or false-positive results may at times occur when there is inadequate opacification of the bowel loops.

On sonography, abscesses appear as relatively well-defined hypoechoic lesions with or without a layering of debris in the collection. On CT, abscesses appear as well-defined phlegmonous mass lesions which undergo central liquefaction and have thick peripheral enhancing walls. Occasionally, there may be gas within the collection indicating infection by a gas forming organisms. This is the surest sign of an abscess. The differential diagnosis of abscesses is pseudocysts, cysts, urinomas, biliomas, loculated ascites, old hematomas and necrotic tumors. The clinical setting as well as radiographic appearances helps to differentiate the varying pathologies. Differentiation can sometimes only be achieved by percutaneous aspiration.

IMAGING-GUIDED PROCEDURES

Over the years, technological improvements in imaging modalities and catheter design have considerably helped to improve the safety, simplicity and effectiveness of imaging-guided procedures. This has therefore led to a greater acceptance of these procedures.

Drainage of Localized Intra-Abdominal Suppuration

Drainage of an intra-abdominal abscess is commonly performed in critically ill patients under either US or CT guidance.

Sonography is also useful for percutaneous transhepatic drainage, cholecystostomy and percutaneous nephrostomy. These procedures may be performed under sonographic guidance or with the help of fluoroscopy.

Contraindications

Contraindications for drainage of a collection are: (1) lack of a safe access route, i.e. through the bowel or vascular structures; (2) associated coagulopathy; (3) subdiaphragmatic abscesses which cannot be approached without traversing the pleura; (4) poorly formed abscesses–such as pancreatic necrosis; (5) multiloculated and multicompartment abscesses.

Methods of Drainage

There are two main methods employed in the insertion of drainage tubes—one being the Seldinger technique and the other the Trocar technique. In the Seldinger technique, a 22 gauge needle is introduced first and fluid is aspirated to confirm that the needle is in the collection. Once this is confirmed by imaging, the needle is removed and dilators passed over the guidewire to dilate the tract. Dilators (from size 6 Fr upward) are used progressively in increments of 2 Fr and constantly watched under fluoroscopy. Depending on the size of the pigtail catheter, the track is dilated to a 2 Fr size above the size of the catheter required. Generally for thin fluid collections or bile an 8 Fr size catheter is adequate, while for thicker collections like pus 10–13 Fr is necessary. For even thicker material a catheter up to about 24 Fr can be inserted. The catheter is advanced over the guidewire into the collection. Once in the collection the guidewire is removed and fluid or pus aspirated and drained via the catheter. Following complete aspiration, contrast is injected and a cavitogram is performed to ensure that the cavity is totally drained, as well as to see if there are any other pockets of collection or fistulas opening in to the GI tract. The catheter is then secured to the skin. An important point to note is that at all times the guidewire should be held at the skin site so that it is not dislodged from the collection.

The Trochar technique is a very convenient technique as it does not involve a guidewire, and hence the chances of the guidewire slipping are absent. Also it is a rapid technique and can be performed under sonography or CT guidance. The main limitation is that only catheters up to 8 of 10 or 12 Fr can be used. However, this thickness has been found to be more than adequate for drainage of thick pus. In this technique, the pigtail catheter is loaded on the needle. The needle is introduced into the collection, the stylet removed, pus aspirated and the pigtail advanced over the needle into the collection. The pigtail coils in the collection and the needle is then removed. The pigtail is then fastened to the skin and a drainage bag is attached.

When selecting the guidance system for drainage, it is important to keep the following points in mind: (1) note if the patient can be transported; (2) check regarding availability of the equipment; (3) check whether adjacent structures are adequately visualized; (4) localize the anatomical area to be aspirated or drained. The most important factor is safety and accuracy of the guidance system. CT is the best modality for guidance as it can visualize the extent of the abscess, visualize the bowel, lung and free air, display the entire abdomen, visualize through postoperative drains and dressings, and can confirm accurate and adequate drainage. The main disadvantage of CT is the need to transport the patient to the CT scanner suite.

CHAPTER 12

Anirudh Kohli *MD, DNB, DMRD. Head of Department of Radiology, Breach Candy Hospital, Mumbai, Maharashtra, India*

GENERAL CONSIDERATIONS

Computerized tomography (CT) scanning was introduced in the mid-seventies and enabled a direct visualization of the brain parenchyma, ventricles and cisterns. CT imaging, thus replaced invasive diagnostic radiology techniques such as air encephalography, ventriculography and cisternography; it also decreased the use of carotid/vertebral angiography. Magnetic resonance imaging (MRI) was introduced in the mid-eighties, and this became another important modality in the evaluation of the central nervous system (CNS). MRI has a better intrinsic contrast of images and a higher sensitivity for pathologic changes on T2-weighted images (T2WI). One of the important advantages of MRI over CT is its ability to image soft tissues in the absence of artefacts from overlying bone. This makes MRI the modality of choice in evaluating the brainstem, posterior fossa, extra-axial regions and the spinal cord.

The advantages of CT over MRI are that bony abnormalities, calcification and hyperacute hemorrhage are well detected. Another important advantage is that critically ill patients can be more easily monitored during CT than during MRI. Though MRI compatible ventilators, pulse oximeters and respiratory monitors have now been introduced, they are not widely available, and further in the event of a cardiorespiratory arrest, the patient needs to be removed from the MRI room because defibrillation and ECG monitoring cannot be performed close to the magnet. MRI is contraindicated in patients with cardiac pacemakers, implanted auto defibrillators, thermodilution Swan-Ganz (S-G) catheters, and cochlear implants.[1] Implanted drug infusion pumps may also stop during imaging.[2] Ferromagnetic objects in a patient may move or become dislodged producing damage to the patient, or artefacts in the images. The majority of intracranial aneurysmal clips are ferromagnetic; movement of these clips in the MRI can have disastrous consequences. Non-ferromagnetic clips are now available. However, most hemostatic vascular clips, staples, carotid artery clamps (except Poppen-Blalock carotid artery clamp),[1] wire sutures, vascular access ports, plastic endotracheal tubes, chest tubes, catheters (except S-G catheters), orthopedic devices, prosthesis, prosthetic heart valves (except Starr-Edwards 6000 valve), intravascular coils, stents and filters are safe in the MRI. Most bullets are non-ferromagnetic[3] (in doubtful cases, a similar bullet is taken to the MRI suite and checked). Another disadvantage of MRI is the longer examination time as compared to CT, though newer MRI machines with echoplanar MRI are as fast as or even faster than CT.

With the advent of carotid Doppler and MRI angiography, and spiral CT angiography, the use of angiography has reduced considerably. However, none of these techniques can totally replace angiography, as angiography is required prior to surgery in carotid stenosis, intracranial aneurysms and angiomatous malformations. Cerebral angiography is also being now used for interventional purposes—carotid angioplasty, embolization of aneurysms and angiomatous malformations.

HEAD INJURY

Computerized tomography is far superior to MRI in the evaluation of patients with acute head injury as it is more sensitive than MRI in the detection of acute hemorrhage and fractures. Further, patients who have polytrauma require CT for imaging the thorax and abdomen; CT head can be done at the same time. MRI is useful in the evaluation of subacute/chronic subdural hematomas, and is far superior in the

evaluation of diffuse axonal injury. A plain X-ray of the skull can only demonstrate the presence of a fracture, and help determine if the fracture is depressed. If there is a fracture, a CT must be performed. A basal fracture may not be seen on a skull X-ray. However, air in the subarachnoid space points to a fracture of the base of the skull. Other areas that can be evaluated for fractures on a plain X-ray are the orbit/paranasal sinuses and upper cervical spine.

On CT, fractures appear as linear breaks in the calvarium. A depressed fracture is seen as a bony fragment compressing the underlying brain. It is important to see if there is any underlying hematoma or hemorrhagic contusion, because elevation of the fragment can cause an increase in the size of an underlying hematoma.

Extradural Hematoma

An extradural hematoma occurs due to a tear of an artery traversing between the dura and the calvarium, resulting in a hematoma which strips the dura from the inner table of the skull. There is usually an associated overlying fracture, the common sites being the frontal and temporal regions near the branches of the middle meningeal artery. On CT, extradural hematomas are seen as very hyperdense, well-defined collections, which have a biconvex or lenticular appearance. They may cross the midline as they are limited only by sutural margins. Internally they may contain areas of lower attenuation due to presence of unclotted blood. These hematomas tend to be brighter than other hemorrhages as there is no mixing with cerebral spinal fluid (CSF). Of particular importance are posterior fossa epidural hematomas, as they have a mortality rate of 37–69%.[4] Fortunately, they are relatively uncommon.

Subdural Hematoma

Subdural hematomas are the most common of post-traumatic intracranial hematomas. They occur due to a tear of a bridging vein in the subdural space resulting in a hematoma between the dura and arachnoid. Rarely, they may occur in the posterior fossa due to a tear of a venous sinus. The most common cause of a subdural hematoma is head injury. However, rarely they may occur following shunt placement, coagulopathy, arteriovenous malformations or aneurysmal bleeding. Subdural hematomas are concavo-convex in shape conforming to the contour of the brain; they are limited by the falx cerebri and therefore do not cross the midline but may extend into the interhemispheric fissure. It is important to note that subdural hematomas lying over the convexity below the frontal/occipital lobes, or above/below tentorium are much better imaged by coronal scans. Subdural hematomas are classified according to their age into three types, acute (1–3 days old), subacute (3–22 days old), and chronic (more than 22 days old).

Acute subdural hematomas are best imaged by CT as MRI is relatively insensitive to acute hemorrhage. These appear as crescentic high attenuation lesions causing mass effect on the ipsilateral cortex with effacement of the sulci and a shift of the midline structures to the opposite side. Rarely in severe anemia with hemoglobin less than 5 g/dL, acute subdural hematomas may appear to be of low attenuation, resembling chronic hematomas. As subdural hematomas age, they decrease in attenuation appearing in a spectrum between mildly hyperdense to mildly hypodense, with a certain proportion being isodense with brain parenchyma. Due to the minimal density differences between these hematomas and brain parenchyma they may be difficult to detect.

There are indirect signs which may help to detect a subacute or isodense subdural hematoma. These are: (1) effacement of the cortical sulci; (2) a subtle inbuckling of the gray/white matter interface on the ipsilateral side, as the brain parenchyma is displaced away from the calvarium; (3) compression of the ipsilateral ventricle. Rarely but not uncommonly bilateral isodense subdurals may be present; as the ventricular system is compressed from both sides it appears very small and pinched. In doubtful cases, intravenous contrast may be used as this enhances the membrane of the subdural hematoma along with the cortex of the brain, thereby helping to define the subacute subdural easily. If doubt still exists, an MRI is warranted. Due to the presence of methemoglobin in subacute subdural hematomas, these hematomas appear very bright on MRI resulting in very easy depiction.

Chronic subdural hematomas are often not accompanied by a clinical history of head injury as the patients are usually elderly, alcoholic or have psychiatric problems. On CT, they are seen as crescentic hypodense fluid collections causing effacement of the sulci, shift of the midline structures and compression of the ipsilateral ventricle. On MRI these appear as hypointense on T1-weighted images (T1WI) and hyperintense on T2WI. These may be difficult to differentiate from subdural hygromas, which appear similar on CT and MRI. The only differentiating factor is the presence of a membrane, which is present in hematomas. Occasionally, a chronic subdural may mimic an acute subdural due to rebleeding into the subdural.

Contusions

Contusions occur due to a shearing injury and are most commonly seen in the anterior portions of the frontal and temporal lobes. They may be hemorrhagic or non-hemorrhagic. They may be small or very large causing significant mass effect, and are often multiple and bilateral. On CT they appear as ill-defined hyperdense areas with peripheral hypodensity, or multiple ill-defined hyperdense areas, which tend to get confluent with peripheral hypodensity. The non-hemorrhagic contusions appear hypodense and are better detected on MRI than CT.

Magnetic resonance imaging is far superior in the evaluation of diffuse axonal injury especially in patients with severe post-cognitive disorders in whom the CT is often negative. These axonal injuries are seen as multiple ovoid/round areas of altered signal intensity in the corpus callosum, centrum

semiovale and at the gray/white matter interfaces. Eighty percent of these lesions are non-hemorrhagic. The cortex is usually spared but larger lesions may involve the cortex. Occasionally these lesions are seen on the dorsolateral aspect of the brainstem and the cerebellum.

A rare form of subcortical hemorrhage is seen with focal areas of hemorrhage in the upper brainstem, basal ganglia, thalamus and around the third ventricle. Patients with these findings are usually comatose, have a low Glasgow Coma Score, and often die early.

Stroke

The primary purpose of imaging in acute stroke is to differentiate a non-hemorrhagic infarct from acute hemorrhage. The modality which best meets this purpose is CT, as MRI is relatively insensitive to the detection of acute hemorrhage. Infarcts are detected earlier on MRI, as early as 6 hours after the cerebrovascular accident. Also, small lacunar infarcts in the basal ganglia, internal capsule and posterior fossa may never be seen by CT, and may be visualized only by MRI. On CT the infarcted area is seen as an ill-defined hypodense area with associated mass effect, which becomes more hypodense as it ages. In the subacute phase, the infarct may become isodense and may be missed on a plain CT. This is due to revascularization of the infarct and is known as the fogging phase. In this situation, intravenous contrast may be useful as it will demonstrate dense peripheral gyral enhancement. This is also known as luxury perfusion, which starts at 6 days and persists till 6 weeks. Flooding of an infarct with ionic contrast has been known to increase the incidence of necrosis of the infarct. Nonionic contrast however has not shown any of these adverse effects; therefore, in cases of stroke, if contrast is to be administered, nonionic contrast should be used.[5] If the infarct is deep in the brain (as for example in the basal ganglia), then instead of peripheral gyral enhancements, ring enhancement may be seen. Chronic infarcts appear as very hypodense (CSF attenuation) areas with associated gliosis.

Infarcts typically conform to a vascular territory, unless they lie between vascular territories and are known as watershed infarcts, e.g. in the frontoparietal region between the anterior cerebral artery and the middle cerebral artery, and in the parieto-occipital region between the middle cerebral artery and the posterior cerebral artery. These infarcts are commonly seen in hypoxia or due to hypoperfusion distal to a high grade carotid stenosis. Occasionally, large infarcts may be seen involving the anterior cerebral artery, middle cerebral artery territory, with or without the ipsilateral posterior cerebral artery territory or the opposite anterior cerebral artery territory. These are usually due to internal carotid artery occlusion. On MRI, an echogenic area may be seen in the internal carotid artery representing a thrombus.

On MRI infarcts appear iso- to hypointense on T1WI, and bright on T2WI. As the infarct ages, it becomes more hypointense on the T1WI. Diffusion images are particularly sensitive to detection of acute infarcts, within a few minutes of the ictus changes are observed on diffusion images. A chronic infarct is of CSF intensity on the T1WI with associated gliotic changes. When larger areas of hemorrhage are seen within an infarct, i.e. hemorrhagic infarct, the possibility of a venous infarct or embolic infarct should be considered. The possibility of an embolic infarct should be also considered when there are infarcts in multiple vascular territories. Venous infarcts are often hemorrhagic and do not conform to any vascular territory. They are often cortical or deep such as bilateral thalamic infarcts. MRI is useful in demonstrating an associated venous sinus thrombosis, as venous sinuses are seen as flow void areas. Thrombosis of a venous sinus replaces this flow void with isointense or hyperintense signals.

Intracerebral hemorrhage occurs most commonly in hypertensive patients due to rupture of a small deep vessel. There are five typical sites, basal ganglia, thalamus, gray/white matter junction, cerebellum and pons. On CT, hemorrhage is seen as a confluent high density area with mass effect and edema. Progressive expansion of the hematoma may cause hydrocephalus or cerebral herniation. There may be associated intraventricular or subarachnoid extension of the hemorrhage. As the hemorrhage resolves the clot becomes smaller, and the edema, mass effect and density of the hematoma become less. In this subacute stage, if intravenous contrast is administered there may be ring enhancement of the capsule or hematoma. In the chronic stage, only a gliotic area is seen with no enhancement. The appearances of hemorrhage on MRI are very complex as they depend upon the paramagnetic effects of the blood degradation products. The blood degradation products are oxyhemoglobin, deoxyhemoglobin, intracellular and extracellular methemoglobin, hemosiderin and ferritin. These are serially formed as the hematoma evolves. Hyperacute hemorrhage (first 24 hours) mainly consists of the first breakdown product oxyhemoglobin, which has no paramagnetic properties; it may not be detected by MRI at all, or may be hypointense on T1WI and hyperintense on T2WI, thus resembling an infarct. Therefore, in the acute stage of a stroke, a CT and not an MRI should be performed, as only a CT will detect a hemorrhage.

Deoxyhemoglobin, intracellular and extracellular methemoglobin, hemosiderin and ferritin have relatively typical appearances. Deoxyhemoglobin appears hypointense on T1WI and more hypointense on T2WI. Methemoglobin appears hyperintense on T1WI, the appearance on T2WI depending on whether the methemoglobin is intra- or extracellular. Intracellular methemoglobin is dark or hypointense, whereas extracellular methemoglobin is bright or hyperintense on T2WI. Hemosiderin and ferritin are similar to deoxyhemoglobin; hypointense on T1 and becoming more hypointense on T2WI, with some associated blooming due to paramagnetic effects.

A significant number of strokes occur as a result of a shower of emboli from atherosclerotic disease at the carotid bifurcation. Carotid endarterectomy is currently recommended in cases of symptomatic high grade carotid stenosis to prevent a stroke. The gold standard for evaluating

carotid stenosis is angiography. Duplex color Doppler, MRI angiography and spiral CT angiography are noninvasive imaging techniques, which are proving very useful in the evaluation of carotid stenosis. These are essentially used as screening techniques. Doppler ultrasound is the most widely used screening modality. Its limitations are that it is operator-dependent resulting in a wide variability of interpretation. Tortuous carotid arteries may in addition cause diagnostic problems, and difficulties may arise in differentiating subtotal from total occlusion. Color Doppler sonography is used to determine the sites of flow abnormality and grade the severity of stenotic lesions.[6]

Magnetic resonance (MR) angiography has been recently demonstrated to be a sensitive noninvasive tool in the diagnosis of internal carotid artery stenosis. The major advantage of MR angiography is that it displays the carotid bifurcation anatomy in a format similar to carotid angiography. The degree of stenosis may however be overestimated by both MR angiography, as well as carotid Doppler in a non-proportional manner.[7] Therefore, a conversion factor cannot be calculated to correct this overestimation. Arteriography is a road mapping procedure; in addition it can detect tandem lesions such as intracranial stenosis and stenosis of the origin of the carotid artery. Recently it has been proposed that a combination of color Doppler and MR angiography can almost totally replace the need for angiography. In addition to lowering the preoperative diagnostic costs, the use of color Doppler and MR angiography reduces the complication rate to nearly nil. This has been countered by the recent development in angiography of digital subtraction angiography (DSA), which involves the use of thinner catheters, and the use of nonionic contrast medium. The use of DSA has helped to reduce the complication rate from 1–4% with traditional angiography, to 0.09–0.3%.[8]

Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) occurs following rupture of an aneurysm, arteriovenous malformation, or due to trauma. A CT scan is very sensitive in detecting SAH, which is seen as hyperdensity in the sylvian fissures, the interhemispheric fissures, and along the cortex or basal cisterns. Some amount of blood may also be seen layering in the ventricles. It must be remembered that 10% of SAH may have a negative CT and if the clinical suspicion for SAH is high, a lumbar puncture is mandatory for diagnosis.

Following the demonstration of SAH, a DSA is required to detect an aneurysm. The common sites for aneurysms are at the junction of the anterior cerebral artery/anterior communicating artery, bifurcation of middle cerebral artery and junction of internal carotid artery and posterior cerebral artery. If an aneurysm is detected, it is important to demonstrate the neck of the aneurysm for surgical purposes. MRI can detect aneurysms a small as 3 mm in diameter. As flowing blood is seen as a flow void on MRI, an aneurysm appears as a circular flow void area. A partially thrombosed aneurysm is seen as a signal void area with a peripheral thrombus. This is important as on angiography only the signal void portion, i.e. the patent lumen is demonstrated. Following surgery or in the follow-up of SAH patients, a CT is necessary to monitor ventricular size, strokes (due to vasospasm) or re-bleeding. The presence of a clot helps to localize the site of an aneurysm.

Angiomatous malformations are best evaluated by MRI where they are seen as serpiginous/curvilinear signal void areas. There may be associated areas of hemorrhage or brain atrophy due to the steal phenomenon. CT scan with contrast can demonstrate enhancing curvilinear/serpiginous areas with large draining veins and feeding arteries. Angiography is useful to provide a vascular map of the arteriovenous malformation with special reference to feeding/draining vessels. This information is necessary prior to embolization/radiotherapy or surgery.

Central Nervous System Infections

Both CT and MRI are extremely useful in the evaluation of CNS infections; however, MRI is more sensitive than CT in the evaluation of both meningeal and parenchymal inflammation. Intravenous contrast enhancement is mandatory with CT and provides valuable information in an MRI scan as well.

Meningitis

Imaging in bacterial and viral meningitis is usually negative. Occasionally, leptomeningeal enchancement with intravenous contrast may be seen along the convexity of the brain. In granulomatous diseases like tuberculous meningitis, sarcoid and fungal meningitis, intravenous contrast enhanced CT or MRI may demonstrate dense enhancement in the region of the basal cisterns. The main role of imaging in meningitis is to detect complications such as communicating hydrocephalus, cerebritis, abscess, subdural effusion/empyema, ventriculitis and cortical or subcortical infarcts. Infarcts may be seen in the basal ganglia due to involvement of perforating basal vessels by associated vasculitis. Venous infarcts may occur due to venous sinus thrombosis.

Cerebritis and Abscess

There are four stages in the formation of an abscess, early cerebritis stage, late cerebritis stage, early capsule stage, late capsule stage. Most cases are detected in the late cerebritis stage or early capsule stage. MRI is considered superior to CT in the evaluation of these lesions as it is much more sensitive to subtle parenchymal changes, especially to white matter changes. On CT, cerebritis appears as an ill-defined hypodense lesion with associated mild to moderate mass effect with usually no enhancement. Occasionally, in this stage, there may be ring enhancement, which fills in later on delayed scans. On MRI, cerebritis appears as an ill-defined area, which is hypointense on T1WI and hyperintense on T2WI. Abscesses appear on CT as necrotic hypodense rounded areas with perifocal edema. After administration of intravenous contrast

the capsule/wall of the abscess enhances; the capsule is well formed on the cortical side but the ventricular side is usually thinner. This helps to differentiate abscesses from metastases, which usually have thicker, shaggier, more nodular enhancing walls. Occasionally, abscesses may be multilocular or may be associated with multiple peripheral daughter abscesses. On MRI, abscesses appear as rounded hypointense areas on T1W1 and turn hyperintense with a thin well-defined dark capsule on T2WI. There is a fair amount of perifocal edema about the abscess. As on CT, the capsule enhances with intravenous contrast on MRI.

Encephalitis

Parenchymal infections are usually most often due to a viral etiology. MRI detects changes earlier than a CT; it also provides a better estimate of the extent of the lesion, particularly when lesions involve the white matter.

Herpes simplex type I infection is an important treatable infection of the neuraxis. Herpes simplex encephalitis occurs due to latent herpes simplex virus in the Gasserian ganglion, which spreads along the trigeminal nerve retrogradely to involve the temporal and inferior frontal lobes. Rarely there may be brainstem involvement due to retrograde spread of the virus along IX, X, XI cranial nerves. MRI is far superior to CT in the detection of the subtle changes associated with herpes simplex virus (HSV) encephalitis. The changes seen on imaging are classically in the temporal and inferior frontal lobes and are seen on T2WI as ill-defined hyperintense areas. Often there is bilateral involvement of both cortex and white matter. As the lesion progresses medially, it is limited by the basal ganglia which are spared giving rise to a characteristic sharp medial margin. The disease may extend superiorly across the Sylvian fissure to involve the island of Reil. Small petechial hemorrhages are often present and are seen as hyperintensities on T1WI or hypointensities on T2WI. CT scan usually demonstrates the changes much later than MRI. The lesions are seen as hypodense areas in the temporal and inferior frontal regions. The subtle bilateral involvement seen on MRI is usually not picked up on CT. On contrast studies, there is no significant enhancement. When HSV affects immunocompromised patients, especially HIV positive patients, there may be multiple sites of involvement and it does not conform to the typical appearance as described above. Following resolution of the HSV encephalitis, necrotic and gliotic areas are seen.

Varicella zoster virus encephalitis is usually seen as brainstem encephalitis due to spread along the V and VII cranial nerves to the brainstem. On MRI, similar changes are seen on T2WI in the form of hyperintense areas in the brainstem with more involvement of white matter than gray matter. This form of encephalitis may be accompanied by vasculitis.

Cytomegalovirus encephalitis, which is usually seen in immunocompromised patients, is seen to affect both white and gray matter, with areas of altered signal intensity on T2WI. This form of encephalitis is usually accompanied by ependymitis. Post-contrast MRI reveals considerable enhancement along the ependyma. This form of enhancement may make it difficult to differentiate this pathology from primary CNS lymphomas, which also show diffuse ependymal enhancement. Usually, CNS lymphomas are accompanied by diffuse nodular enhancing lesions in the centrum semiovale and the periventricular region.

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is an encephalitis due to infection by JC virus (papovirus) in the immunocompromised patient. The early lesions of PML are small, round, begin in the subcortical white matter and spread to deeper white matter, becoming larger and confluent. There is sparing of the cortical gray matter giving rise to a typical scalloped appearance of the gray white matter junction. PML is usually bilateral but asymmetrical, with a predilection for involvement of the posterior centrum semiovale. Periventricular and gray matter (basal ganglia, thalamic) involvement is rare. Ten percent of cases may have lesions, which are purely infratentorial. These lesions rarely show enhancement with contrast.

HIV Encephalitis

The clinical diagnosis of HIV encephalitis usually antedates convincing radiologic evidence of the disease. On MRI, there may be diffuse areas of altered signal intensity seen in the supratentorial white matter which may be solitary or confluent. With progression of the disease, there is involvement of the cortex, basal ganglia, brainstem and cerebellum. MRI mainly displays the secondary changes of HIV encephalitis, atrophy and demyelination.

Acute Disseminated Encephalomyelitis

Magnetic resonance imaging demonstrates diffuse, ill-defined, patchy hyperintensity in the deep/subcortical white matter of the cerebrum. Occasionally, changes are seen in the midbrain, pontine and cerebellar regions, and spinal cord white matter. The lesions are few, asymmetrically distributed, without evidence of mass effect and hemorrhage. Embolic infarction, vasculitis, acute hemorrhagic leukoencephalopathy and acute multiple sclerosis need to be differentiated from acute disseminated encephalomyelitis (ADEM). Embolic infarction usually conforms to a vascular distribution. Vasculitis is not necessarily limited to white matter. There are hemorrhagic changes in acute hemorrhagic leukoencephalopathy; no hemorrhagic changes occur in ADEM. Acute multiple sclerosis and ADEM are not easily differentiated on plain MRI, but on contrast, MRI all the lesions in ADEM enhance, whereas in multiple sclerosis only active plaques enhance.

Toxoplasmosis

This is one of the most common opportunistic infections seen in patients with AIDS. Parenchymal lesions in toxoplasmosis are seen on CT as mildly hyperdense nodular lesions with

perifocal edema. On a contrast, study there is ring or nodule enhancement. These lesions are typically seen in the basal ganglia, periventricular region and the brainstem. On MRI the lesions appear iso- to hypointense on T1WI, and turn hypo- or hyperintense on T2WI with perifocal edema. With gadolinium DTPA there is ring or nodular enhancement of the lesions. Occasionally, evidence of hemorrhage may be detected within the lesions on MRI. The presence of enhancement on CT/MRI helps to differentiate active from inactive lesions. As these lesions resemble and may coexist with other parenchymal granulomas and lymphomas, the best confirmation of the diagnosis lies in the response of the lesions to antitoxoplasmal therapy. Following resolutions of the lesions, the scans may return to normal, or there may be residual gliosis. Rarely, toxoplasmosis can present as a fulminant, necrotizing meningoencephalitis in which CT/MRI can be negative.

Cryptococcosis

Intraparenchymal cryptococcal granulomas are seen typically in the basal ganglia as hypodense nonenhancing areas appearing similar to lacunar infarcts on CT, or bright areas on T2W MRI. These are in fact gelatinous masses of cryptococcal organisms inciting minimal or no inflammatory response. These may be associated with cryptococcal meningitis.

Neurocysticercosis

Disseminated neurocysticercosis is an important cause of status epilepticus in our part of the world. The cysts may be in the live, dying, dead stages, or in a combination of all three stages. Both CT and MR are very useful in demonstrating these lesions. However, MR is considered superior to CT as it is able to demonstrate the scolex better, as well as detect small live cysts thereby giving a more accurate depiction of the cyst burden. Live cysts appear as rounded CSF attenuation/intensity lesions with an eccentric scolex; no perifocal edema or cyst wall enhancement is seen with administration of intravenous contrast. Dying cysts have a similar appearance as live cysts (CSF attenuation/intensity lesions), but perifocal edema and cyst wall enhancement are present. As the scolex is often not visualized in dying cysts, they may resemble other granulomatous lesions. Dead cysts are seen as calcified foci, which are better detected on CT than MR. In disseminated neurocysticercosis, cysts are also often present in striated muscles as in the thigh, calf, tongue, myocardium, and the orbital muscles. The thigh is the commonest extracranial site; clinically, there is enlargement of the thigh muscles resulting in a pseudotumor appearance. The cysts can be demonstrated easily in these locations on imaging (CT/MR).

Spinal Cord Infarction

Infarction of the cord is most often the result of inadvertent occlusion of the anterior spinal artery during the repair of thoracic aortic aneurysms. Other causes are embolic disease, vasculitis, cardiac arrest and dissecting aortic aneurysm. MRI is the only imaging modality, which will demonstrate a spinal cord infarction, which is seen on T1W1 as a generalized swelling of the cord; on T2WI there is increased signal intensity in the involved region of the cord.

Transverse Myelitis

The role of imaging in transverse myelitis (TM) is to exclude spinal cord compression. Occasionally, in cases of TM intrinsic abnormalities may be seen in the cord on MRI. T1WI may show no change, but on T2WI ill-defined hyperintensities will be seen at the level of the affected segment. With gadolinium there may be subtle enhancement in these regions.

Spinal Trauma

Plain X-rays of the spine are extremely useful in evaluating vertebral body fractures and dislocations. However, CT provides far more information regarding the extent of the fracture, intraspinal fragments, posterior element fractures, thecal sac compression and presence of intraspinal or paraspinal hematomas. MRI is useful as it demonstrates the cord. Intrinsic cord abnormalities are not uncommon in spinal trauma and MRI is the only modality, which can demonstrate them. Intrinsic cord abnormalities may be in the form of edema of the cord due to compression by vertebral fracture; this is seen as a hyperintensity in the cord on T2WI. Other abnormalities may be the presence of hemorrhagic or non-hemorrhagic cord contusions. Hemorrhagic contusions are seen as bright areas within the cord on T1WI, and non-hemorrhagic contusions as hypointense (dark) areas on T1WI which turn bright on T2WI. Rarely there may be transection of the cord, which is best appreciated on sagittal images as a discontinuity of the cord. The presence of intrinsic abnormalities in the cord is of importance as it provides prognostic information. Extradural hematomas may occasionally cause cord compression and are best appreciated on axial MRI images as well defined hyperintense areas compressing the cord. A traumatic disc protrusion is not uncommon, and this is also well-evaluated on a sagittal or axial MR image. As bony abnormalities are well-visualized on CT, this modality has an advantage over MRI in the evaluation of posterior arch fractures, as well as in the visualization of intraspinal fragments.

Fig. 13: Aspiration pneumonia. Frontal radiograph reveals ill-defined opacities in the right mid and lower zones representing consolidation due to aspiration. There is an associated effusion

Fig. 14: Lobar pneumonia. Ill-defined consolidation seen in right lower lobe with evidence of break down

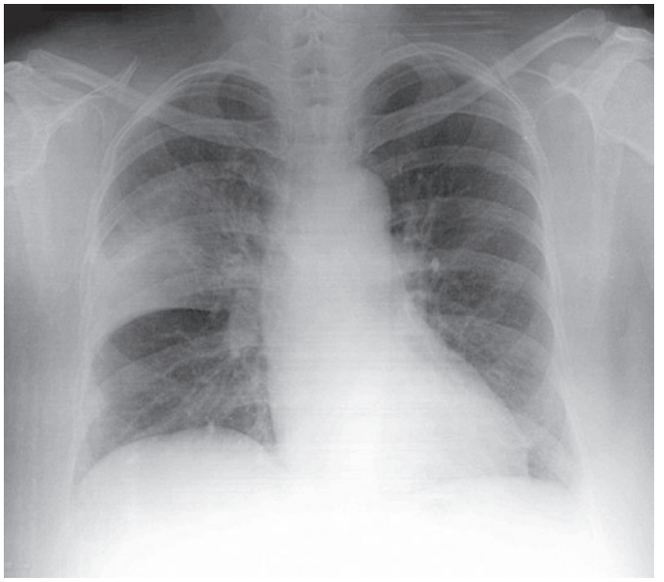

Fig. 15: Right upper lobe lobar pneumonia. Large right upper lobe consolidation limited by interlobar fissure

Fig. 16: Bronchopneumonia. Frontal radiograph presents ill-defined fluffy opacities in both lung fields as a result of bronchopneumonia

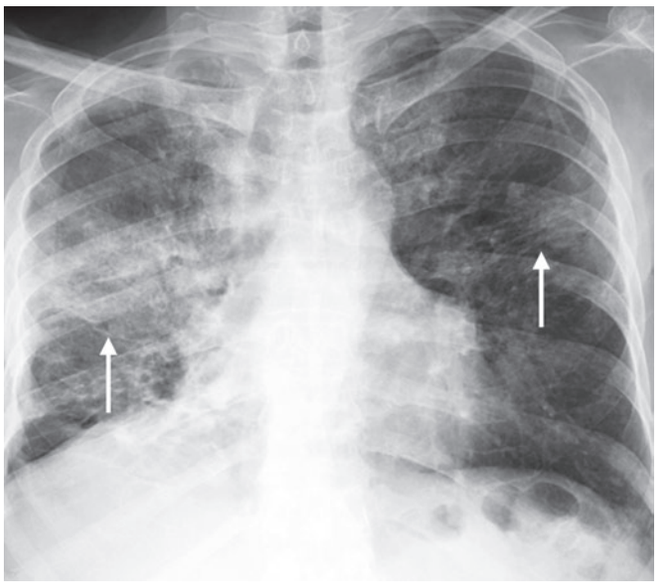

Fig. 17: Interstitial pneumonia. Frontal radiograph reveals ill-defined linear and reticular opacities which appear to conglomerate in both mid zones, more so on the right side, these would be as a result of an interstitial pneumonia

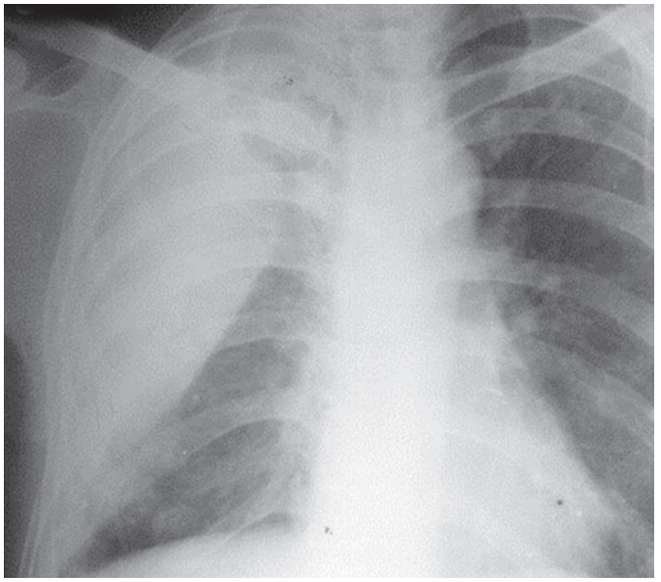

Fig. 18: Empyema. Large homogenous opacity in right hemithorax which has a wide pleural margin with obtuse angles representing an empyema

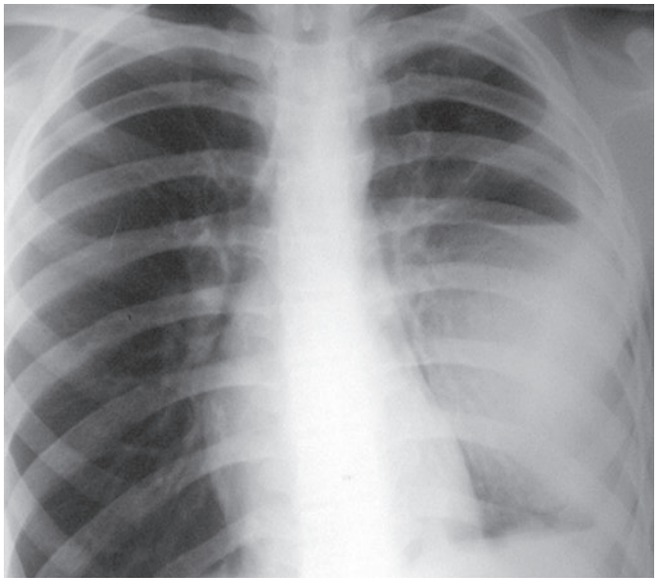

Fig. 19: Lung abscess. Frontal radiograph demonstrates a large homogenous opacity with an air fluid level representing an abscess. Note: Angle with chest wall are acute as compared to empyema with obtuse angle

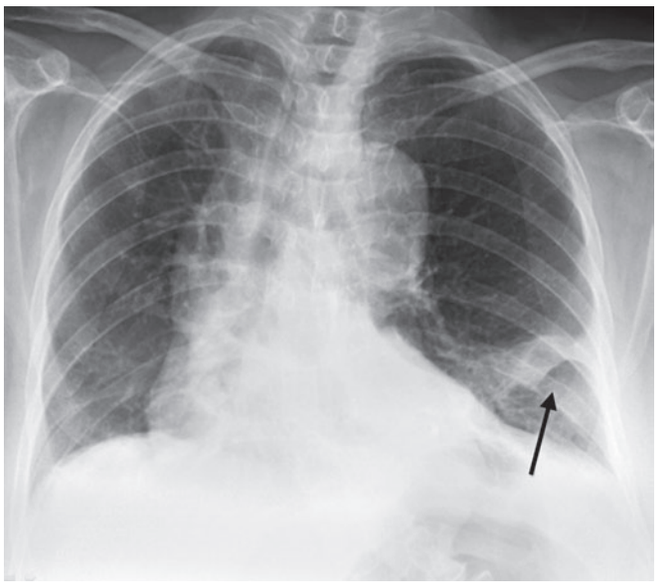

Fig. 20: Segmental atelectasis. Frontal radiograph demonstrates a segmental band-like opacity representing segmental atelectasis

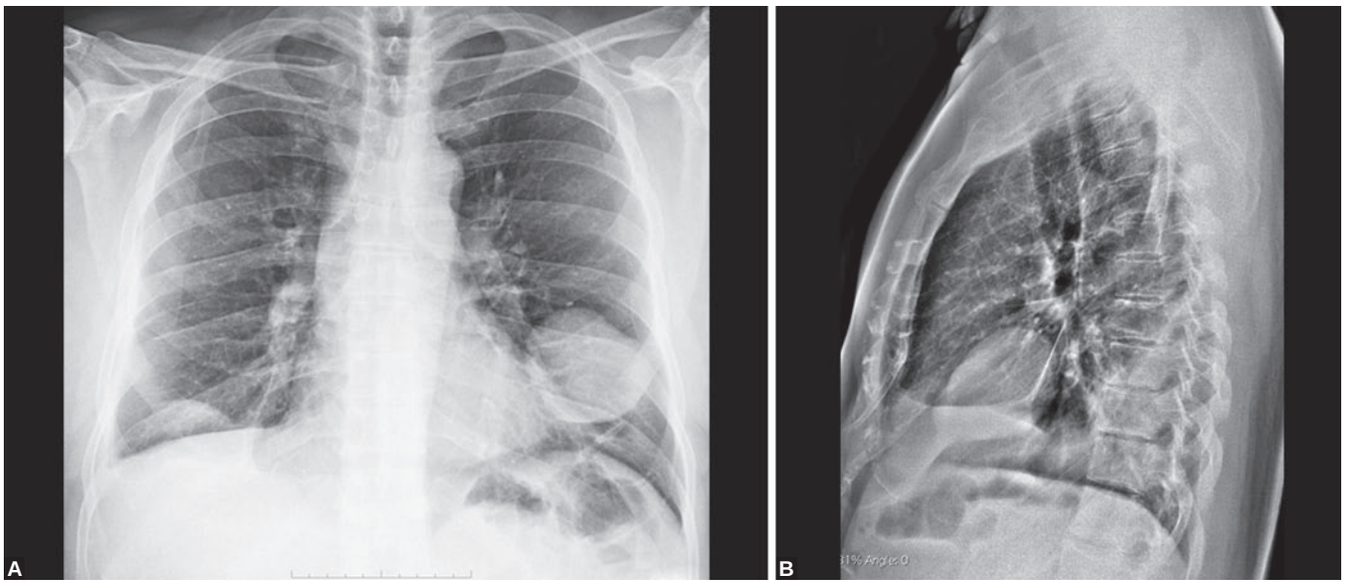
Fig. 21: Pleural effusion. Frontal radiograph demonstrates a homogenous opacity in right lung base extending along right lateral chest wall representing a pleural effusion



Figs 22A and B: Loculated interlobar effusion. (A) Well-defined homogenous opacity in left lower zone; (B) Lateral chest X-ray reveals the loculated fluid collection to be in relation to the interlobar fissure indicating this represents a loculated pleural effusion in the interlobar fissure

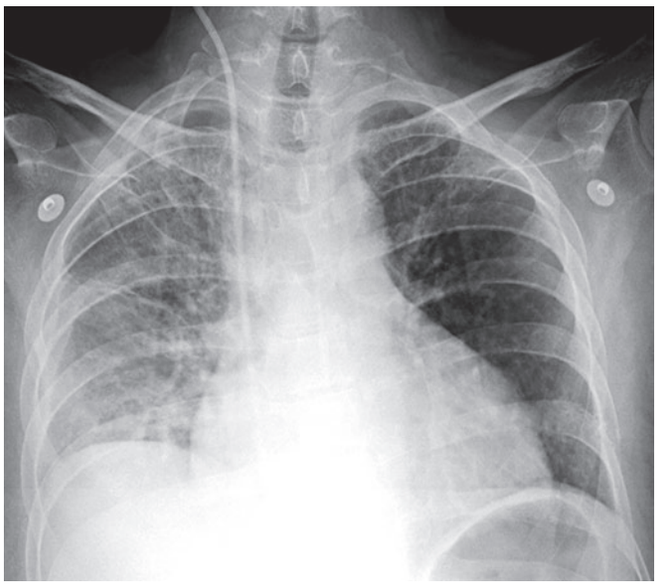


Fig. 23: Pleural effusion in supine patient. Supine radiograph reveals diffuse homogenous opacities in right hemithorax representing a pleural effusion layering along the hemithorax contributing to the opacity

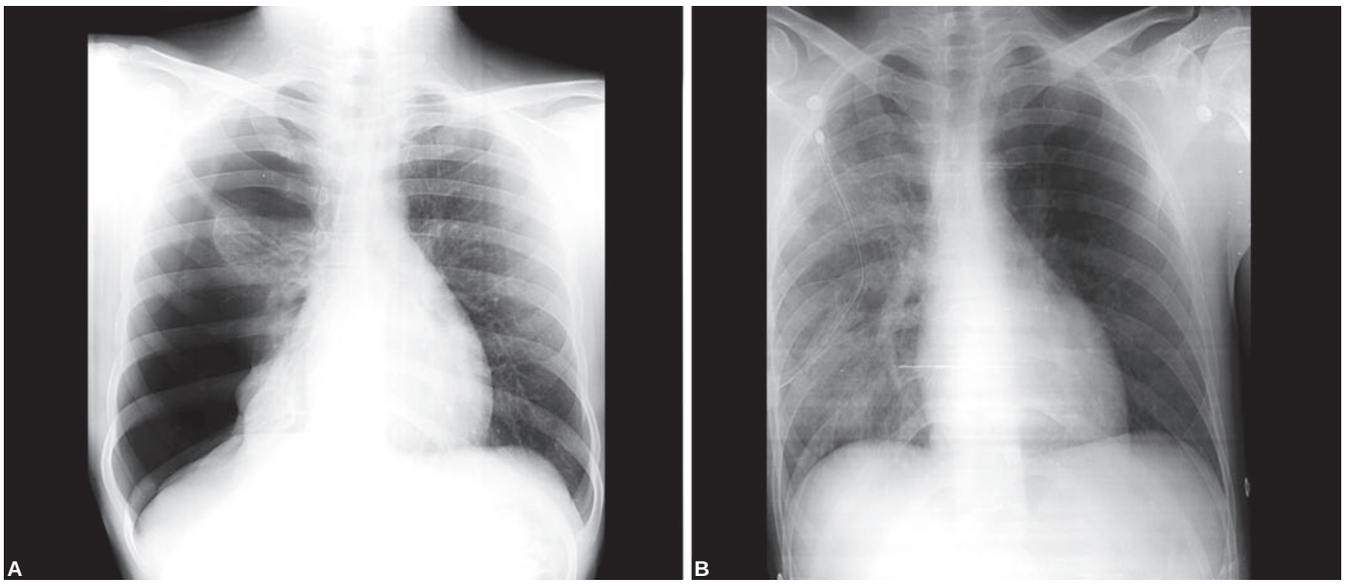
Fig. 24: Subpulmonic effusion. Frontal radiograph demonstrates homogenous opacity in right base. This may be as a result of elevation of right dome of diaphragm or a subpulmonic effusion. Sonography confirmed this to represent a subpulmonic effusion



Figs 25A and B: Re-expansion pulmonary edema. (A) Frontal radiograph demonstrates a large right pneumothorax; (B) Demonstrates intercostal drain (ICD) in situ, ill-defined fluffy opacities in right lung field due to re-expansion pulmonary edema

Fig. 26: Pneumothorax. Frontal radiograph demonstrates a large pneumothorax on the left side with collapse of left lung and shift of mediastinum to right

Fig. 27: Pneumothorax. Frontal radiograph reveals ill-defined opacities in both lung fields due to acute lung injury. There is a left pneumothorax as evidenced by thin visceral pleural line as well as extensive subcutaneous edema

Fig. 28: Tension pneumothorax. Frontal radiograph reveals a large right pneumothorax with inversion of diaphragm, displacement of mediastinum to left and herniation of pneumothorax across the midline to the left

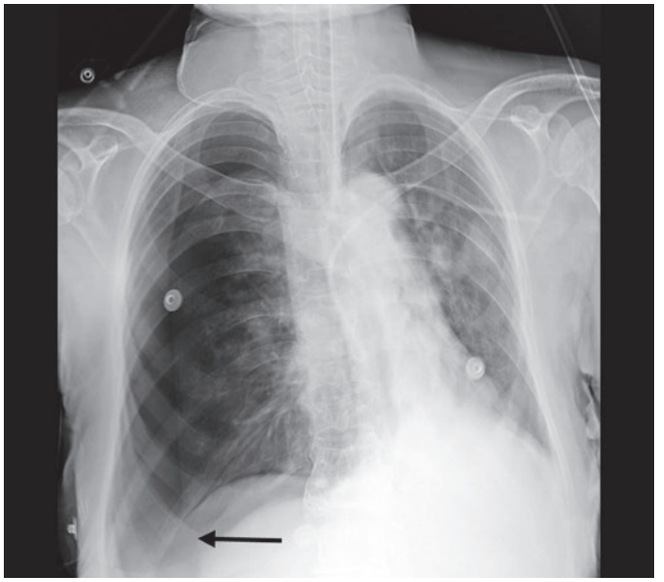


Fig. 29: Pneumothorax in a supine patient. Supine chest X-ray reveals a large lucency overlying the liver representing a pneumothorax with collection of air in the pleural space. Note shift of mediastinum to left

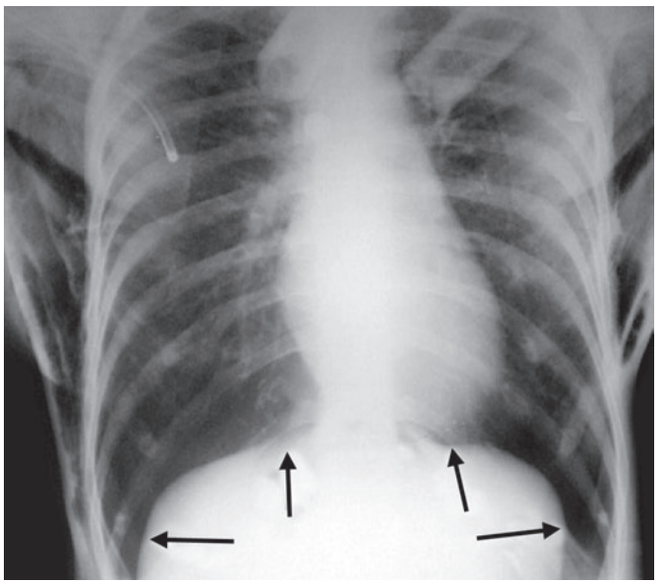

Fig. 30: Bilateral pneumothorax in a supine patient. Frontal supine chest X-ray demonstrates bilateral deep costophrenic sulcus with sharply defined diaphragm. This is because there is air collected in the pleural space

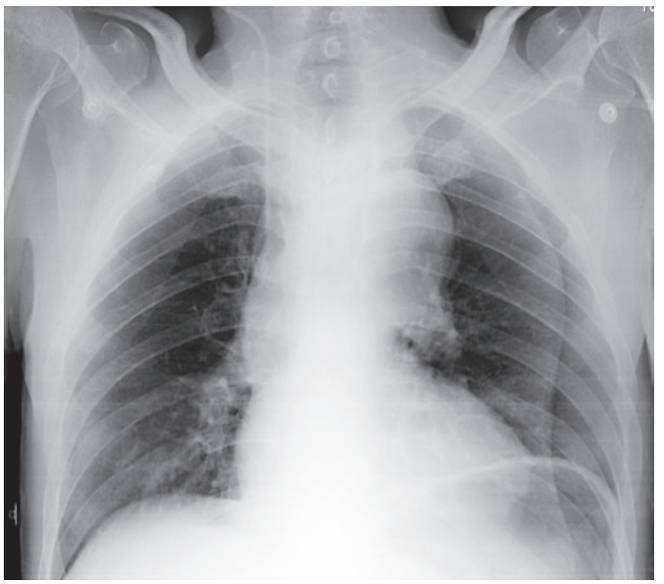

Fig. 31: Skin fold mimicking a pneumothorax. Frontal chest X-ray reveals a thin curvilinear line overlying the left hemithorax resembling a pneumothorax. This is a skin fold and not a pneumothorax as the line is seen to extend beyond the thorax over the abdomen

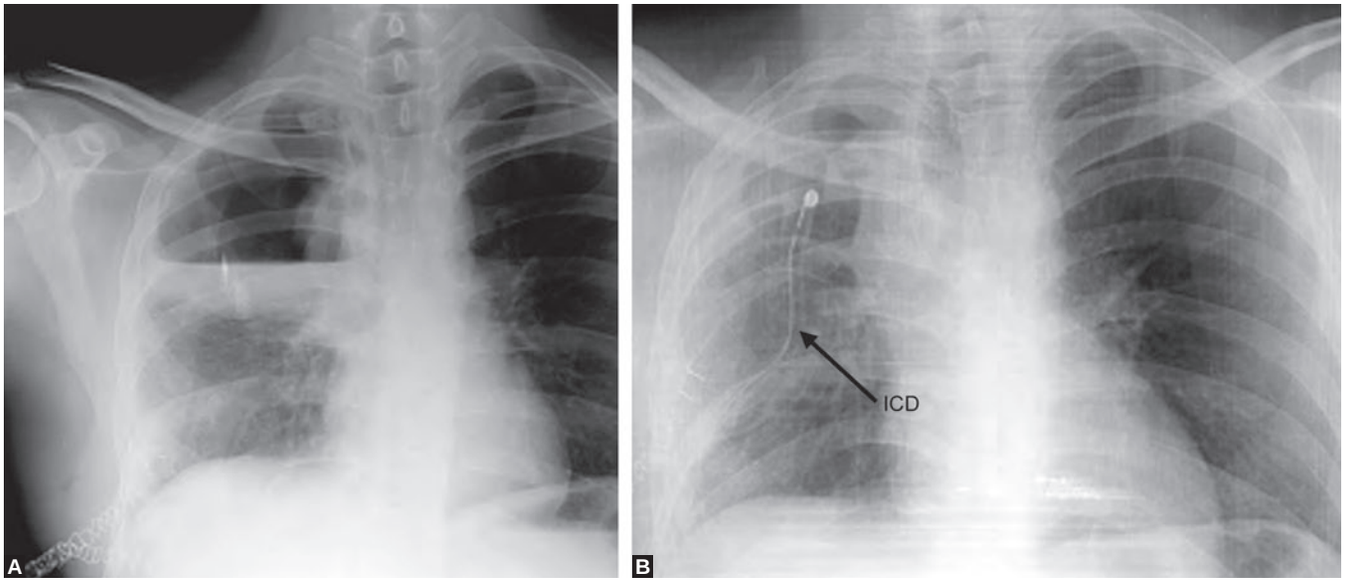

Figs 32A and B: Hydropneumothorax. (A) Chest X-ray demonstrates air fluid level in the right upper zone representing a hydropneumothorax; (B) This has been drained by an intercostal drain (ICD)

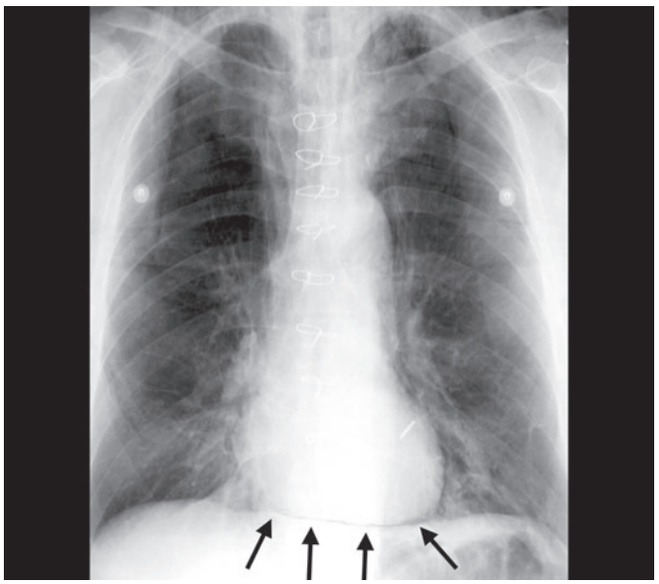

Fig. 33: Pneumomediastinum. Frontal chest X-ray demonstrates a thin air streak separating diaphragm from cardiac silhouette. These two structures usually are inseparable as both of soft tissue density, these become separable when there is air interspersed between the two as in a pneumomediastinum

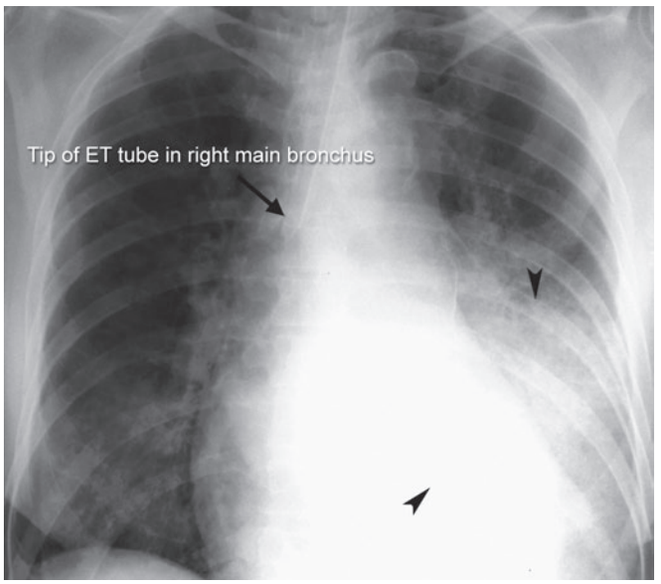

Fig. 34: Endotracheal tube in right main bronchus. Chest X-ray reveals endotracheal tube in right main bronchus. Consequently, there is hyperinflation of right lung and partial collapse of left lung

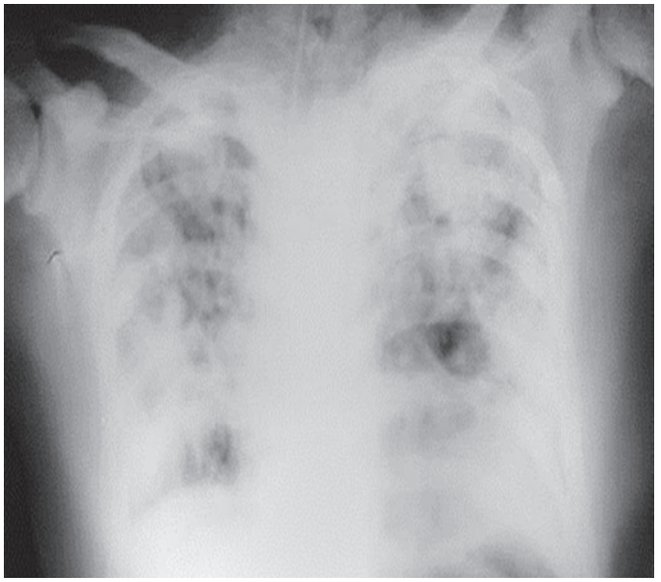

Fig. 35: Esophageal intubation. Chest X-ray reveals ill-defined opacities in both lungs. There is also hypoventilation

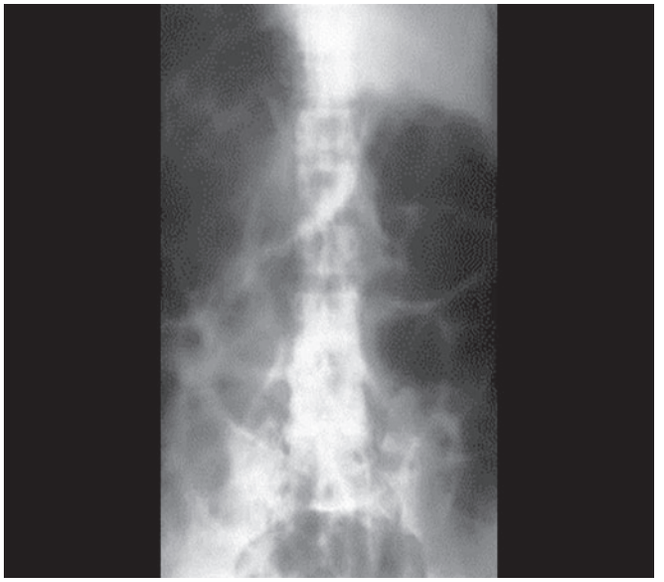

Fig. 36: Esophageal intubation. Abdominal X-ray reveals gross distension of bowel loops. Esophageal intubation has resulted in hypoventilation of the lungs and gross overdistension of the bowel

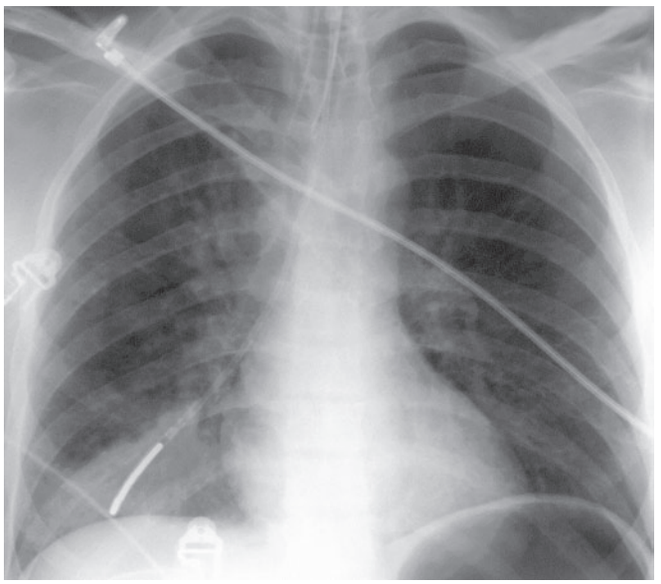

Fig. 37: Ryle's tube in right bronchus. Frontal chest X-ray reveals a Ryle's tube extending into the right lower lobe bronchus

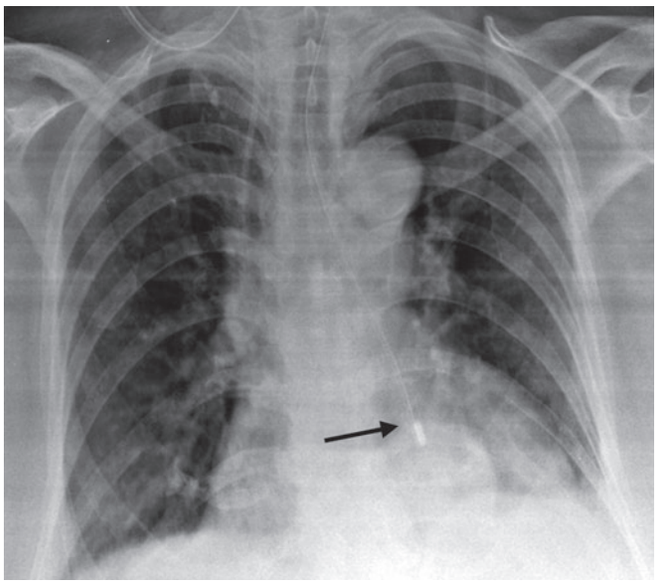

Fig. 38: Ryle's tube in left lower lobe bronchus. Chest X-ray demonstrates Ryle's tube in left lower lobe bronchus

Fig. 39: Central line too high. Chest X-ray demonstrates central line in right innominate vein. Its placement is too high

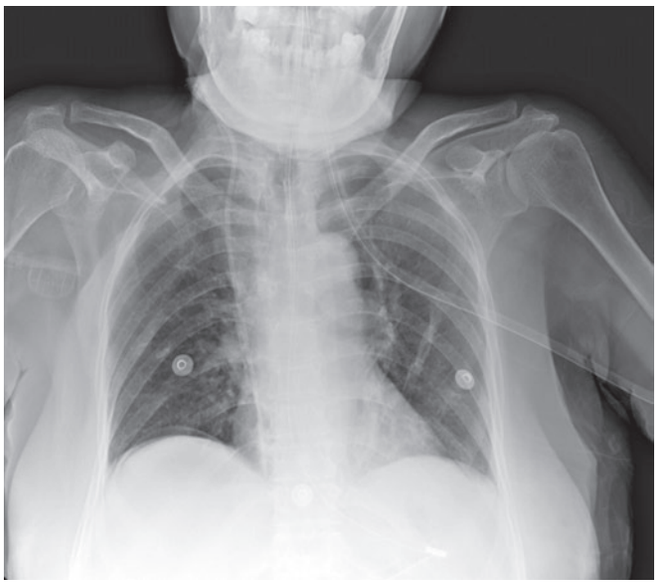

Fig. 40: Central line is placed too low. Chest X-ray reveals the central line is extending way too low into the right atrium

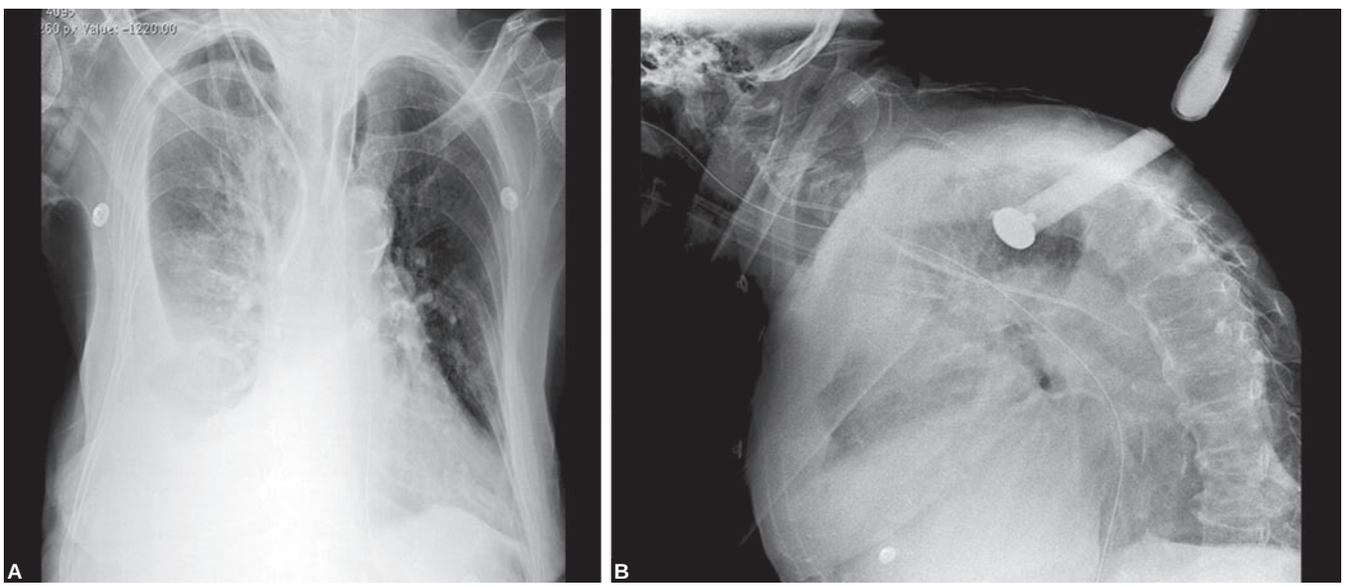

Figs 41A and B: Frontal chest X-ray reveals a right pleural effusion with a central line in situ. (A) The central line appears to be in good position, however the pleural space kept filling up with every infusion; (B) Lateral chest X-ray reveals tube extending posteriorly and not in the superior vena cava

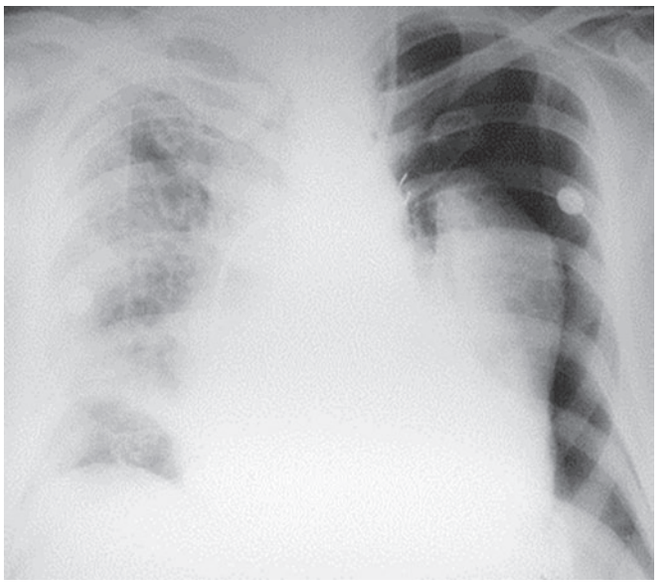

Fig 42: Post-central line pneumothorax. Chest X-ray demonstrates a central line on the left side. There is a pneumothorax on the left side, secondary to placement of central line

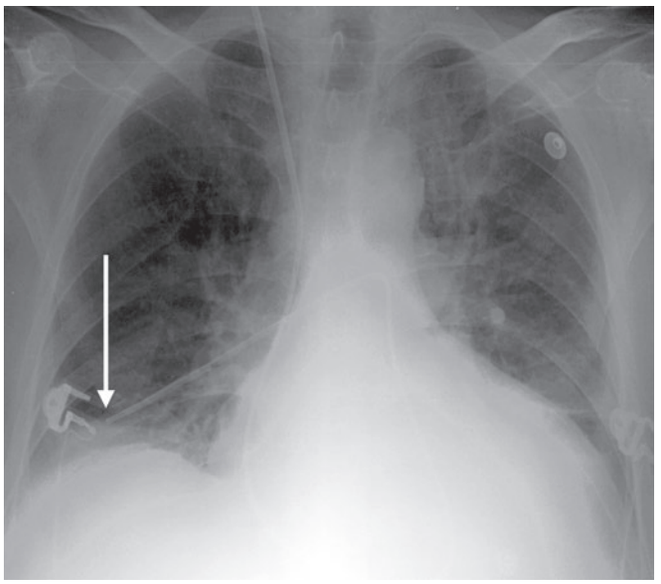

Fig. 43: Swan-Ganz catheter too far. Chest X-ray reveals Swan-Ganz catheter in right lower lobe. The tip should be within 2 cm of the hilum

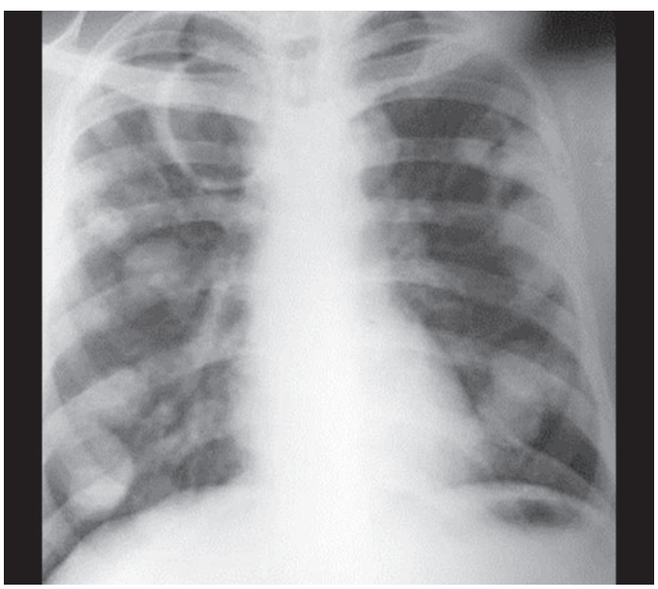

Fig. 44: Septic emboli. Chest X-ray reveals multiple well-defined round and cavitating lesions in both lung fields representing septic emboli

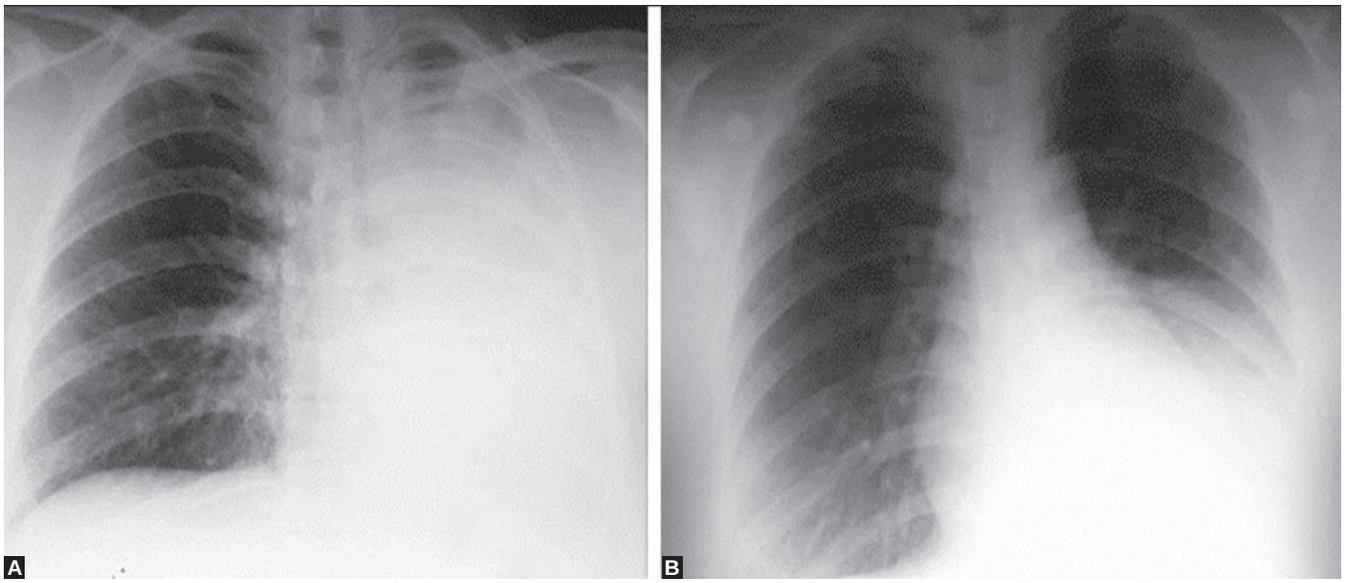

Figs 45A and B: Mucus plug. (A) Chest X-ray reveals dense opacity in left hemithorax with shift of mediastinum to left. In view of the volume loss, dense opacity in left hemithorax bronchoscopy performed; (B) Chest X-ray post scopy reveals clearing of most of the opacity following removal of mucus plug in left main bronchus

Imaging Techniques in the Abdomen

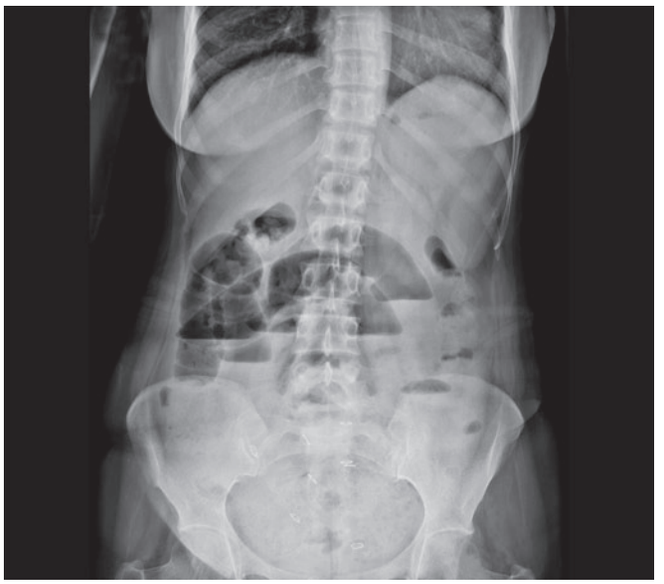

Fig. 2: Small bowel obstruction: Erect abdominal X-ray demonstrates dilated small bowel loops with multiple air-fluid levels

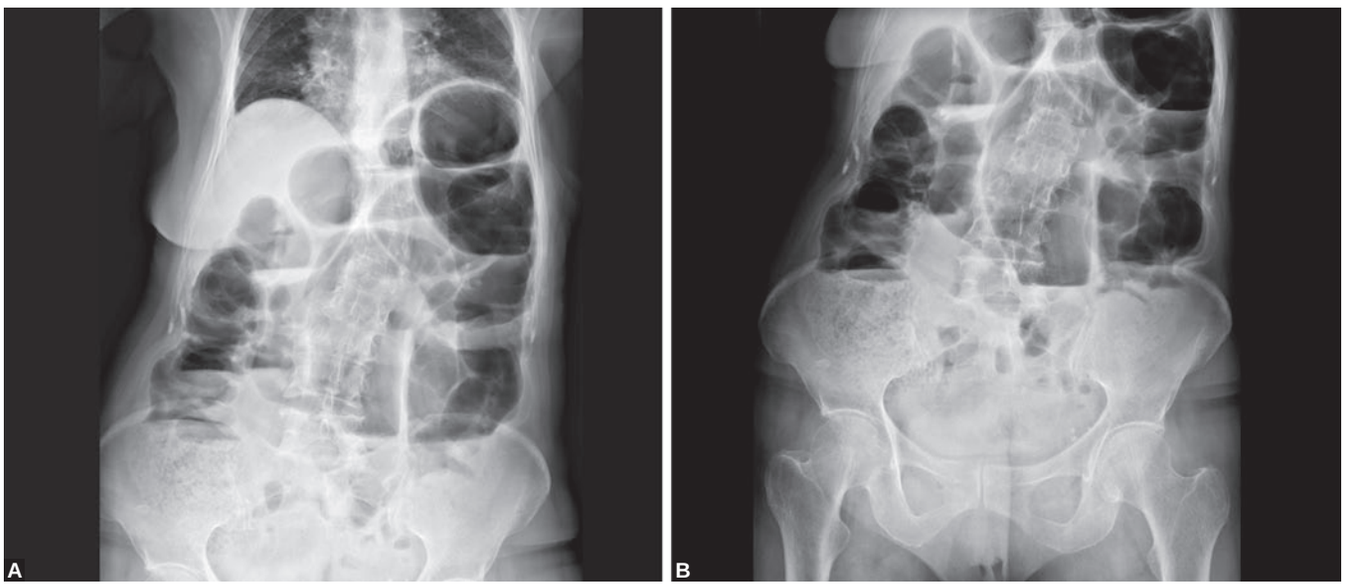

Figs 3A and B: (A and B) Large bowel obstruction: Erect abdominal X-ray demonstrates dilated colonic loops with fluid levels in a patient with colonic obstruction due to sigmoid volvulus

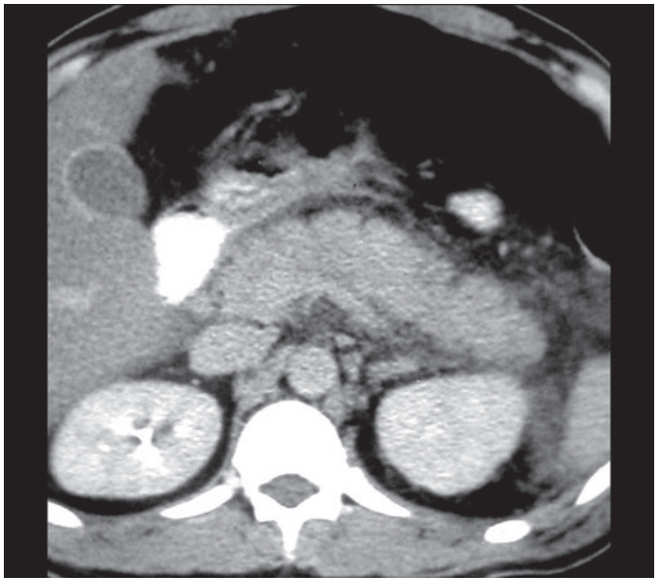

Fig. 4: Acute edematous pancreatitis: Computed tomography (CT) study after administration of contrast reveals an enlarged pancreas with no focal necrosis

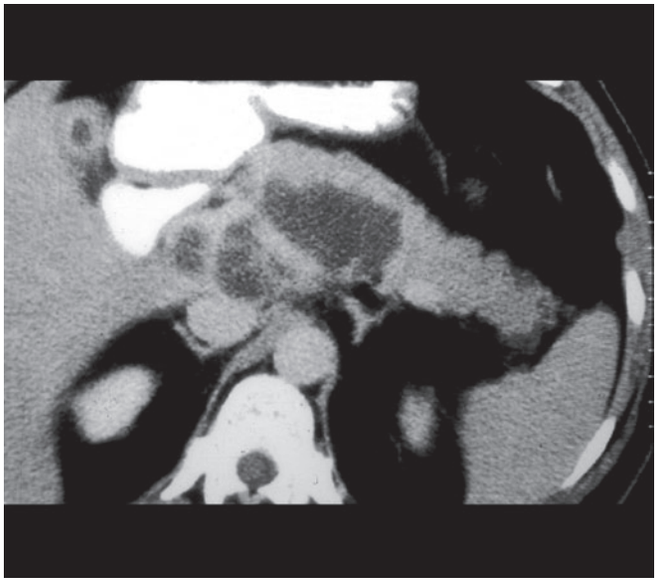

Fig. 5: Necrotizing pancreatitis: Computed tomography (CT) study after contrast reveals focal hypodensities in an enlarged pancreas representing necrotizing pancreatitis

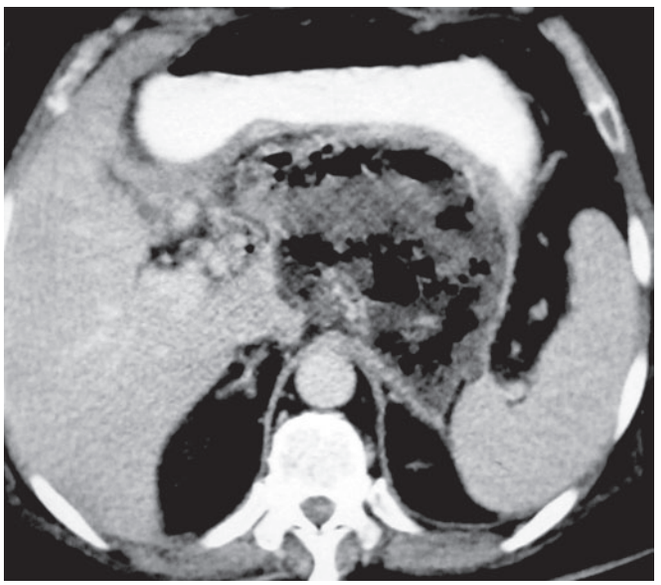

Fig. 6: Pancreatic sepsis: Computed tomography (CT) study after contrast reveals a large collection in the lesser sac with air within, in a case of acute pancreatitis representing pancreatic sepsis

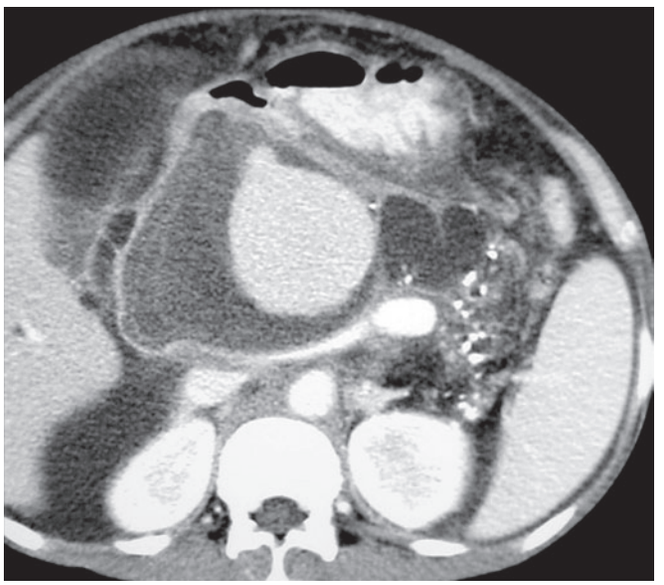

Fig. 7: Pseudoaneurysm following acute pancreatitis: Computed tomography (CT) study after administration of intravenous (IV) contrast demonstrates a large aneurysm with a peripheral thrombus

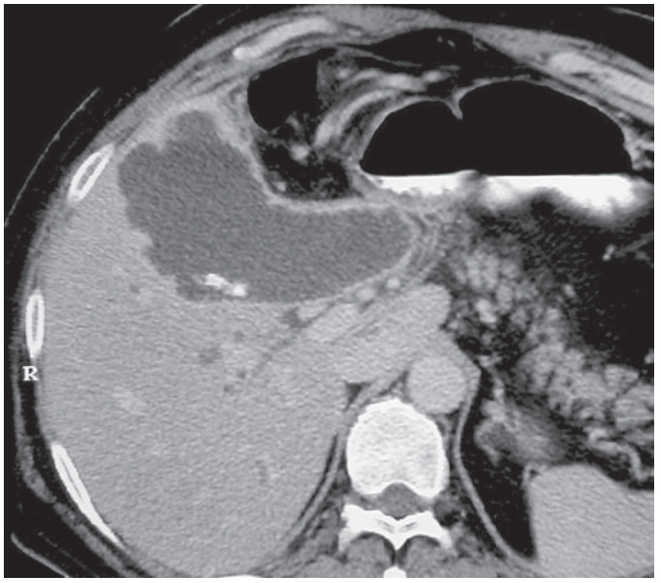

Fig. 8: Acute cholecystitis: Computed tomography (CT) study demonstrates distended gallbladder with an irregular inner surface representing sloughing of mucosa due to gangrenous changes

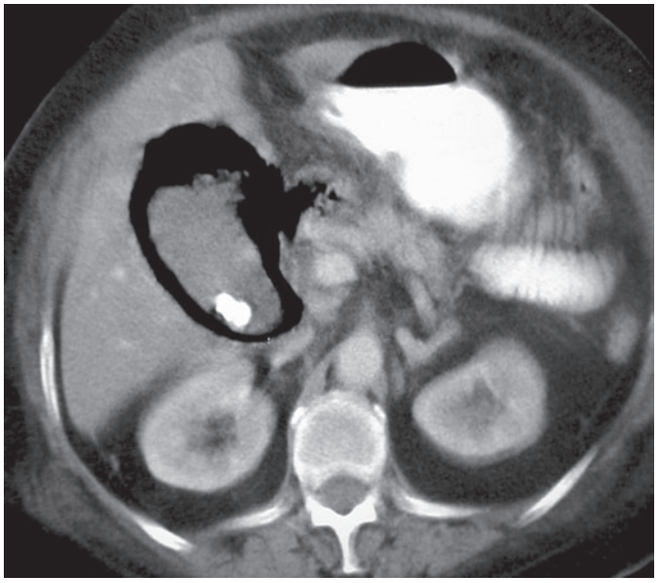

Fig. 9: Emphysematous cholecystitis: Computed tomography (CT) study demonstrates air in gallbladder wall due to emphysematous cholecystitis

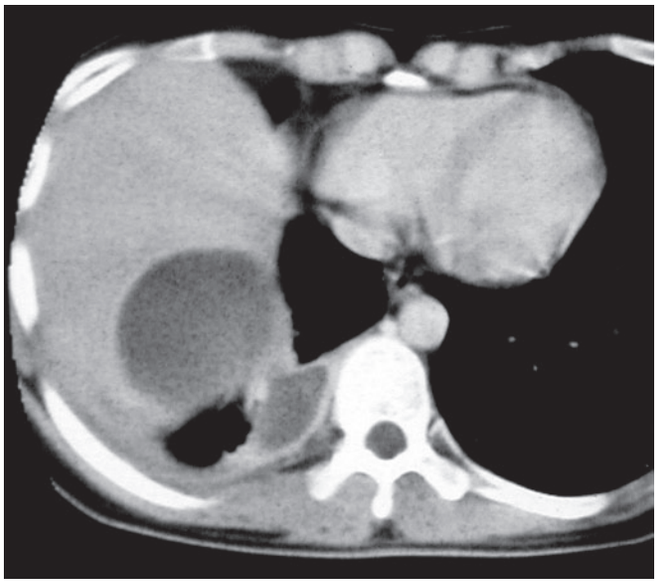

Fig. 10: Ruptured amebic abscess: Computed tomography (CT) demonstrates a well-defined hypodense lesion in the liver with extension into the pleural space

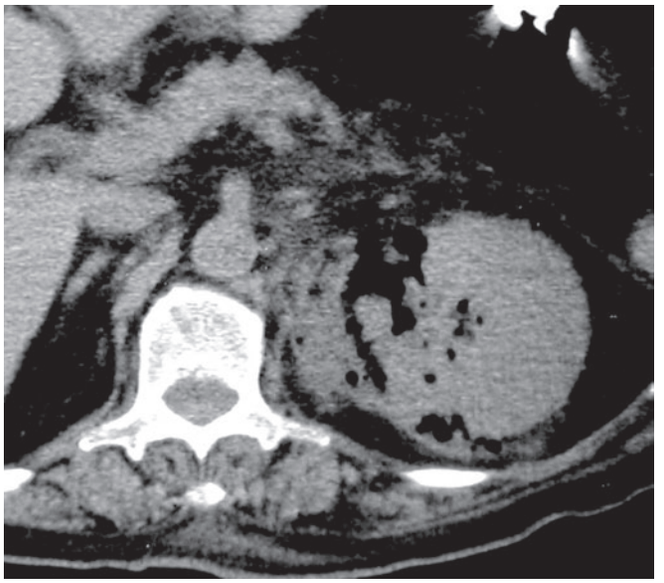

Fig. 11: Emphysematous pyelonephritis: Computed tomography (CT) demonstrates air in the left kidney as a result of emphysematous pyelonephritis

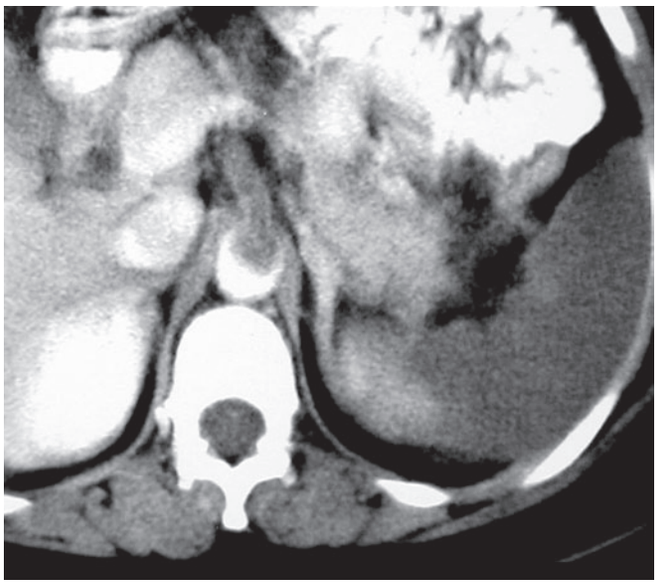

Fig. 12: Splenic infarction: Computed tomography (CT) demonstrates a thrombus in the celiac artery. Note hypodense non-enhancing spleen which is infarcted

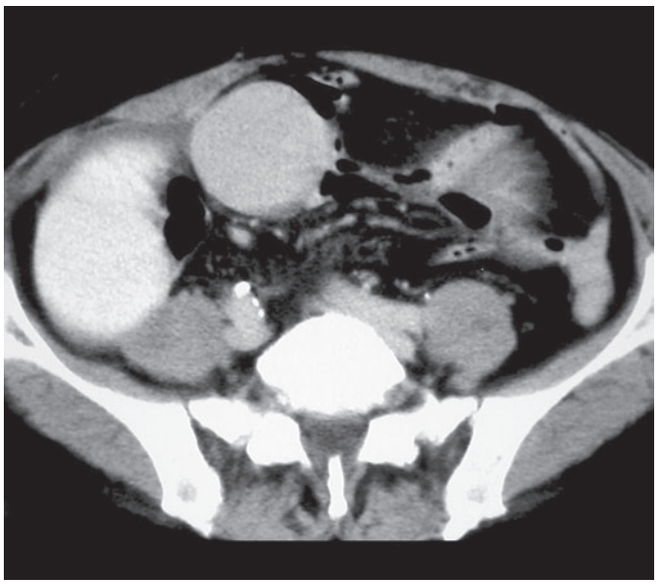

Fig. 13: Small bowel obstruction due to adhesions: Computed tomography (CT) demonstrates dilated small bowel loops, a zone of transition and nondilated loops. There is no mass lesion or obstructing pathology at the zone of transition indicating the obstruction would be due to adhesions or bands

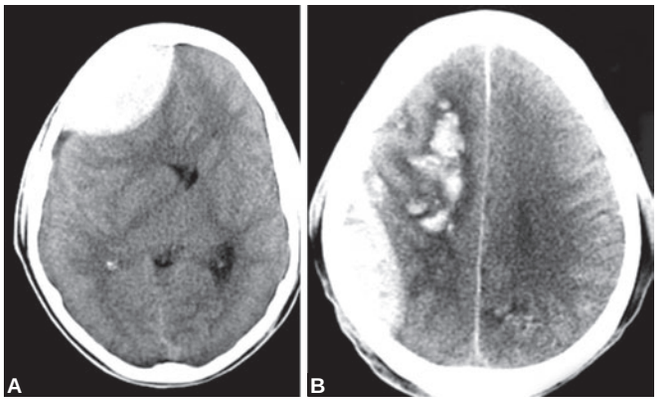
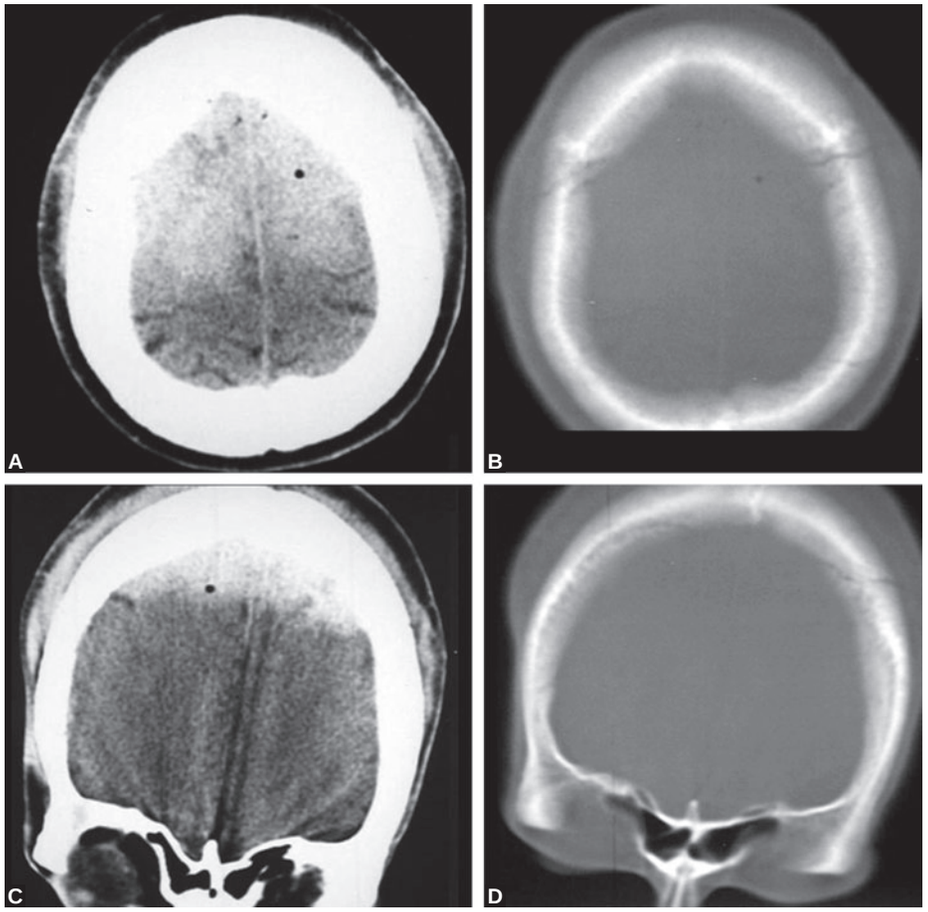


Figs 1A and B: (A and B) Extradural hematoma: Large biconvex extra-axial hyperdensity representing an extradural hematoma



Figs 2A to D: (A to D) Extradural hematoma: Axial and coronal CT demonstrate hyperdensity in the high parietal region in an extra-axial location crossing the midline representing an extradural hematoma

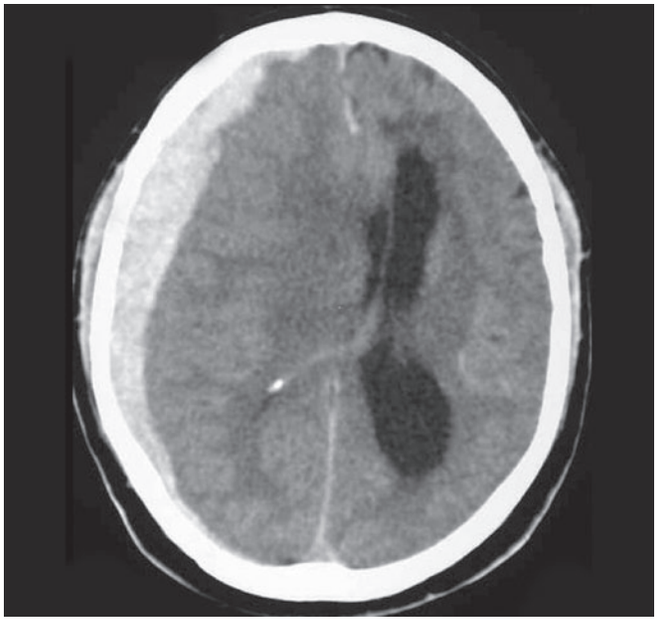


Fig. 3: Acute subdural hematoma: Plain CT brain reveals right concavo-convex hyperdense bleed with compression of the underlying brain parenchyma, there is a shift of the midline structures with consequent dilatation of the left lateral ventricle

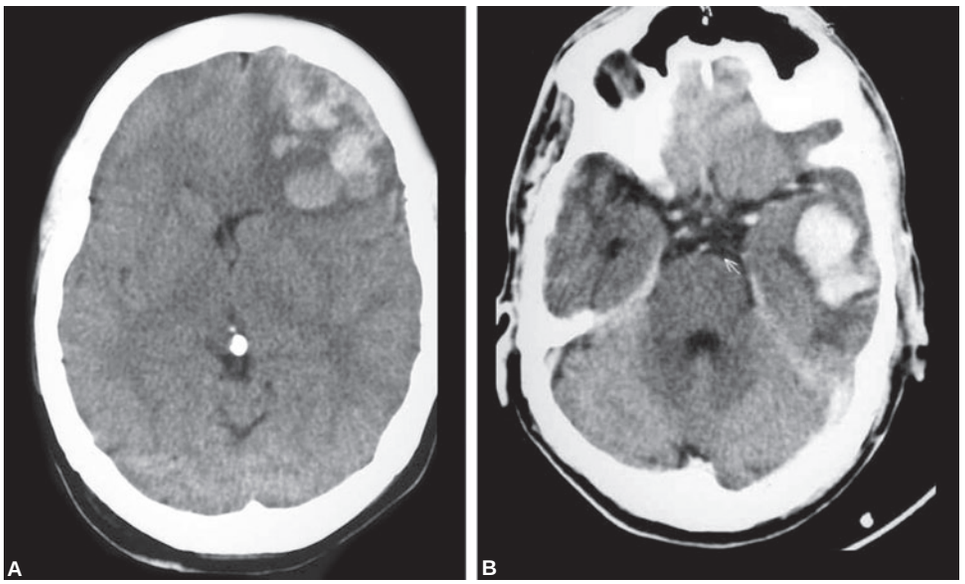

Figs 4A and B: (A and B) Hemorrhagic contusions: There are multiple ill-defined hyperdense areas in the left frontal and temporal region causing mass effect on the left lateral ventricle

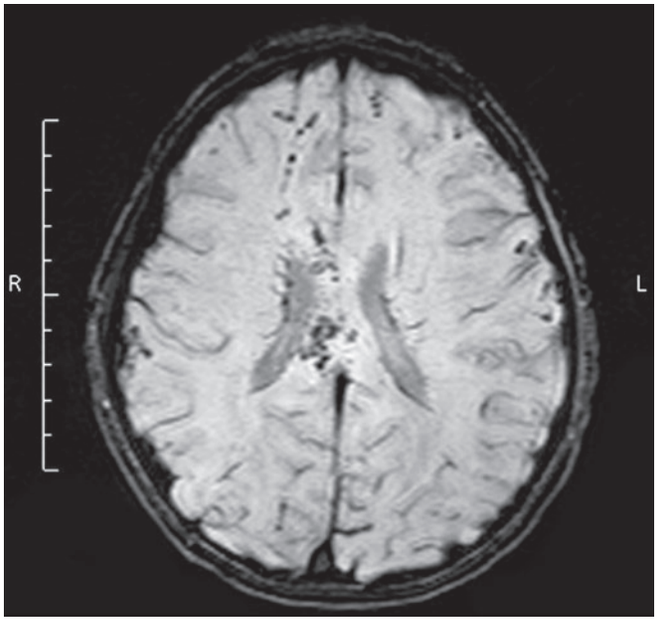

Fig. 5: Diffuse axonal injury: MRI study using susceptibility-weighted imaging (SWI) sequence—demonstrates small petechiae of hemorrhage in the body of the corpus callosum and fronto parietal cortices as a result of shearing injury

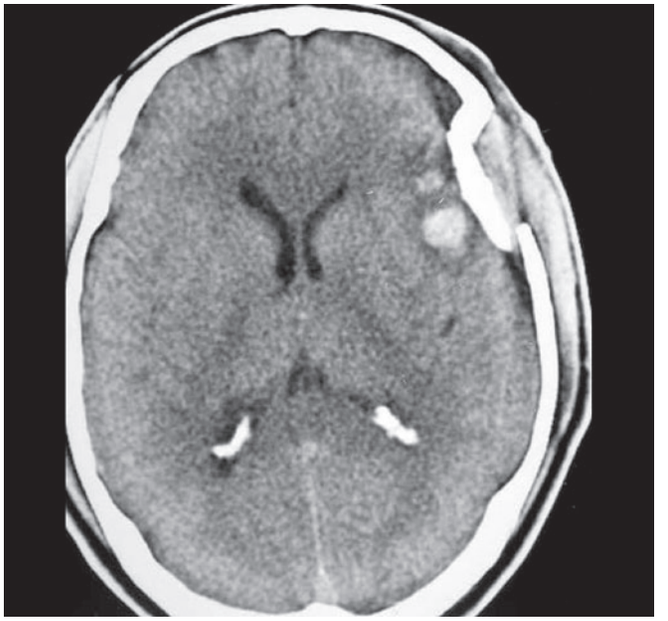

Fig. 6: Depressed fracture with hemorrhagic contusions: Plain CT demonstrates a depressed fracture in the left frontal region with underlying hemorrhagic contusion

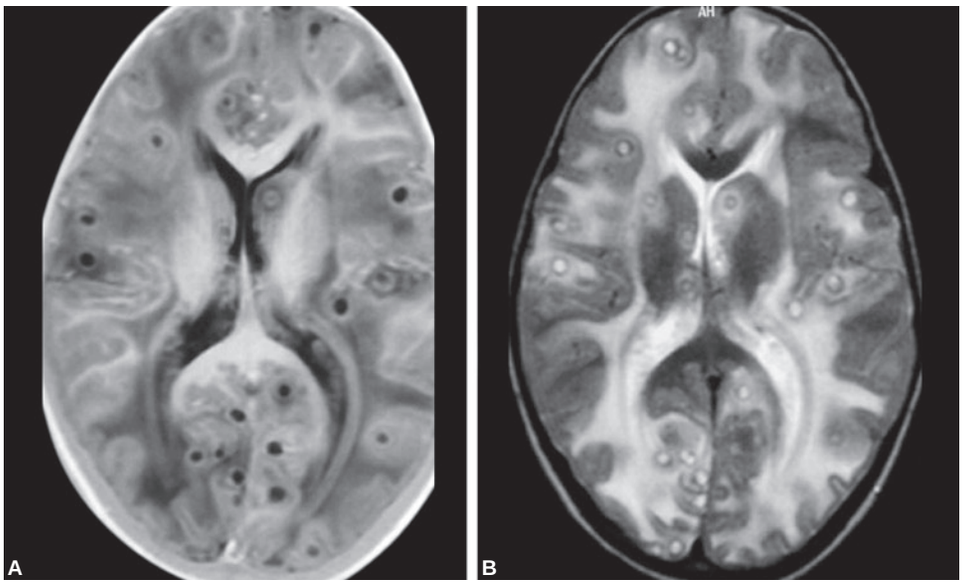
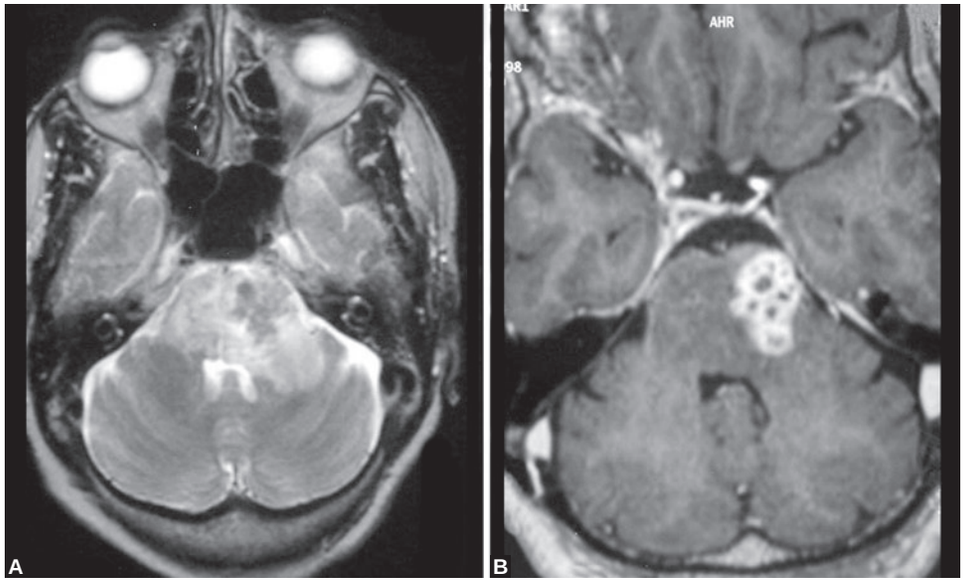
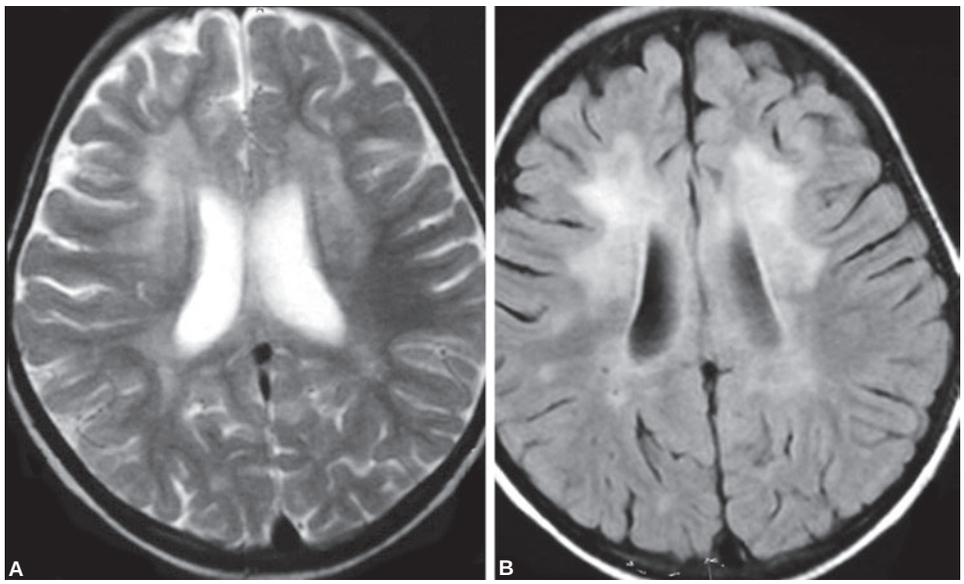


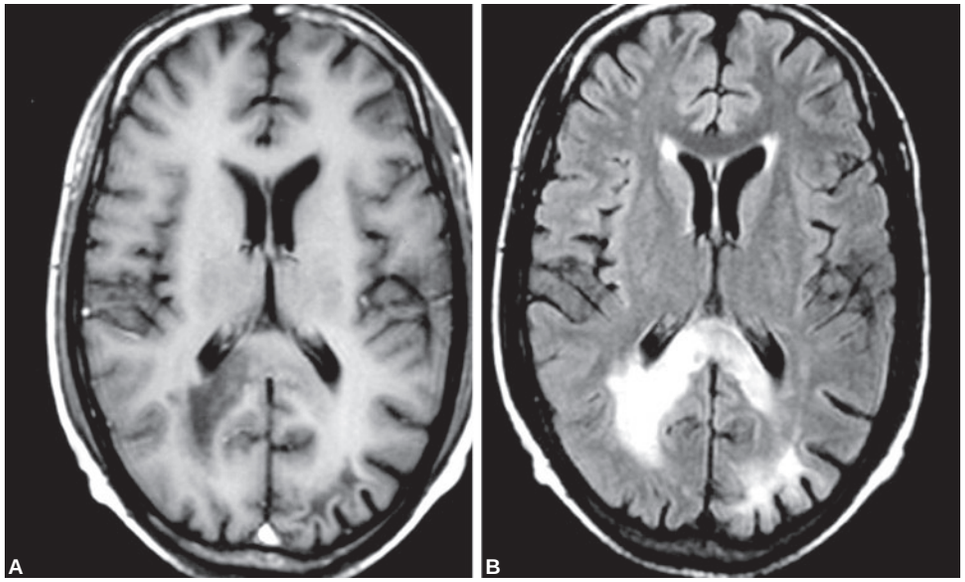
Figs 7A and B: (A and B) Neurocysticercosis: MRI study demonstrates Multiple T1 hypointense and T2 hyperintense well-defined lesions with perifocal edema representing dying cysticerci



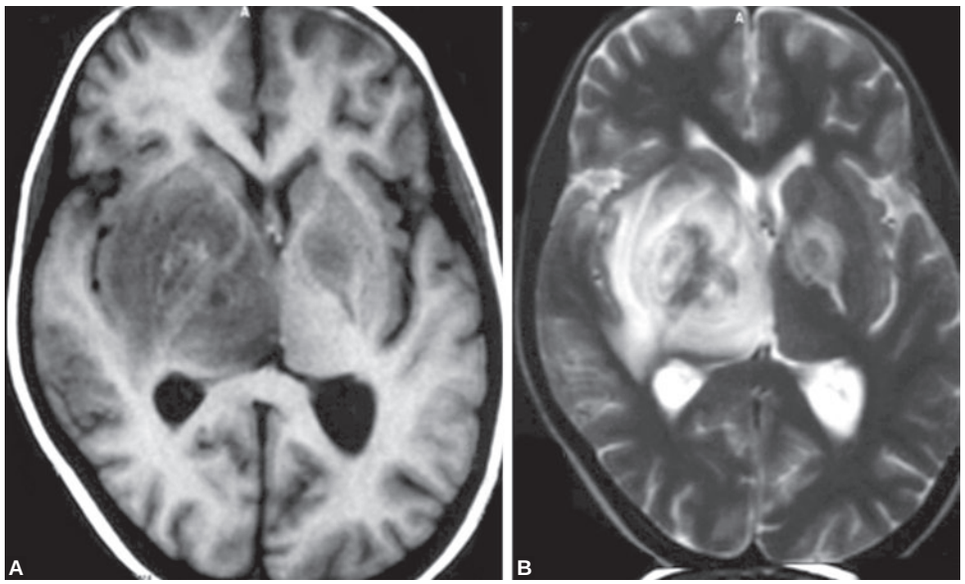
Figs 8A and B: Tuberculomas: (A) Axial T2-weighted image demonstrates conglumerative T2 hypointense lesions in left pons with perifocal edema; (B) Axial post-contrast MRI demonstrates conglumerative ring enhancement



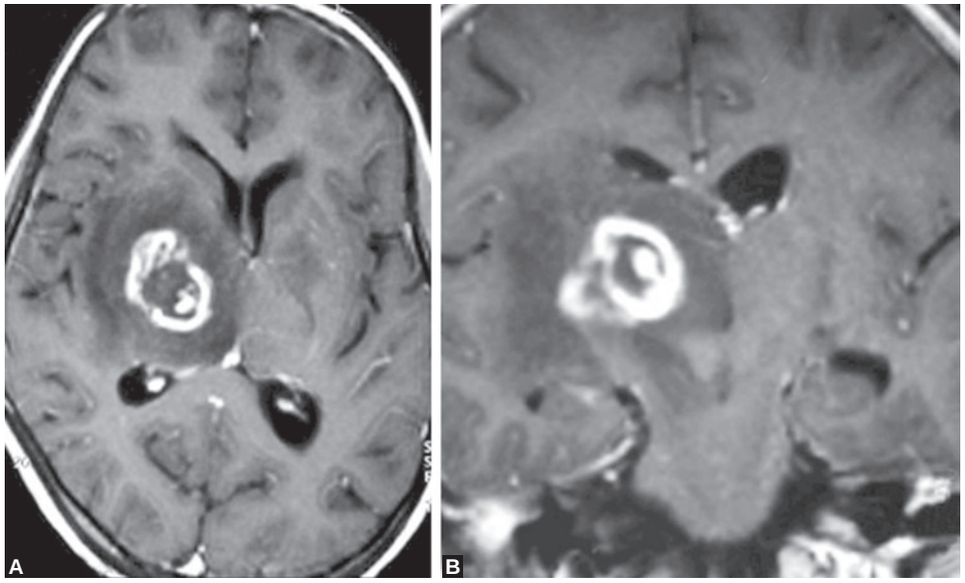
Figs 9A and B: (A and B) HIV encephalitis: Axial T2 and FLAIR images demonstrate hyperintensity periventricular white matter due to HIV encephalitis



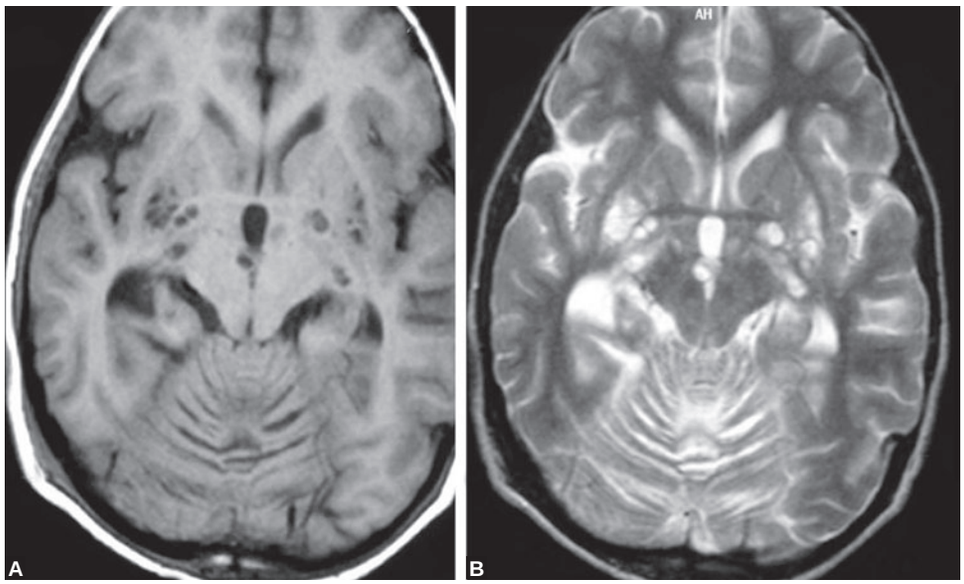
Figs 10A and B: (A and B) PML: T1-weighted image and FLAIR images demonstrate altered signal intensity in the splenium of the corpus callosum with extension to the occipital subcortical white matter



Figs 11A and B: (A and B) Toxoplasmosis: T1- and T2-weighted MRI demonstrates altered signal intensity in both basal ganglia. There are focal T2 hypointense lesions in the basal ganglia with perifocal edema and mass effect



Figs 12A and B: Toxoplasmosis: (A and B) On the post-contrast scans there is peripheral enhancement. The basal ganglia location is characteristic for toxoplasmosis



Figs 13A and B: (A and B) Cryptococcosis: Axial T1- and T2-weighted MRI demonstrates well-defined cerebrospinal fluid (CSF) attenuation areas with no associated perifocal edema in the basal ganglia indicative of gelatinous psuedocysts of cryptococcosis

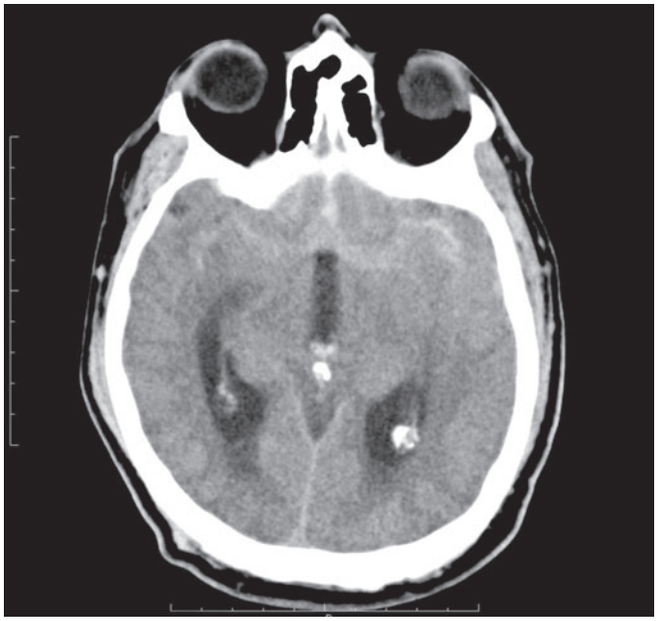


Fig. 14: Subarachnoid hemorrhage: Axial CT demonstrates hyperdensity in subarachnoid space due to subarachnoid hemorrhage

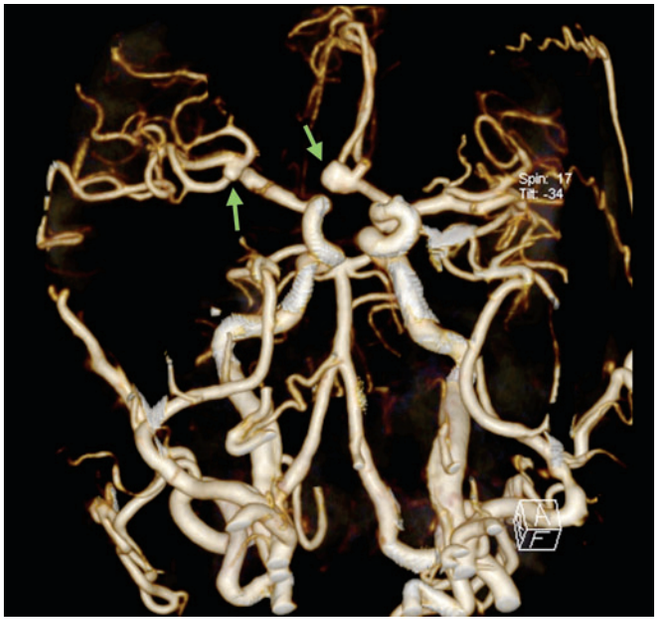

Fig. 15: CT Angio demonstrates anuerysms in relation to anterior communicating artery (ACom) and M2 segment of right middle cerebral artery (MCA)

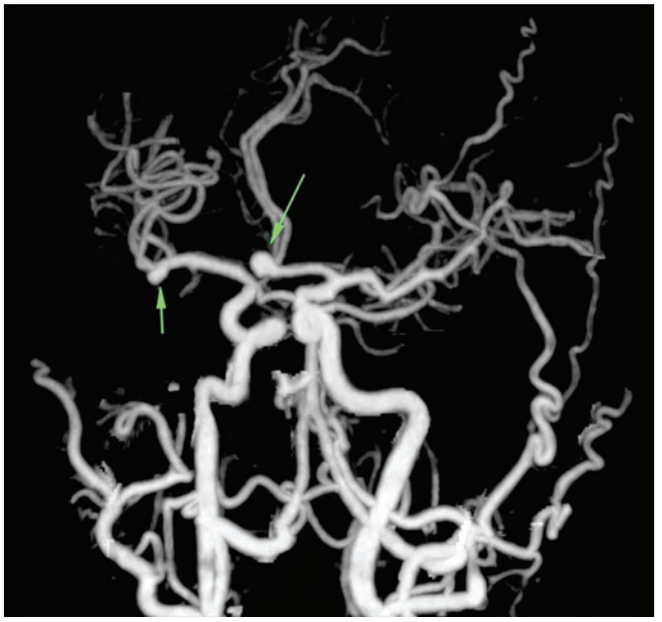

Fig. 16: MRI Angio demonstrates anuerysms in relation to anterior communicating artery (ACom) and M2 segment of right middle cerebral artery (MCA)

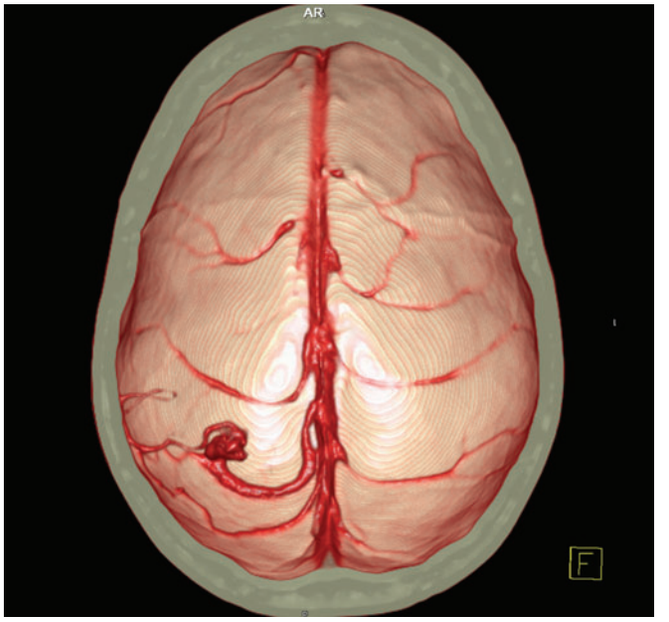

Fig. 17: Arteriovenous malformations (AVM): CT Angio demonstrates an angiomatous malformation in the right parietal region, feeding artery and draining vein are demonstrated

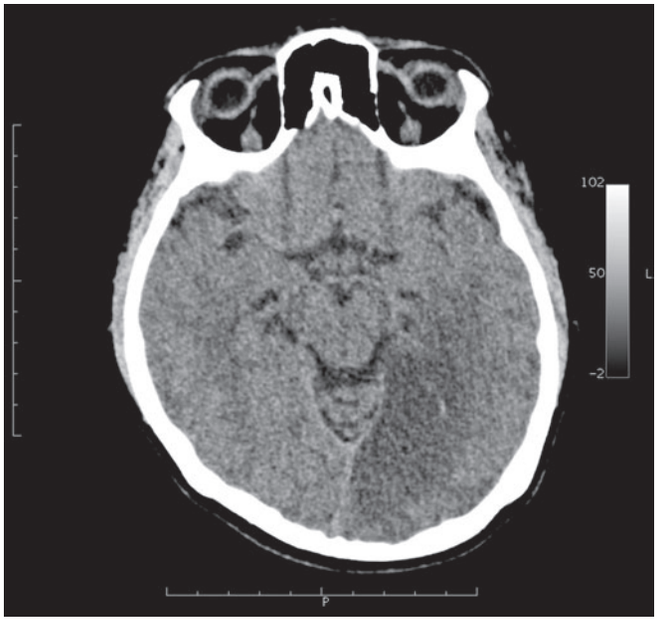

Fig. 18: Acute infarct: CT demonstrates a large hypodensity in the left occipital lobe involving the cortex representing a fresh infarct in the left posterior cerebral artery (PCA) territory

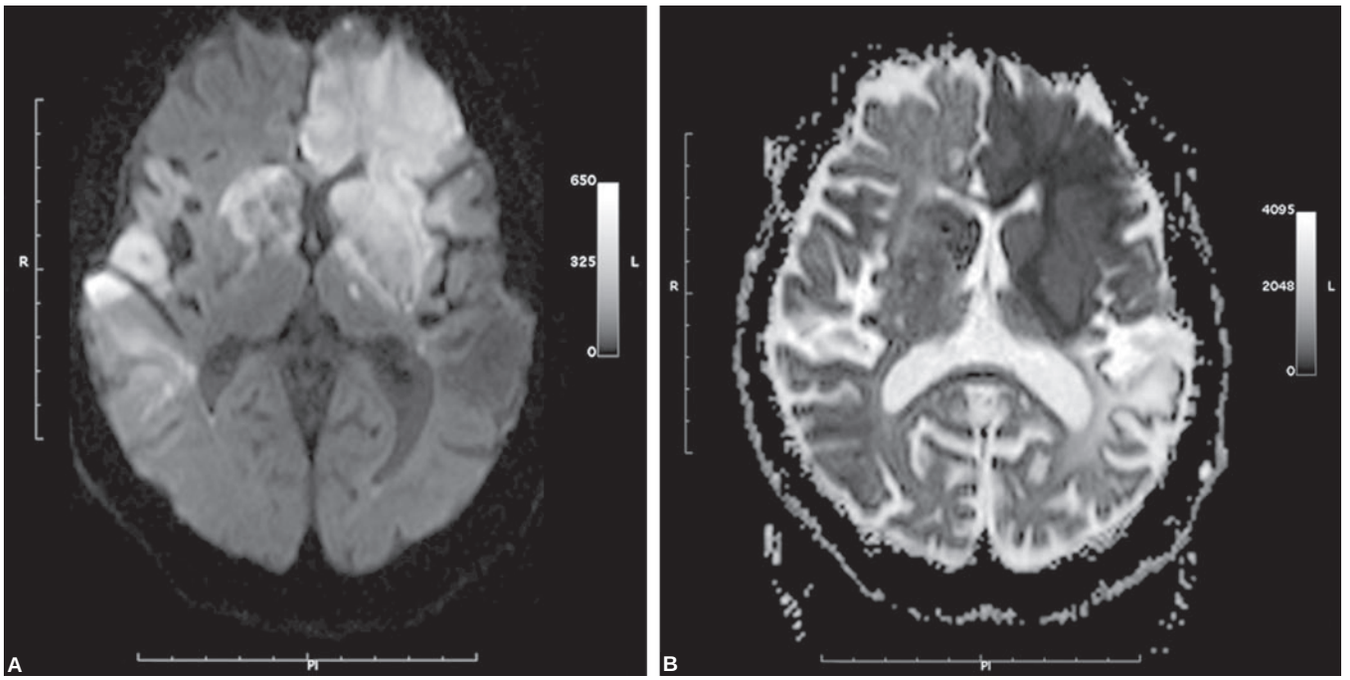

Figs 19A and B: (A and B) Diffusion weighted imaging (DWI) and apparent diffusion coefficient (ADC) images to show a large Lt middle cerebral artery (MCA) territory infarct. With diffusion restriction and ADC drop. Additionally, focal areas of restricted diffusion and ADC drop in the right sylvian cortex and subcortical region

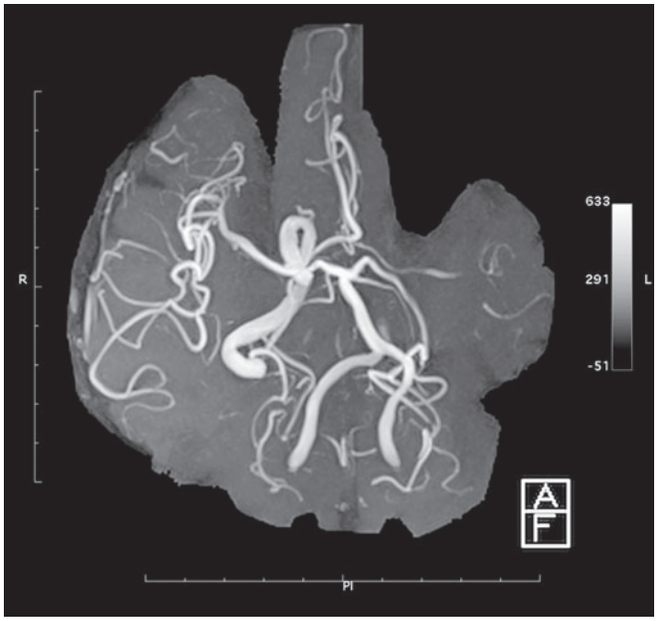

Fig. 20: MR Angio demonstrates total occlusion of left middle cerebral artery

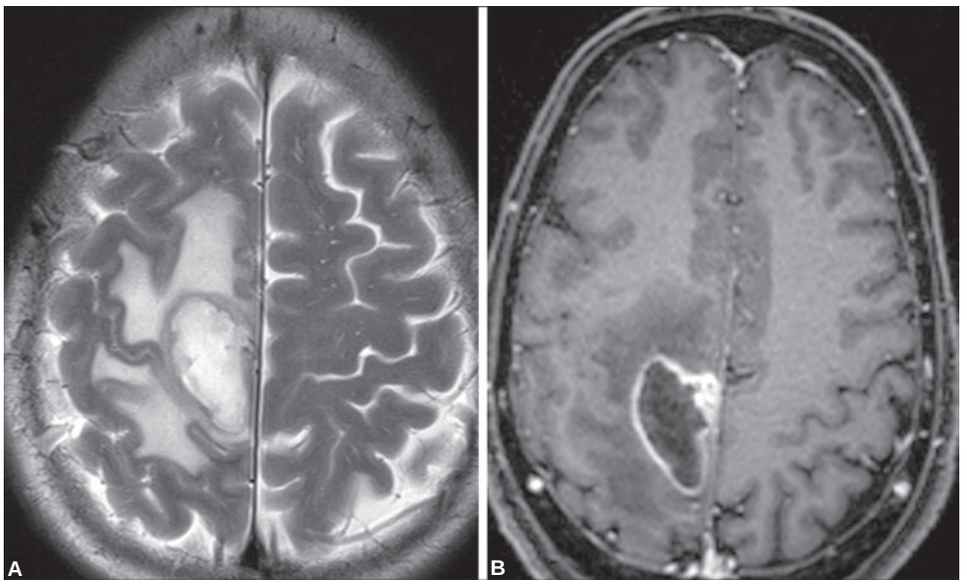
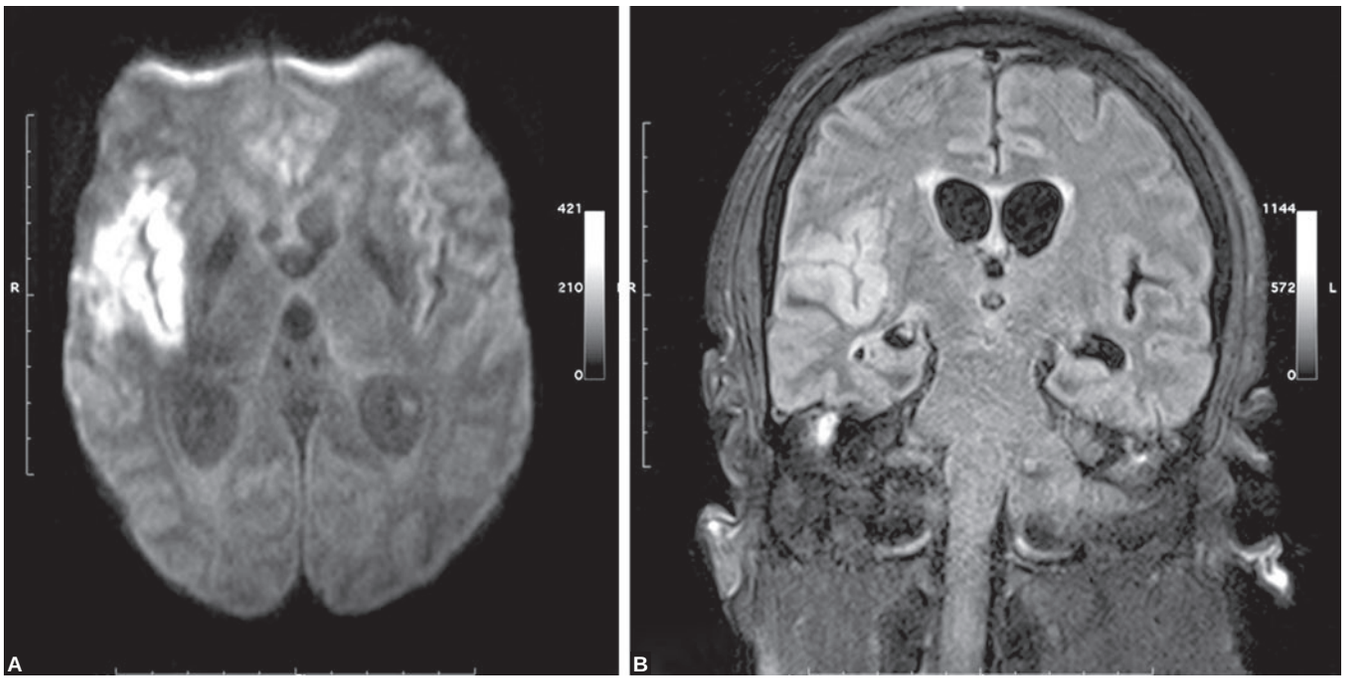


Figs 21A and B: (A and B) Cerebral abscess: Axial T2-weighted image shows an ill-defined hyperintense lesion in the right high parietal region with a T2 hypointense capsule and perifocal edema; (B) Post-contrast MRI demonstrates ring enhancement indicative of a cerebral abscess



Figs 22A and B: Herpes simplex encephalitis: (A and B) Diffusion images demonstrate restricted diffusion in the right perisylvian region. A typical location for herpes simplex encephalitis

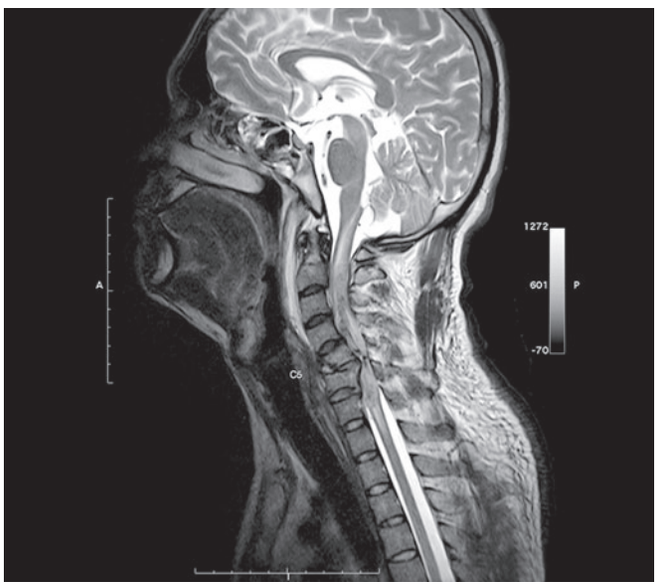


Fig. 23: Cervical trauma: Sagittal MRI demonstrates compression fractures with retro pulsion of c5/c6 vertebral bodies causing significant compression and altered signal intensity in the cervical cord

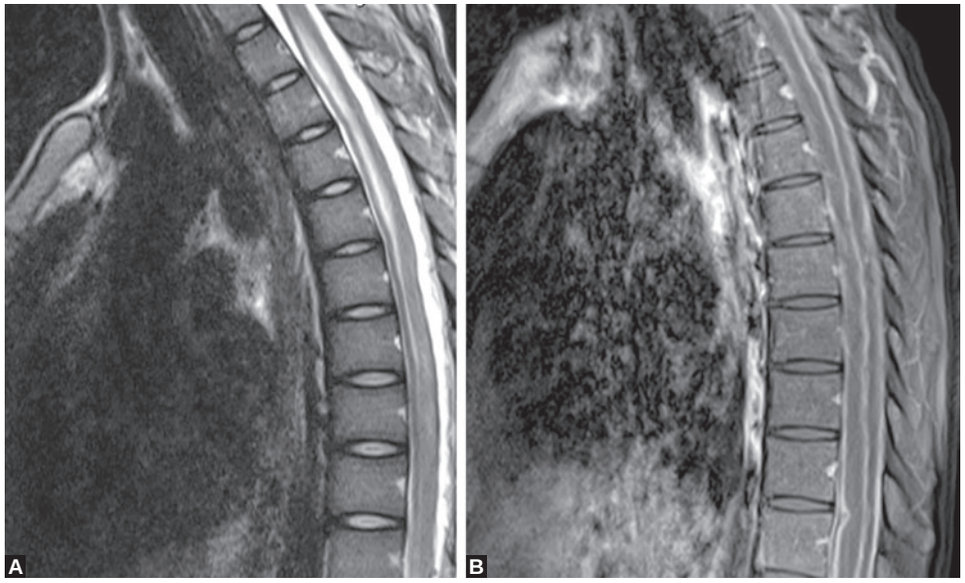

Figs 24A and B: (A and B) Myelitis: Sagittal T2-weighted image demonstrates altered signal intensity in the dorsal cord, post-contrast MRI demonstrates enhancement along the cord surface and dura. This was of tuberculous etiology

Clinical Shock Syndromes

- Overview of Shock Syndromes
- Hypovolemic and Hemorrhagic Shock
- Cardiogenic Shock
- Sepsis and Septic Shock
- Cardiac Compressive Shock
- Anaphylactic Shock

CHAPTER 13

Overview of Shock Syndromes

GENERAL CONSIDERATIONS

Shock is a state of acute circulatory failure in which there is reduced tissue perfusion, resulting in tissue hypoxemia, the oxygen supplied to the tissues being inadequate to meet their metabolic requirements. It is a syndrome, a symptom-complex recognized by clinical features many of which are subjective and therefore imprecise. Shock on a close analysis is not a single physiological entity, but a group of life-threatening circulatory syndromes with varying physiological profiles. Though hypotension is a feature of severe shock, the shock syndromes cannot just be equated to hypotension or to a fall in cardiac output (CO) or to accompanying changes in circulatory hemodynamics. It is a major misconception that correction of hypotension and restoration of a normal hemodynamic profile is the be-all and end-all in the management of shock. Shoemaker[1] evaluated the significance of restored hemodynamic parameters in a series of critically ill survivors and non-survivors with shock. With therapy, mean arterial blood pressure (ABP mean), heart rate (HR), central venous pressure (CVP), pulmonary capillary wedge pressure (PCWP) and CO were restored to normal in 76% of non-survivors who still went on to die. Obviously, though restoring the hemodynamic profile in shock to as near normal as possible is important, it is simply not enough. Thus, a restored hemodynamic profile in shock may for various reasons be associated with an impaired microcirculation to various organs leading to persistent hypoperfusion and hypoxia to tissue cells. There is more to the management of shock than the mere restoration of circulatory hemodynamics.

What needs to be stressed is the concept that every form of severe shock is characterized by inadequate tissue oxygenation. Marino[2] expresses this succinctly when he points out that shock is buried in the tissues and that an approach that helps assess tissue oxygenation should be central to its management. What complicates matters is that in shock, different tissues may have different or varying needs for oxygen. To accurately evaluate the effects of restoration of the circulation on the oxygenation of tissues within different organ systems, particularly in critically ill individuals, may therefore seem an impossibly difficult task. How does one ensure that the oxygen uptake by tissues ($\dot{V}O_2$) is matched to metabolic needs? The balance between $\dot{V}O_2$ on the one hand, and the metabolic rate or needs on the other, can be indirectly determined by measuring the lactate levels in arterial blood.[2] A blood lactate level well above normal, points to anaerobic tissue metabolism, which again suggests that tissue requirements for oxygen are not being met.

MICROCIRCULATORY MITOCHONDRIAL DYSFUNCTION SYNDROME[3]

In this condition, the hemodynamic profile of shock may through treatment return to normal, yet tissue hypoxia can persist because of an abnormal capillary microcirculation. This may well be associated with cell mitochondrial dysfunction. Though mitochondrial dysfunction may be the result of poor tissue perfusion because of microcirculatory dysfunction, it may occur independently of the latter. This syndrome has been studied particularly in patients with septic shock. It should be suspected when a rise in the serum lactate persists in spite of a normal hemodynamic profile and a normal oxygen delivery (DO_2). It is discussed further in the Chapter Sepsis and Septic Shock.

One other important manifestation of circulatory shock (besides hypoperfusion, hypoxia detected by increased

lactate levels in blood) is the inducement of the systemic inflammatory response syndrome (SIRS).[4] Hypoperfusion and resuscitation (ischemia—reperfusion) can initiate SIRS which then literally feeds upon itself through various mechanisms touched upon in the Chapter Sepsis and Septic Shock. The inflammatory component may be less marked (as in quickly resuscitated hypovolemic or cardiogenic shock), large (as in septic shock) or intermediate (as in many patients with traumatic shock). This inflammatory component of shock (particularly in patients with septic shock and shock due to trauma) often determines the final outcome as it sets into motion a vicious downward spiral that can lead to progressive multiple organ dysfunction, failure and death.

Survival in shock is determined by the ability of the circulation to match oxygen supply to tissue needs for oxygen. It is important that this is achieved before permanent tissue damage has occurred. Therapy, which is adequate but delayed, may be ineffective, for there comes in the natural history of shock, a point beyond which there is no return.

CLASSIFICATION OF SHOCK

Shock can be due to a number of etiological factors. Basic forms of shock include hypovolemic shock, cardiogenic shock, obstructive shock and vasogenic or distributive shock. The different types of shock have been classified in Box 1. The basic hemodynamic profiles of each of these shock syndromes are briefly described below.

Hypovolemic Shock

Shock due to hypovolemia is characterized by a loss in circulatory volume which results in a decreased venous return, a decreased filling of the cardiac chambers, and hence a decreased CO which leads to an increase in the systemic vascular resistance (SVR). The hemodynamic profile on monitoring of flow pressure variables shows a low CVP, a low PCWP, a low CO and cardiac index (CI), and a high SVR. The arterial blood pressure may be normal or low.

Cardiogenic Shock

Cardiogenic shock is primarily dependent on poor pump function. Cardiogenic shock due to acute catastrophic failure of left ventricular pump function is characterized by a high PCWP, a low CO and CI, and generally a high SVR. When overall pump function of both right and left ventricles fails, the hemodynamic profile is more complex (see Chapter Cardiogenic Shock).

Obstructive Shock

Obstructive shock is usually due to acute pulmonary embolism, cardiac tamponade and tension pneumothorax. The filling pressures are raised due to outflow obstruction, impaired ventricular filling; the blood pressure and cardiac output are low and the systemic vascular resistance increased. The hemodynamic profile may closely resemble that observed in cardiogenic shock.

Box 1: Classification of shock

- Hypovolemic and hemorrhagic
- Cardiogenic—
  - Acute myocardial infarction
  - Cardiomyopathy
  - Cardiac arrhythmias
  - Mechanical causes, e.g. valvular disease, outflow tract obstruction, ruptured ventricular septum or chordae tendinae
- Obstructive—
  - Pulmonary embolism
  - Cardiac tamponade
  - Tension pneumothorax
- Distributive or vasogenic—
  - Septic shock, toxic shock syndrome
  - Anaphylactic
  - Neurogenic

Vasogenic or Distributive Shock

This shock syndrome occurs with a number of etiological factors and is characterized by a poor vascular tone in the peripheral circulation (low SVR). There is also a maldistribution of blood flow to organs within the body. The CO varies but is usually raised. A common hemodynamic profile is a low or normal PCWP, a high CO, a low arterial blood pressure, and a low SVR. Vasogenic shock is typified by septic shock and the toxic shock syndrome. It is also observed in traumatic shock, neurogenic shock following spinal cord trauma, in postoperative shock, shock in pancreatitis and in anaphylactic shock. Septic shock, toxic shock syndrome and anaphylactic shock have been described in subsequent chapters. The hemodynamic profiles in the various categories of shock are given in Table 1.

Though the above categories of shock and their hemodynamic profiles are easily understood and generally accepted for teaching purposes, in actual practice, problems in assessment and management of shock syndromes are often complex and difficult. For example, the features of hypovolemia, myocardial dysfunction and sepsis may all be present in the same individual. Similarly, hypovolemia may be present in some patients with cardiogenic shock. Patients in

Table 1: Hemodynamic profiles in the various categories of shock

	MAP	PAWP	CO	SVR
Hypovolemic, hemorrhagic shock	↓	↓	↓	↑
Cardiogenic shock	↓	↑	↓	↑
Obstructive pulmonary embolism, pericardial tamponade, tension pneumothorax	↓	↔↑	↓	↑
Distributive, vasogenic shock, septic shock, adrenal insufficiency, anaphylaxis, neurogenic	↓	↔↓	↔↑	↓

Abbreviations: CO, cardiac output; MAP, mean arterial pressure; PAWP, pulmonary arterial wedge pressure; SVR, systemic vascular resistance.

cardiogenic shock following myocardial infarction and cardiac surgery may develop vasodilation due to active mediator release and thereby also show features of distributive shock. Acute circulatory failure triggers a chain of compensatory responses, chiefly mediated by neurohormonal mechanisms. These compensatory responses alter the hemodynamic profile induced by the initial insult to the circulation. Compensatory features in shock, particularly changes in SVR vary from patient to patient. Old age, neuropathies and diabetes mellitus are some important background factors that can blunt the systemic vascular response and other compensatory responses. Then again, various therapeutic modalities instituted in the management of shock can alter the hemodynamics of shock and its hemodynamic profile, and this alteration may last for only a short period of time. Finally, not only compensatory mechanisms but also decompensation within the circulatory system can further produce varying hemodynamic profiles in different shock syndromes.

Hence, the assumption that each cause of shock necessarily has a characteristic profile, and that therapeutic principles in management are dependent on analyzing one single profile at any one point in time, is simplistic and beset with difficulties. Various permutations and combinations of the above basic hemodynamic profiles can lead to a number of possible patterns. However, familiarity with the basic profiles described above helps the intensivist analyze the hemodynamic changes that can occur in shock syndromes, and aids in management.

MONITORING TISSUE HYPOXEMIA AND PERFUSION FAILURE

The restoration of a normal blood pressure, normal CO and vascular resistance correlates poorly with survival in critically ill patients, particularly in septic shock or shock related to trauma.

This observation has led to the monitoring of indices of tissue oxygen metabolism as markers of tissue perfusion. Newer studies to observe microvascular blood flow in regional vascular beds have also been devised.

Lactate Concentration in Arterial Blood

An increase in serum lactate levels (normal <2 mmoL/L) denotes anaerobic tissue metabolism and tissue hypoxia. An increased lactate level has a serious prognostic significance; a persistence of this increase in spite of resuscitative efforts carries an even worse prognosis. In patients with septic shock, increased lactate levels may be also related to factors other than hypoperfusion—these include decreased hepatic clearance of lactate, increased muscle ATPase activity, decreased pyruvate dehydrogenase activity and cell mitochondrial dysfunction.

Base Deficit

Elevation of the base deficit is an important marker of tissue hypoxemia and acidosis. The normal range of base deficit is –2 to +2 mmoL/L. Increase in base deficit may be mild (–2 to –8 mmoL/L), moderate (–6 to –14 mmoL/L), or severe (< –15 mmoL/L). Magnitude of the base deficit has been shown to correlate with the extent of blood loss in hemorrhagic shock, and a correction of the base deficit within hours of resuscitation carries a favorable prognosis.[2]

Measurement of Mixed Venous Oxygen Saturation

The mixed venous oxygen saturation ($S\dot{v}O_2$) is measured from blood taken from the pulmonary artery via a pulmonary artery catheter and is an index of overall global tissue oxygenation. Increased oxygen extraction from blood perfusing tissues is an important mechanism to maintain oxygen consumption ($\dot{V}O_2$). Hence, a decrease in $S\dot{v}O_2$ is a marker of compromised tissue perfusion. This is particularly so in both hypovolemic and cardiogenic shock. In the latter, a falling $S\dot{v}O_2$ denotes a worsening tissue perfusion due to a falling CO. This relation does not necessarily hold in septic shock and in other conditions where the relation between $S\dot{v}O_2$ and tissue oxygenation is altered by maldistribution of blood flow. In such circumstances, the $S\dot{v}O_2$ may be normal or even increased in spite of tissue hypoxia and anaerobic metabolism. In summary, though a low $S\dot{v}O_2$ is indicative of tissue hypoxemia, a normal or high $S\dot{v}O_2$ does not exclude tissue hypoperfusion.

Measurement of Central Venous Oxygen Saturation ($ScvO_2$)

Measurement of central venous oxygen saturation ($ScvO_2$) through a central venous catheter in the superior vena cava is now increasingly being used as a substitute of $S\dot{v}O_2$. The $ScvO_2$ in critically ill patients is generally 5% higher than the $S\dot{v}O_2$. This correlation is however not always consistent. The advantage of measuring $ScvO_2$ as a substitute for $S\dot{v}O_2$ is that it obviates the need for invasive monitoring through a pulmonary artery catheter.

Oxygen Delivery, Oxygen Consumption Measurements[5]

Oxygen delivery (DO_2) and $\dot{V}O_2$ are global markers for tissue oxygen metabolism.

$$\text{Oxygen consumption } \dot{V}O_2 = Q_T \times CaO_2 - CvO_2$$

where CaO_2 and CvO_2 equal oxygen content in arterial and venous blood respectively and Q_T is the cardiac output.

Oxygen delivery is calculated from CO, Hb and oxygen saturation and is a measure of total oxygen delivered to the tissues.

A reduced DO_2 portends danger. A reduced $\dot{V}O_2$ even in the presence of a normal or increased DO_2 can, if uncorrected, lead to tissue hypoxia. Ordinarily, tissues extract 25% of the oxygen from the blood perfusing them. When DO_2 falls or if metabolic requirements of tissues increase, more oxygen is extracted from the blood perfusing the tissues. This is a

compensatory mechanism that allows the tissues to meet their oxygen demands. If however the oxygen extracted from the blood by the tissues is more than 50% tissue hypoxemia results. Thus, DO_2 and $\dot{V}O_2$ are good markers that help the clinician gauge tissue oxygenation.

End-Tidal CO_2 and Tissue CO_2 Measurements

End-tidal CO_2 and tissue CO_2 measurements are chiefly useful in monitoring cardiopulmonary resuscitation following cardiac arrest. Cardiac arrest leads to absence of blood supply to the lungs, with a sharp fall in CO_2 excretion and therefore a fall in end-tidal CO_2, which approaches zero. The end-tidal CO_2 increases with successful resuscitation and is useful as a marker for the adequacy of resuscitative efforts.

Measures to Estimate Regional Perfusion

Many efforts have been made to use measurements of regional or local perfusion as markers for global perfusion. These include measurements of subcutaneous oxygen tension and transcutaneous oxygen tension. Gastric tonometry and more recently sublingual tonometry have been used to assess CO_2 excess in the vascular beds, and equate this excess as a marker for global hypoperfusion. There are practical difficulties in the above measurements and it is doubtful if they significantly add in the management of the shock syndromes or improve their outcome.

Assessment of Microvascular Blood Flow[6,7]

- Use of near infrared spectroscopy (NIRS) to assess level of oxygenated Hb in the skeletal muscle. The actual value and the response of tissue Hb saturation to reactive hyperthermia are believed to predict survival.[6]
- Orthogonal polarization spectral (OPS) imaging and sidestream dark-field (SDF) imaging have been used to directly visualize microcirculatory flow. A decrease in the microcirculatory flow was noted to correlate with decreased survival rates in septic and cardiogenic shock.[7] Hypoperfusion was seen to persist even after resuscitation had restored a normal hemodynamic profile. It is to be determined whether therapeutic measures directed toward improvement of microcirculation observed by the above techniques will alter the outcome in shock syndromes.

AN OVERVIEW OF MANAGEMENT STRATEGIES IN THE SHOCK SYNDROMES (BOX 2)

The principles of management are as follows—

Treat the Cause Whenever Possible

In hemorrhagic shock, it is important to arrest the source of bleeding in so far as this is possible. Sepsis should be managed by draining local pockets of infection surgically, ensuring that the source of sepsis is eradicated, and by the very early use of appropriate antibiotics. Shock due to pulmonary embolism may warrant thrombolytic therapy. Traumatic shock, shock in an adrenal crisis and in anaphylaxis need appropriate specific therapy outlined in other chapters of this book.

Box 2: Overview of management strategies in the shock syndromes

1. Treat the cause whenever possible
2. Interpret and manage hemodynamic abnormality—
   a. Low CVP and PCWP, hypotension—
      » Volume load to raise CVP >10 mm Hg and PACP to 15–18 mm Hg
      » Use vasopressors or dopamine only if hypotension persists after adequate volume load
   b. Low CO, hypotension, and a normal SVR—
      » If the PCWP is low or normal, it should be pushed to the upper limit or even above normal by a suitable volume load, before starting vasopressor support. Inotropic support may also be necessary
      » If the PCWP is in the upper limit of normal, use vasopressor support. Inotropic support may also be necessary
   c. Low CO, hypotension, and a raised SVR—
      » Volume load to upper limit of filling pressures; if hypotension persists use inotropic support
      » If SVR remains high in spite of adequate volume load, lower SVR with a titrated IV infusion of nitroglycerine
   d. A low CO, hypotension, normal filling pressures, with a low SVR—
      » Filling pressures should be raised by a volume load to the upper limit or even above normal
      » Inotropes and if needs be vasopressor support
   e. A low CO, hypotension, increased SVR, high filing pressures with equalization of PCWP, right ventricular diastolic and right atrial pressures—
      » Cardiac tamponade – tap pericardial fluid
3. Ensure adequate tissue oxygenation—
   – Increase DO_2 to meet tissue metabolic requirements – thereby ensure adequate $\dot{V}O_2$

Interpretation of the Hemodynamic Pattern

A hemodynamic profile can only be obtained through data obtained by invasive monitoring, generally through the use of a PA catheter. Should one hazard a diagnosis of the etiology of the shock syndrome on the basis of the hemodynamic profile? Though the cause of shock may well be suggested by the hemodynamic profile observed, this need not necessarily be so. It is wise not to always expect any particular or fixed profile in the different etiological forms of shock mentioned earlier. The etiology and the nature of circulatory disturbances causing shock in a patient should be arrived at by an overall perspective of background factors, clinical features, laboratory investigations and the hemodynamic profile observed over a period of time. The sum total of evidence is far more important than the mere consideration of the hemodynamic profile at a given point in time.

Hemodynamic Management

This is based on correct interpretation of the hemodynamic findings. A number of permutations and combinations of these variables are seen in clinical practice. Invasive monitoring, in particular the use of the pulmonary artery catheter, is not necessary in many patients. Hemodynamic measurements including CO and vascular resistance are now possible without using the PA catheter. Thus optimization of preload, and cardiac index in all forms of shock may be guided by measurement of stroke volume variation (SVV) and cardiac index by using lithium dilution (LiDCO). PiCCO is another method which allows determination of intrathoracic blood volume index, extravascular lung water index, stroke volume variation and cardiac index.[8] However, in very critical and complicated conditions, we feel that the PA catheter helps in management.

A management protocol, dependent on some of the important parameters observed, is summarized below as a guide to patient care in patients with complicated or severe shock.

- Low filling pressures (low PCWP and CVP) and hypotension. Therapy should always include a volume load to raise the filling pressures to normal or just above normal, i.e. PCWP is raised to 15–18 mm Hg. If hypotension persists, a vasopressor or dopamine is indicated.
- Low CO, hypotension and a normal SVR. If the PCWP is in the upper limit of normal or even moderately raised, a low CO deserves to be treated with inotropic support. Dopamine would be the drug of choice, as besides providing inotropic support it can increase the SVR. If the PCWP is normal, it should be pushed to the upper limit of normal or even above normal by a suitable volume load, before starting inotropic support.
- Low CO, hypotension and a raised SVR. In the presence of high, normal or raised filling pressures, inotropic support is provided by dobutamine or a combination of dopamine and dobutamine, or a combination of dobutamine and amrinone. The raised SVR in the presence of an increased filling pressure is lowered by titrated intravenous infusion of nitroglycerin.
- A low CO, hypotension, and normal filling pressures, with a low SVR. Filling pressures should be raised by a volume load to the upper limit of normal or even to a little above normal. If the CO still remains low, the use of inotropic agents is indicated; dopamine besides being an inotropic agent also increases the SVR.

Box 2 gives a summary of the abnormal hemodynamic profiles often met with in clinical practice and measures instituted for their correction.

As a general rule, vasoconstrictors must be used with caution, as they can elevate a low blood pressure but can reduce blood flow to vital organs and increase the afterload on the heart. Dopamine is the drug of choice in most instances because of its inotropic effect and a vasoconstrictor action on the peripheral circulation. Norepinephrine is preferred as first choice by some units. The use of both dopamine and noradrenaline is warranted in some patients. Dobutamine alone or with dopamine is used for inotropic support when the CO is low. Vasopressin is generally resorted to when dopamine and noradrenaline fail to produce the desired rise in blood pressure. Adrenaline infusions may also be administered particularly during resuscitation following cardiac arrest. Details of drugs used in the shock syndromes are described in subsequent chapters.

Certain points need to be stressed and recapitulated in the hemodynamic management of shock syndromes.

- As a general rule, inotropes and vasopressors should not be used unless volume replenishment is first accomplished. Perhaps in a pulseless, pressureless, well-nigh moribund shocked patient, rapid fluid replenishment and vasopressors may be perfused simultaneously for salvage, but this is a rare exception. Large volumes of fluid may need to be infused in patients with septic shock to ensure adequate circulatory volume and an adequate oxygen supply to tissues. The different fluids used for volume replacement have been discussed in the next chapter.
- Though one generally estimates an adequate intravascular volume status by filling pressures (CVP, PACP) pushed to the upper limits of normal, this estimation may be fallacious. There may well be a poor correlation between ventricular filling pressures and ventricular volumes.[9] This discrepancy may be related to a lowered compliance of the ventricles (i.e. decreased distensibility) due to a number of other possible factors, in particular increased sympathetic activity. Filling pressures may then be misleadingly high and may overestimate ventricular volumes in hypotensive patients. Therefore, if there is no evidence of pulmonary edema and if in spite of the filling pressures being pushed to the upper limits of normal, hypotension and shock persist, a bolus of 300 mL of normal saline is given quickly over 20 minutes. If the hemodynamic state, clinical picture, urine output improve and if the CVP after a brief rise comes back roughly to its original level, the patient needs to be carefully further volume loaded. If there is no change in the clinical picture and a bolus produces significant sustained rise in the CVP, further volume loading is inadvisable.[10]

A good predictor of volume responsiveness is the presence of SVV with respiration. This can be easily obtained through analysis of the arterial waveform tracing. When SVV is 9.5% or greater, a 100 mL volume load generally increases stroke volume by 5%. SVV is not useful in patients with atrial fibrillation, or in patients with multiple ectopic beats, as wide fluctuation in the baseline stroke volume is present.

An equally good dynamic test pointing to hypovolemia is a fall in the amplitude of the arterial pulse during inspiration and its rise in expiration when a patient is on ventilator support.

- If hypotension persists after an adequate volume load or if filling pressures are high to start with, inotropes and vasopressors are used, but they need to be used with caution. Very high doses of dopamine (>20–25 μg/kg) or noradrenaline (>20 μg/minute) can markedly increase

the afterload of the heart and lead to a fall in CO, thereby worsening the clinical situation. Details of inotropes and vasopressors used in the shock syndrome are described in subsequent chapters.

- The oxygen supply to tissues (DO_2) is dependent not only on the CO, PaO_2 and oxygen saturation of Hb but also on the Hb content. A low Hb must be corrected by RBC infusions. Though Hb levels of 7–9 g/dL are deemed adequate, patients with ischemic heart disease and poor cerebral circulation may require a higher Hb concentration up to 10 G% to allow an adequate DO_2.
- It must never be forgotten that however satisfactory the hemodynamic parameters, the battle for survival in shock is fought within the tissues. The DO_2 must be adequate and perhaps in some instances more than adequate if $\dot{V}O_2$ is to meet tissue demands. A persistent increase in the blood lactate level or in the base deficit are easily determined and are ominous signs of global tissue hypoxia. Lactic acidosis is best countered by improving the circulatory state. Infusions of bicarbonate have not been shown to improve prognosis and should be resorted to as a temporary measure only when the arterial pH is dangerously low (<7.2).
- Multiorgan dysfunction and failure can occur with any type of shock but is particularly observed in septic shock. Organ support is vital for survival.
- An adequate supply of oxygen to tissues is as much dependent on good lung function as on adequate CO. Almost all patients with severe shock, in particular cardiogenic and septic shock, require ventilatory support.

MULTIORGAN FAILURE AS A SEQUEL TO UNCORRECTED SHOCK

Persistent unrelieved tissue hypoxia results in impaired cell function and ultimately cellular death. The period following restoration of blood pressure and even CO to within the normal range can often be associated with continued ischemia and progressive tissue and organ damage. Postresuscitation injury is probably related to the following factors—

- *No reflow* There is persistent hypoperfusion following an ischemic insult. The mechanism is believed to be due to a calcium influx into the vascular smooth muscle during the period of ischemia, leading to intense, persistent vasoconstriction of the small vessels within various organs. This persists for hours after the blood pressure and CO are restored to normal, and results in progressive multiorgan dysfunction and multiorgan failure which carry a high mortality.
- *The development of the microcirculatory mitochondrial dysfunction syndrome (MMDS)*[11] A disturbance in the microcirculation and/or mitochondria can result in tissue hypoxia even when hemodynamic parameters are satisfactory, as has already been mentioned.
- *Reperfusion injury*[11] Reperfusion of organs after the ischemic insult leads to the distribution of toxic substances (which accumulate during the ischemic period) to various organs of the body. These toxic substances are oxygen metabolites and free oxygen radicals which readily produce widespread cellular injury.
- *Oxygen debt* During the shock state when hypotension or poor tissue perfusion is the key feature, oxygen uptake and $\dot{V}O_2$ may be inadequate for tissue needs. This represents an ongoing ischemia and it is during this ischemic period that the tissues accumulate an oxygen debt. This debt must be repaid by a compensatory period during which DO_2 and $\dot{V}O_2$ are well above normal. Patients in whom this compensatory mechanism does not occur are at greater risk of increasing cellular injury, multiple organ failure and death. In addition to the development of oxygen debt, circulatory shock results in an increase in tissue carbon dioxide, and hence an increase in the tissue PCO_2. The hypercarbonic acidosis in tissues (resulting from poor perfusion) in relation to cell and organ function may well be significant.

  The above considerations lead to an important but debatable feature in the management of severe shock states.
- *Ensuring tissue oxygenation*[9] Patients having a lower than normal $\dot{V}O_2$ have a higher mortality than those with a normal $\dot{V}O_2$. Also the $\dot{V}O_2$ may be within the normal range, yet be insufficient for tissues having an increased metabolic rate as in sepsis. An inadequate $\dot{V}O_2$ in relation to tissue needs can be determined, as mentioned earlier, by estimating blood lactate levels.

The normal lactate level in arterial blood in healthy individuals is less than or equal to 2mM/L and in stressed individuals greater than 4 mm/L. It has been shown that mortality in shock increases as lactate levels increase above 2 mm/L.[12] It has been suggested that if after the blood pressure and CO are restored the $\dot{V}O_2$ is still low (<110 mL/min-m^2), then the CO should be further increased by either volume infusion (if PCWP <18 mm Hg) or by inotropic support (if PCWP >18 mm Hg). A combination of volume load and inotropic support may be used. It has been further suggested that if the $\dot{V}O_2$ is normal or even above normal, but the lactate level is >4 mmoL/L, the CO and $\dot{V}O_2$ should be even further increased to supranormal levels, using a further volume load and/or by inotropic support of dopamine and dobutamine. Shoemaker[1] is the champion advocate of supranormal increase in CO and $\dot{V}O_2$ in shock. In his opinion, if this is achieved, survival is more likely. *Yet current opinion is that attempting to achieve supramaximal cardiac outputs and $\dot{V}O_2$ in shock does not improve survival and may even have an adverse effect.* It is possible that pushing CO and $\dot{V}O_2$ to supranormal levels may help in the small subset of intraoperative and postoperative patients who develop the hemodynamic features of shock.[1] Perhaps, the above policy is successful if it is used very early in the natural history of shock

and is unsuccessful if used later in the natural history when organ failure has already set in.

From the practical point of view, at least in the medical ICU, we have often found it impossible to raise both CO and $\dot{V}O_2$ to supranormal levels. When we have managed to do so, we have not observed any improvement in morbidity and mortality.

In conclusion, stress on adequate oxygenation of tissues in relation to their needs is probably the key factor that determines survival in severe shock states. The sooner this is achieved in the natural history of shock, the more likely are we to succeed. The difficulty lies in devising easily ascertainable accurate methods to determine $\dot{V}O_2$ and tissue oxygen requirements in critically ill patients. The practical approach of meeting the oxygen demands of the tissues in severe shock is difficult, debatable and needs further study.

CHAPTER 14

Hypovolemic and Hemorrhagic Shock

INTRODUCTION

Hypovolemic shock[1] results from a decrease in circulating volume, which leads to a diminished cardiac output (CO) and poor tissue perfusion. The commonest cause of hypovolemic shock is trauma resulting in external or concealed hemorrhage from blunt or penetrating injuries. Blood loss into surrounding tissues following fractures of long bones or the pelvis is an important cause of hemorrhagic shock. Nontraumatic causes of bleeding constitute an important cause of hemorrhagic shock. Important nontraumatic causes include bleeding from a peptic ulcer, acute mucosal erosions, esophageal varices or from other pathologies into the gastrointestinal (GI) tract, dissection of the aorta, rupture of an aneurysm of a large vessel (e.g. a ruptured aortic aneurysm), and bleeding caused by blood dyscrasias or coagulopathies.

Hypovolemic shock is also frequently due to loss of water and electrolytes, with a fall in effective circulating volume. This is seen in burns, in vomiting and/or diarrhea from any cause,[2] in severe water loss as in diabetes insipidus, in diabetes mellitus, adrenocortical insufficiency, exfoliative dermatitis, and following excessive sweating in hot, humid climates. Sequestration of fluid with loss of effective circulating volume and hypovolemic shock can occur in intestinal obstruction, pancreatitis and peritonitis. Quick reaccumulation of a large volume of ascitic fluid after paracentesis can also occasionally lead to a fall in effective circulating volume with features of hypovolemic shock. Table 1 lists the important causes of hemorrhagic and hypovolemic shock.

Table 1: Causes of hemorrhagic and hypovolemic shock

Traumatic	*Nontraumatic*
Hemorrhagic Shock	
Blunt or penetrating injury	GI bleeds (e.g. peptic ulcer, gastric mucosal erosions, esophageal varices, typhoid bleeds, bleeds in sepsis, DIC)
Fractures specially of long bones and pelvic fractures	Aortic dissection
	Rupture of aneurysm of a large vessel, e.g. aorta
	Erosion of a large vessel, e.g. in pancreatitis or due to tumor infiltration
	Diffuse inflammation of mucosal surfaces, e.g. ulcerative colitis
	Blood dyscrasias or coagulopathies
Hypovolemic Shock	
Burns	Fluid loss from vomiting and/or diarrhea, e.g. in cholera, other GI infections
Crush injuries	Fluid loss in diabetes mellitus, adrenal insufficiency, excessive sweating, exfoliative dermatitis, diabetes insipidus, reaccumulation of ascites after tapping
	Sequestration of fluid, e.g. in intestinal obstruction, pancreatitis, peritonitis

Abbreviations: GI, gastrointestinal; DIC, disseminated intravascular coagulation.

PATHOPHYSIOLOGY[1,3,4]

Hypovolemia from any cause, if severe and untreated, causes increasingly poor perfusion of tissues, ischemia and injury to tissue cells, and ultimately death.

A fall in circulating volume leads to decreased venous return, decreased filling pressures on the right and left sides of the heart and a decreased CO, which leads to tissue hypoxemia. The loss of intravascular volume initiates several compensatory mechanisms, the ultimate purpose of which is

directed towards maintaining perfusion of vital organs such as the heart and the brain. The effectiveness of these mechanisms is dependent on the rate of fluid loss and the degree of volume depletion present.

Neurohormonal Compensatory Mechanisms

Volume depletion stimulates baroreceptors within the intrathoracic vessels and the carotids, as also organ-specific baroreceptors within the kidneys resulting in an increased sympathetic discharge, increased release of stress hormones like catecholamines and cortisol, increased secretion of antidiuretic hormone and activation of the renin-angiotensin system. Activation of the renin-angiotensin aldosterone system leads to conservation of sodium by the kidneys. The sodium and water that are retained help to increase circulating blood volume. The retained sodium is also distributed uniformly in the extracellular fluid, thereby replenishing the interstitial fluid deficit caused by the intracapillary refill, as explained in the next section.

The increased sympathetic discharge leads to tachycardia, increased systemic vascular resistance (SVR), maintenance of systemic blood pressure, and maintenance of perfusion to the brain and the heart at the expense of perfusion to other organs (skin, muscles, kidneys, gut).

Shift of Fluid from the Extravascular to the Vascular Compartment[1]

Total body water comprises 60% of the lean body weight (or 600 mL/kg) in man and 50% of the lean body weight (or 500 mL/kg) in woman. Fifty-five percent of the total body water is intracellular and 45% extracellular. The interstitial fluid content is 20% of the total body water, while plasma constitutes just 7.5% of total body water, and in a 70 kg male amounts to 3–3.2 liters.[1] With a hematocrit of 45%, the blood volume in a 70 kg male would be about 5.5–5.7 liters (or 66 mL/kg) and in a female would be about 60 mL/kg. The blood volume thus constitutes just 13% of the total body fluids. Ordinarily, an acute loss of 35–40% of the blood volume can be fatal, which means that human survival is determined by about 4% of the fluid in the body.[1] Therefore, to reduce mortality, it is imperative to prevent a bleeding patient from losing this 4% fluid volume.

Besides the neurohormonal compensatory mechanisms, shift of fluid from the interstitial compartment into the vascular compartment helps in some measure to restore blood volume in hemorrhagic shock. This occurs in three phases (Fig. 1).

Phase 1 Within an hour of blood loss, there is a shift of fluid from the interstitial compartment into the capillaries. This continues for 40 hours and the volume shift can be as high as one liter. The interstitial compartment however stands depleted due to this shift.

Phase 2 A depleted blood volume activates the renin system, leading to sodium retention. Sodium diffuses into the extravascular compartment, and the retained sodium leads to water retention, thus helping to replenish the interstitial fluid.

Phase 3 Blood loss stimulates erythropoiesis within a few hours. Between 15–50 mL of cell volume is produced daily, and complete replenishment of depleted cells takes as long as 2–3 months.

The neurohormonal changes described above and the shift of interstitial fluid into the vascular compartment work hand in hand to preserve tissue perfusion, particularly to vital organs. Compensatory mechanisms however can only work up to a point. They can maintain an adequate blood volume if blood loss is less than 15% of total blood volume. A larger volume loss (>15% of total blood volume) if not adequately and quickly replaced, inevitably leads to tissue ischemia and metabolic acidosis. Tissue damage results and this induces cellular and humoral inflammatory responses which further exacerbate circulatory abnormalities that ultimately lead to irreversible widespread cell injury and death. The importance of early restoration of a depleted blood volume by vigorous infusions of intravenous fluids cannot be overstressed, if hemorrhagic and hypovolemic shocks are to be reversed.

CLINICAL FEATURES[3,4]

Clinical features of hemorrhagic and hypovolemic shock are similar, and depend on the age of the patient, pre-existing background medical problems, the degree of volume loss, the time period over which the volume loss has occurred, and the ability of a patient to bring the compensatory mechanisms outlined above into play.

A young previously healthy individual may suffer a loss of 10% to as much as 15% of the blood volume with few or no clinical symptoms and signs, since the blood volume is quickly replenished by transcapillary refill. An elderly individual

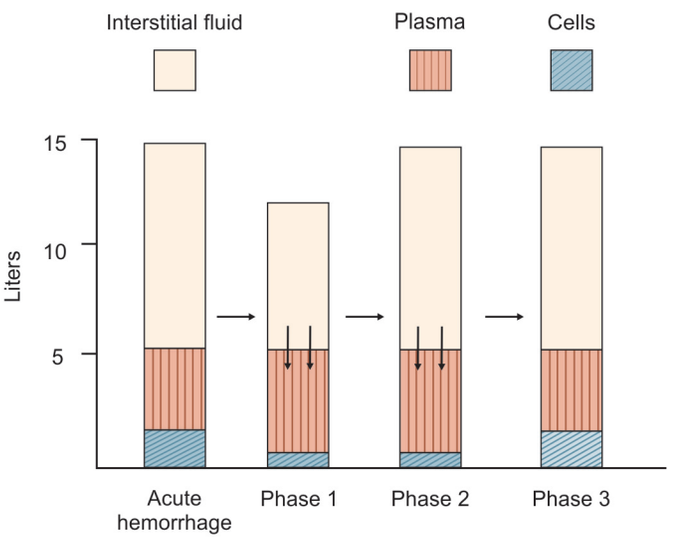

Fig. 1: Response to mild hemorrhage. Phase 1: Shift of fluid from interstitial fluid compartment into capillaries with decrease in volume of the interstitial fluid compartment. Phase 2: Depletion of blood volume activates the renin system, resulting in sodium retention, water retention and replenishment of interstitial fluid compartment. Phase 3: Erythropoiesis stimulation due to blood loss

or one who is critically ill, or who has a background of cardiopulmonary problems or has a hemoglobin (Hb) less than 8 g/dL to start with, will manifest symptoms and signs with blood loss of as little as 350–400 mL. The first manifestation of an abrupt occult blood loss of as little as 300 mL in a critically ill patient in the intensive care unit (ICU) is a worsening of his overall critical state with regard to his vital signs and urine output. The reason for this worsened state can easily be missed.

The early clinical features of blood loss exceeding 500–700 mL include tachycardia, pallor, a heightened anxiety and restlessness. Tachycardia may be mild or even absent (except when the blood loss is acute) in young individuals with a blood loss of less than 500 mL. The skin may be cold and clammy. Sudden, inexplicable, profuse sweating may be the first symptom or sign of an occult or fairly severe blood loss as in an upper GI bleed. Unless blood or volume loss is very severe and acute, the blood pressure is often initially maintained. Even so, orthostatic hypotension may be demonstrated by a drop in systolic blood pressure more than 10 mm Hg on changing from the supine to the sitting posture and more than 20 mm Hg on changing from the supine to the standing posture, the postural fall in blood pressure being often accompanied by a complaint of dizziness. The neck veins are collapsed, unlike patients in cardiogenic shock where the neck veins are full. Oliguria is present (urine output <0.5 mL/kg per hour), and may progress to complete anuria.

Compensatory mechanisms in severe shock ultimately fail. The systolic blood pressure then drops and the patient's mental state may get progressively obtunded. In many patients, the systolic blood pressure is maintained (between 100 and 120 mm Hg) in spite of significant blood loss. This should never lull the physician into a false sense of complacency. When the blood pressure does fall in these patients, it crashes precipitously, frighteningly to unrecordable levels, with disastrous consequences. In hemorrhagic shock, a significant drop in pressure (>30 mm Hg) in the supine position, together with marked oliguria, suggests a loss of more than 30% of blood volume, or an effective loss of about 2L in a 70 kg patient. By this time, tachycardia is invariably present, the pulse being feeble and thready. In patients who have a poor sympathetic drive (as in the elderly) the degree of tachycardia is much less marked in relation to the degree of blood loss. Bradycardia may be observed terminally in such patients. Increasing metabolic acidosis is the classic sign of increasingly poor tissue perfusion. Towards the end, the patient is pulseless, pressureless and almost anuric. If cerebral perfusion is preserved, the patient may remain alert; more often than not, he is obtunded and confused.

Four categories of blood loss have been tabulated in Table. 2. Compensatory responses chiefly in the form of tachycardia and vasoconstriction may be blunted in elderly patients, diabetics, alcoholics, in patients with chronic renal and liver cell dysfunction, and in patients enfeebled by debilitating illnesses. Tachycardia may be less marked or even absent in these situations, and hypotension may occur early with little blood loss.

Monitoring Hypovolemic Shock[1]

Clinical monitoring of vital parameters, like the pulse, blood pressure, respiratory rate, skin and core temperature, capillary refill, urine output, oxygen saturation, jugular venous pressure, arterial pH and blood gases, is essential. An arterial line is indicated if the blood pressure is low, as otherwise false very low readings are obtained with the noninvasive blood pressure measurement technique.

Monitoring the hematocrit, the hemodynamic pattern, oxygen supply to tissues (DO_2), oxygen consumption ($\dot{V}O_2$), oxygen extraction, and the end-tidal CO_2 are briefly described below. It needs to be mentioned, particularly for our part of the world, that it is not always necessary to measure oxygen extraction DO_2,$\dot{V}O_2$ and end tidal CO_2 for the proper management of hypovolemic shock. Even the pulmonary artery catheter to monitor the hemodynamic profile is being used with increasing infrequency. Yet there are occasions when these measurements are of help to understand the nature of a difficult problem confronting the intensivist.

Hematocrit[1,5]

It is important to remember that acute blood loss produces no immediate change in the Hb, red blood cells (RBCs) count, or the hematocrit. This is because if whole blood is lost, the

Table 2: Classification of hemorrhage[3]

Parameters	*Class*			
	I	II	III	IV
Blood loss (mL)	<750	750–1,500	1,500–2,000	>2,000
Blood loss (%)	<15	15–30	30–40	>40
Pulse rate (beats/min)	<100	>100	>120	>140
Blood pressure	Normal	Decreased	Decreased	Decreased
Respiratory rate (breaths/min)	14–20	20–30	30–40	>35
Urine output (mL/hour)	>30	20–30	5–15	Negligible
CNS symptoms	Normal	Anxious	Confused	Lethargic

Abbreviation: CNS, central nervous system.

Source: Modified from Committee on Trauma.[3]

concentration of RBCs, Hb and the proportion of RBCs to plasma remains unchanged. It may take 24 hours or more for sufficient interstitial fluid to enter the vascular compartment and significantly reduce the Hb and the hematocrit. On the other hand, if the patient has bled slowly, if recognition of blood loss is delayed, or if fluid resuscitation has been prompt, the hematocrit will be low. When hypovolemia results from loss of fluids as in vomiting, diarrhea, fistulae involving the GI system, or in sequestration of fluids as in intestinal obstruction, the hematocrit is high.

Hemodynamic Pattern

The classic hemodynamic pattern (also see Chapter Overview of Shock Syndromes) is a low central venous pressure (CVP), a low pulmonary capillary wedge pressure (PCWP), a low CO and a high SVR. Tachycardia is generally, though not always present, and the blood pressure may be maintained within normal limits because of compensatory increase in SVR. It is important to interpret hemodynamic findings with circumspection and not necessarily let them take precedence over clinical findings. The filling pressures and, in particular, the CVP are not always very reliable in assessing the degree of volume loss in critically ill patients. The following features may interfere with the correct interpretation of the clinical state—

- The CVP is influenced by the compliance of the veins and of the ventricles, and both these may be decreased by hypovolemia. The excessive venoconstriction resulting from sympathetic activation may produce a higher CVP than is expected with the degree of volume loss.
- Higher than expected CVP readings are observed if vasopressors have been used to counter hypotension. This is not uncommon when the etiology of hypotension has been incorrectly diagnosed.
- Higher than anticipated CVP readings may also be observed when the hypovolemia is associated with cardiac tamponade or a tension pneumothorax (as in severe trauma).
- A CVP below +2 cm H_2O signifies volume depletion. However, the CVP is ordinarily low (between 2–10 cm H_2O), and there is little margin for change with hypovolemia. Single pressure readings at a given point in time can be misleading. It is important to interpret changes in trends in pressure readings over a period of time, particularly after fluid resuscitation has commenced, and to correlate these changes with improvement in clinical findings.

Oxygen Extraction[1,3]

According to Fick's principle (see Chapter Basic Cardiorespiratory Physiology in the Intensive Care Unit), the usual response to a lowered CO is an increase in oxygen extraction from the blood perfusing the tissues. This can continue only to a point (where 50% oxygen has been extracted from the arterial blood) after which an oxygen debt occurs and tissue metabolism switches from aerobic to anaerobic. Ideally, mixed venous oxygen saturation and pressure are estimated from blood samples withdrawn from the pulmonary artery via the pulmonary artery catheter. However, blood samples are now generally drawn from a central venous line, on the assumption that the results of central venous oxygen saturation ($ScvO_2$) thus obtained are close to those obtained by the more accurate estimation of mixed venous oxygen saturation ($S\dot{v}O_2$) of blood drawn through a pulmonary artery catheter (see Chapter Overview of Shock Syndromes). Specially devised central venous catheters can give a continuous display of $ScvO_2$ readings on the monitor.

The expected changes in oxygen extraction and $S\dot{v}O_2$ in hypovolemia progressing to hypovolemic shock are given below.

	SaO_2 (%)	*$S\dot{v}O_2$ (%)*	*O_2 extraction (%) (SaO_2–$S\dot{v}O_2$)*
Normal	>95	65–70	about 30
Hypovolemia	>95	50–65	30–50
Shock	>95	<50	>50

An increasing difference between SaO_2 and $S\dot{v}O_2$ is ominous and a difference over 50% generally denotes shock with tissue hypoxia.

End-Tidal CO_2

A decrease in CO results in a decrease in partial pressure of carbon dioxide (PCO_2) of the expired gas. This is a simple method of monitoring a falling CO in hypovolemic shock. The end-tidal CO_2 is normally 3–4 mm Hg less than the partial pressure of CO_2 in the arterial blood. It may drop to below 10 mm Hg in severe shock and shows a progressive rise with successful volume resuscitation. End-tidal PCO_2 can be measured and monitored using standard nasal cannula used to provide oxygen to the patient.

DIFFERENTIAL DIAGNOSIS

Hypovolemic shock may be mistaken for shock due to other causes if bleeding or fluid loss is not externally evident. Cardiogenic shock has similar features except that it is usually associated with distended neck veins. Spinal injury following trauma may produce vasodilatation which is relatively refractory to fluid administration. Shock following trauma is however invariably due to hypovolemia, and other causes should only be entertained after adequate fluid replacement therapy has first been instituted. A state of shock can occur following hypoglycemia due to excessive insulin administration. The patient is cold, clammy, has tachycardia and may be hypotensive. Brainstem signs and decerebrate states when present are seen more frequently in hypoglycemia than in hypovolemic shock. A history of insulin administration should always arouse suspicion. After blood has been sent for glucose estimation, administration of 50 mL of 50% dextrose should promptly produce marked improvement in the patient's condition. The picture of hypotensive shock is also observed in patients with well-marked adrenocortical insufficiency. Mere replacement of volume is not enough for resuscitation. Hydrocortisone 100 mg IV 8 hourly is mandatory

for survival. In fact the persistence of marked hypotension after adequate volume replacement should always raise the possibility of an underlying adrenocortical insufficiency.

MANAGEMENT[1,3]

The principles of management are as follows—

I. Fluid resuscitation. Rapid fluid resuscitation is the keystone of therapy in hypovolemic (including hemorrhagic) shock. Restoring the volume within the vascular compartment increases venous return, increases and supports CO, raises blood pressure and improves tissue perfusion. It reverses the effects of hypovolemic shock.

II. Replacement of Hb with blood transfusions when shock is due to significant blood loss.

III. Monitoring fluid and blood resuscitation clinically, and re-evaluating the overall condition after initial fluid resuscitation. CVP monitoring is essential; in difficult cases (see below), hemodynamic monitoring through a Swan-Ganz catheter may further help management.

IV. Determining the etiology of hypovolemic shock and treatment of the cause in so far as this is possible. In hemorrhagic shock without external bleeding, it is important to determine the site of blood loss and arrest a continuing bleed. External hemorrhage should be controlled by prompt pressure over the site, and surgical control of the bleed. One should never wait for laboratory tests, but should start fluid resuscitation promptly. Investigations to determine the cause of severe hypovolemic shock are carried out after, or pari passu with emergency resuscitation.

I. Fluid Resuscitation[6]

Principles

The ultimate objective in fluid resuscitation is to restore and maintain O_2 uptake in vital organs of the body so as to preserve organ function.

$$\dot{V}O_2 = CO \times (CaO_2 - CvO_2)$$

where, CaO_2 is oxygen content of arterial blood and CvO_2 is oxygen content of venous blood.

In acute severe fluid loss it is the CO alone which needs to be urgently restored and sustained. In severe acute blood loss, $\dot{V}O_2$ is compromised both by a low CO and a low Hb. Unquestionably a low CO has far more dangerous consequences than anemia. The prime objective therefore in shock due to acute blood loss is to first restore CO and improve blood flow; correcting Hb deficit is the next objective. Therefore, in severe hypovolemic or hemorrhagic shock, fluids should be infused rapidly to quickly correct the volume deficit and thereby increase CO and blood flow. In young, previously healthy patients, the infusion in severe hypovolemic shock is given at the maximal rate through a large bore (14–16 gauge) catheter used to cannulate a vein. In older patients, or in those with cardiac disease, the infusion should be given less rapidly with a close watch for hypervolemia and complicating pulmonary edema.

Cannulation Site

In severe shock, it is mandatory to have access to two veins through two large bore (16 gauge) intravenous catheters. Central venous catheters do not permit rapid fluid replacement in severe hypovolemic shock, because of their long length and because the lumen of the usual central lines is too small to allow rapid fluid flow (see below). It is best therefore, to insert a short 14–16 gauge catheter into a peripheral vein. If this is impossible because of totally collapsed peripheral veins, a large bore catheter can be placed in the femoral vein, or a central line necessarily has to be secured.

Catheter Dimensions and Relation to Flow Rate

The maximum infusion rate is dependent on the size (i.e. lumen) of the catheter, and not on the size of the vein that is cannulated. To be more precise, the infusion rate is directly related to the pressure gradient along the catheter, and the fourth power of the radius of the catheter. It is inversely related to the length of the catheter and the viscosity of the fluid infused. The relationship stated above is illustrated in Table 3. It is to be noted that the infusion rate is almost four times greater in the 2" short peripheral 14 gauge catheter, than in the usual 12" long central venous catheter. Table 3 illustrates the importance of the short 2" peripheral catheters for rapid infusions and quick fluid replacement, as compared to the long central venous catheters.

Use of introducer catheters in central veins. Marino[1] has correctly stressed that the adverse effect of catheter length on infusion rate in central venous cannulation, can be overcome by the use of large bore introducer sheath catheters. These introducer sheaths in sizes of 8.5 Fr (2.7 mm internal diameter), and 9 Fr (3 mm internal diameter) are normally used as conduits for multi-lumen catheters or the Swan-Ganz catheters, but can be used by themselves for rapid volume replacement.

Relation of Fluid Viscosity to Flow Rate

Studies have shown the influence of viscosity on flow rates (Table 4). It was shown that the infusion rates of water

Table 3: Influence of catheter size on infusion rate

Infusion device	*Length (inches)*	*Flow rate* (mL/min)*
9-Fr introducer	5½	2407
IV Extension tubing	12	220
Peripheral		
14-gauge catheter	2	195
16-gauge catheter	2	150
Central		
16-gauge catheter	5½	91
16-gauge catheter	12	54

and 5% albumin were similar. The infusion rate of whole blood was slower and that of packed RBCs was the slowest. The importance of using crystalloids and/or colloids for emergency fluid replacement is therefore evident.

Estimating Volume Requirements in Hypovolemic Shock

There is always a tendency to underestimate volume or blood loss in hypovolemic shock. The following approach has been proposed by Marino[1] for a rough estimation of fluid loss—

i. Estimate normal volume In adults the normal blood volume is estimated at 66 mL/kg for males, and 60 mL/kg for females. Lean body weight is used for this estimate. For obese patients, the blood volume is first estimated on the actual body weight and 10% is then subtracted from the value obtained initially.
ii. Estimate the percentage of volume that is depleted This is calculated according to the classification system tabled earlier (Table 2).
iii. Calculate the volume deficit This is done by multiplying the estimated normal blood volume and the percent lost. This quantifies the volume that requires to be replaced.
iv. Resuscitation with reference to the fluids used The volumes are estimated roughly as follows—
   - If whole blood is used for resuscitation, then the volume to be replaced is 1 × volume deficit.
   - If colloids are used for fluid resuscitation, then the volume necessary is 1 × volume deficit.
   - If crystalloids (normal saline, Ringer lactate) are used for fluid resuscitation, the volume that needs to be infused is 3 × volume deficit.

Fluids Used in Volume Replacement

Shoemaker[7] studied the ability of different resuscitation fluids to promote CO. Each of the fluids was administered over an hour and the change in cardiac index was noted at the end of infusion. The resuscitation fluids studied were whole blood (500 mL), packed cells (500 mL), dextran-40 (500 mL), Ringer lactate (1L). The infusion volumes of whole blood, packed RBCs, dextran-40 was similar (500 mL); the infusion volume of Ringer lactate was twice that of the other fluids. Figure 1 shows that the maximum increase in cardiac index was observed with the colloid dextran-40, the next with whole blood, then with Ringer lactate and the least (little or no increase) with packed RBCs. The obvious inference was that colloids were superior to blood products and crystalloids for increasing CO and blood flow. Also, erythrocyte concentrates should not be used to increase blood flow. As has already been stated, the volume of crystalloid fluid should be three times greater than the volume of colloid infusion. Even so, there is still debate as to whether crystalloids or colloids should be used for emergency fluid resuscitation. The colloid-crystalloid controversy is discussed later in this chapter.

Table 4: Influence of fluid type on infusion rate

Fluid	*Flow rate (mL/min)**
Tap water	100
Albumin (5%)	100
Whole blood	65
Packed cells	20

Most units generally use rapid infusions of crystalloids, either normal saline or Ringer lactate. In our country as also in other developing countries, these fluids are cheap, readily available and provide quick though transient intravascular expansion. When signs and symptoms of shock are apparent, 2 L of crystalloid solution is administered to the adult, and 20 mL/kg to a child. As quick equilibration occurs with the extravascular fluid compartment in about 30 minutes, only 25% of the infused fluid can be presumed to remain in the vascular compartment after an infusion of crystalloids. Hence the rough rule that the volume to be replaced is at least three times the volume deficit as calculated in the manner described earlier.

Colloid solutions are equally effective for volume replacement and can increase the cardiac output (CO) more quickly than crystalloid solutions.[7] Colloid solutions in our country are however extremely expensive and in smaller district hospitals not easily available. When hypovolemic shock is associated with marked hypotension, crystalloid solutions can be infused through one vein and colloid solutions can be infused through another. The colloid solution helps to augment CO and blood pressure quickly while the crystalloids further help to correct the sodium loss in the extracellular compartment which is an invariable feature of moderate to severe hypovolemic shock.

Currently studies based on large randomized trials seem to suggest that colloids hold no advantage over crystalloids and that crystalloids alone can be used for resuscitation from hypovolemic shock.

The major complication associated with the use of crystalloid solutions is either underhydration due to inadequate volume replacement, or overhydration resulting in a hypervolemic state. Excessive administration of crystalloids can result in generalized edema. Pulmonary edema is however rare in previously healthy individuals unless overinfusion results in a sharp increase in the PCWP to more than 25–30 mm Hg. A careful monitoring of pulmonary hydrostatic pressure (PCWP) particularly in patients with underlying cardiorespiratory disease is helpful and should prevent this complication. Since the chloride concentration of normal saline is significantly higher than the chloride concentration of plasma, patients resuscitated with large infusions of normal saline develop a hyperchloremic metabolic acidosis which requires renal excretion of chloride for correction. After infusing the first 1.5–2 liters as normal saline in severe hypovolemic shock, normal saline with either Ringer lactate solution or 5% dextrose saline are used alternatively for further correction of the volume deficit. Ringer's solution is preferred

to normal saline infusions in some units for replacing volume deficits. Ringer's solution has a more physiological electrolyte content; the lactate within it is converted to bicarbonate by the liver, except in very ill patients or in those with marked hepatic dysfunction.

It is important not only to replace volume, but also to ensure that the concentration of electrolytes in plasma is kept normal. Hypokalemia is very frequent in hypovolemia produced by vomiting, diarrhea, by fluid loss from fistulae involving the GI tract, or by sequestration of fluids within the gut. Between 40–60 mEq of potassium (K^+) in a dextrose or dextrose-saline infusion are given over 4 hours through a separate vein and repeated if necessary after monitoring serum K^+ levels. *It is a mistake to give large volumes of 5% dextrose for fluid resuscitation as severe hyponatremia results, and this may be difficult to correct against a background of shock.*

Occasionally hypovolemic shock due to vomiting and diarrhea is associated not only with a severe hypokalemia, but also by excessive loss of bicarbonates in the stools with a resulting metabolic acidosis. Cholera (due to the Gram-negative *Vibrio cholerae*), is a classic example where severe hypovolemic shock due to fluid loss from vomiting and diarrhea, is associated both with hypokalemia and metabolic acidosis and with low plasma bicarbonate levels. Intravenous fluid replacement is best undertaken by using a special solution containing 5 gm sodium chloride, 4 gm sodium bicarbonate and 1 gm potassium chloride in 1 liter of distilled water. If the above solution is not available, infusion of 1 liter of isotonic saline is alternated with 500 mL of either isotonic sodium bicarbonate (1.4% in 500 mL), or 1/6th molar sodium lactate. This is continued till volume replacement is judged adequate. In fulminant cases with uncontrolled vomiting, and the continuous passing of large volume rice water stools, 10–12 liters of fluid may need to be replaced in the first 12 hours. Potassium losses may need to be separately replaced in a dextrose-saline drip. The patient needs critical care, but it is advisable to provide this in an isolation ward rather than in an all-purpose critical care unit. Fluid and electrolyte replacement as outlined above, and tetracycline 500 mg four times a day for 10 days, form the cornerstones of therapy. Oral rehydration therapy is both cheap and extremely effective in moderately severe cases. The solution used orally, if necessary through a nasogastric tube, should contain glucose 30 gm, sodium chloride 3.5 gm, and potassium bicarbonate 2.5 gm in 1 liter of water. The rate of administration is 750 mL/hour for patients weighing over 25 kg, and 500 mL/hour for patients weighing less than 25 kg.

Colloid-Crystalloid Controversy

The question that needs to be answered is—should colloids be used at all in the resuscitation of patients in shock, including patients in hypovolemic shock?

The colloids in use are albumin (5% and 20%), a gelatin preparation marketed as Haemaccel and hydroxyl-ethyl starch (HES). Dextrans though powerful plasma expanders are now hardly ever used because of their untoward reactions—chiefly anaphylaxis, renal dysfunction and bleeding. Dextran inhibits platelet adhesion and aggregation, producing a clinical effect similar to von Willebrand's disease. Hydroxy-ethyl starch is infrequently used in our country. It can cause renal dysfunction from starch being deposited in renal tubule cells. We chiefly use albumin, and at times the gelatin solution—Haemaccel.

In theory, colloids because of their increased osmotic pressure and their low permeability through capillary walls should produce quick volume expansion and a quicker increase in cardiac output (CO) as compared to crystalloids. Yet all prospective randomized clinical studies, as also a meta-analysis, maintain that there is no advantage in the administration of colloids as compared to crystalloids for resuscitation from all forms of shock.[8-10]

In 2004, a large randomized control study of normal saline versus 4% albumin for resuscitation in the ICU showed no difference in mortality between the two groups. In another blinded randomized controlled study called the crystalloid versus hydroxyl ethyl starch (HES) trial (CHEST)[9] involving 7,000 adults in the ICU, the use of HES compared to N-saline resulted in no difference in mortality between the two groups. In fact HES has some degree of nephrotoxicity and was associated with a 21% increase in the rate of renal replacement therapy.

Current evidence points to the lack of clinical benefit, potential nephrotoxicity of colloid infusions, and to this is added the increased cost of semisynthetic colloids and albumin. Hence is the use of colloids for resuscitation in shock justified? In spite of evidence to the contrary, colloids continue to be widely used, particularly so in disaster situations, and for resuscitation of the wounded in times of war or conflict. We need to consider certain aspects of the controversy and perhaps use colloids only in certain situations.

1. Every large study has randomly given to patients either colloids or crystalloids. This need not be so in practice. Crystalloids are always given and continued till resuscitation is complete. Colloids should not be solely used for volume replacement and resuscitation. They could however be used with advantage in the following circumstances—
   a. In severe hypovolemic shock with a barely palpable pulse and a barely recordable blood pressure, crystalloids and colloids are started simultaneously (through separate veins). A quicker restoration of blood volume, a rise in CO and blood pressure and a quicker improvement in tissue perfusion is observed. Once the circulatory state has improved, crystalloids are continued and colloids are stopped. The volume of colloids used is then much less than that reported in clinical studies.
   b. In fluid resuscitation for severe burns patients, infusions of IV albumin are used after 24 hours to minimize the formation of edema and water-logging of tissues which would result from further continued administration of large volumes of crystalloids.

c. After resuscitation of severe hypovolemic shock with large volumes of crystalloids, colloids may be used in patients who are water-logged as judged by marked pitting edema over the feet and legs. The increased plasma oncotic pressure mobilizes extravascular fluid into the vascular compartment, the extra fluid being then excreted by the kidneys.

If colloids are used as stated above, the question of solely choosing one (colloid) or the other (crystalloid) does not arise. The controversy would still continue but perhaps in a lower key! It needs to be remembered that the large randomized trials on colloids and crystalloids contained a mixed group of patients with different background factors leading to shock and the need to resuscitate. No study comparing equivalent cohorts has been done. Nor is there a randomized study comparing a cohort of patients receiving crystalloids and colloids with another equivalent cohort receiving only crystalloids. To my mind, no further studies on colloids versus crystalloids are really necessary. Evidence is always welcome and valued but it should not usurp clinical judgment.

II. Monitoring Fluid Replacement and Endpoints in Therapy

Volume replacement by fluids should reverse shock. Clinical parameters, such as a fall in heart rate, increase in blood pressure, restoration of urine output, increased warmth of the skin with evidence of improving or good capillary refill, should be taken into account to determine the adequacy of volume replacement. Restoration of the mental state to normal, and correction of metabolic acidosis are good indicators of improving circulatory function. Correction of metabolic acidosis is gauged by a return of serum lactate to less than 2 mmoL/L and an abolition of the base deficit if the lactate levels and base deficits were increased prior to resuscitation.

Volume replacement is guided by—

- An improvement in the circulatory and metabolic state.
- Monitoring filling pressures which may be increased to the upper limit of normal. It should however be noted that the filling pressures for various reasons cannot always be equated with ventricular volume, so that a patient may require further volume replacement in spite of adequately raised filling pressures (see Chapter Overview of Shock Syndromes).
- A normal $\dot{V}O_2$. This need not be measured in every patient but is a useful marker in critically ill hypovolemic patients.

The quantum of volume replacement to start with should be guided by but not solely determined by the estimated volume loss (Table 2). This is particularly important in hemorrhagic shock in older patients. Severe blood loss causing shock in these patients is associated with a marked compensatory increase in venous tone. Blood transfusions to replace lost blood ordinarily reverse shock and simultaneously cause a reduction in venous tone. However, in some patients the venous tone remains persistently high. An increasing volume in the vascular compartment in association with a raised venous tone can cause a rise in the filling or right atrial pressures to above normal, even when volume replacement is incomplete. In young individuals with normal hearts, this does not usually matter. In older individuals with poor depressed left ventricular function curves, a rise of right atrial pressure by even 3–4 mm Hg above normal can induce a threefold or even greater increase in the left ventricular filling pressure. The latter may rise from 8 to 24 mm Hg or even 30 mm Hg, and cause acute pulmonary edema.

Over-infusions resulting in pulmonary edema can be clinically detected by noting an increased respiratory rate, by careful auscultation for crackles at the lung bases, and by pulmonary congestion which is evident on a chest X-ray. Detailed hemodynamic monitoring of PCWP, CO, SVR through a pulmonary artery catheter is not indicated or necessary in most patients. In fact many units prefer to treat all forms of shock as far as possible without the use of the PA catheter. Invasive hemodynamic monitoring is however helpful in the following circumstances—

- When hypovolemia complicates other forms of shock, e.g. septic or cardiogenic shock.
- When the cause of shock is not clearly evident.
- When hypovolemic shock occurs in patients with known poor cardiac function, or in patients with suspected myocardial dysfunction.
- When during fluid replacement, pulmonary congestion is evident, even though the replaced volume seems to be inadequate.
- In patients where the CVP is persistently higher than expected in the face of shock.
- In patients where inotropic support is required even after adequate volume replacement.
- The endpoint of volume replacement with hemodynamic monitoring is to maintain a PCWP around 15 mm Hg and a CVP within the normal range.

$\dot{V}O_2$ and Serum Lactate

In individuals with severe hypovolemic shock, volume repletion may still be associated with persistent tissue ischemia, either due to the severity of the shock to start with, delay in resuscitation, to the presence of the microcirculatory mitochondrial dysfunction syndrome or perhaps to reperfusion injury. In patients where clear evidence of one or more organ dysfunction persists after volume replacement, $\dot{V}O_2$ and serum lactate measurements should be monitored. If the $\dot{V}O_2$ is found low and the serum lactate measurements are more than 4 mm/L, further volume infusions with or without inotropic support is advocated.

Vasopressors are not indicated in pure hypovolemic shock. If however hypovolemic shock is complicated by myocardial infarction, or poor myocardial function, inotropic agents may be used after volume repletion is complete. Vasopressors with or without inotropes may be necessary if hypotension and poor tissue perfusion persist in spite of complete replenishment of circulatory volume. A fall in filling pressures after fluid replacement with a relapse into a shocked state, should suggest continuing fluid or blood loss. A persistent need for vasopressors or inotropic agents after fluid resuscitation

should also alert the physician to continuing volume loss or myocardial infarction, and in patients with traumatic shock, to pump failure from myocardial contusion, cardiac tamponade or aortic dissection. The clinical features, relevant investigations and response to therapy should help to detect these problems.

III. Replacement of Hb in Shock Due to Blood Loss

Once depleted volume has been replaced, and CO and blood pressure supported by fluid resuscitation, the lost Hb should be replaced, with packed RBC infusions. Neither the hematocrit value nor the Hb concentration is an accurate representation of the total erythrocyte volume in the blood after fluid replenishment. The hematocrit and the erythrocyte volume will fall with an increase in plasma volume (as after fluid replenishment). The hematocrit will remain unchanged even with a change in erythrocyte volume when there is a proportionate change in plasma volume, as after acute blood loss or after transfusion of whole blood. For practical purposes any estimated blood loss approaching 20% or more will require a correction of anemia with the use of packed RBCs, the Hb concentration being kept at approximately 10 g/dL. This increases the oxygen carrying capacity of blood and helps tissue oxygenation. Though probably true for many patients, it may not necessarily be so for all.

McCormick and associates studied the influence of an increase in CO and an increase in hematocrit by blood transfusions on oxygen uptake by tissues ($\dot{V}O_2$) during resuscitation from hemorrhagic shock.[11] They noted that the $\dot{V}O_2$ increased after the CO was raised, but did not increase when the hematocrit was raised by blood transfusions. This may well be possible if the $\dot{V}O_2$ is on the flat portion of the curve relating oxygen delivery to oxygen consumption. Marino[1] is of the opinion that indications for transfusions in normovolemic patients are: (i) $\dot{V}O_2$ below the normal range; (ii) Blood lactate levels more than 4 mmoL/L; (iii) Oxygen extraction ratio more than 0.5. To physicians practising in poor countries, these conditions for infusing packed cells in hemorrhagic shock (after restoring fluid volume and CO) are impractical. We strongly feel that the traditional dictum of maintaining the Hb at around 10 g/dL holds true.

In patients with continuous profuse bleeding as in severe trauma, massive surgery, blood dyscrasias, coagulopathies, whole blood transfusions and fluids are used simultaneously to counter severe hemorrhagic shock. For every three units of blood given, the patient should be given a unit of fresh frozen plasma. Massive whole blood transfusions can cause or worsen a coagulopathy.

IV. Determining and Treating the Etiology of Hypovolemic or Hemorrhagic Shock

In the tropics and in poor developing countries, cholera is an important cause of acute vomiting and diarrhea. *Salmonella* infections or violent GI infections with Gram-negative organisms (in particular *Klebsiella* or *E. coli*), can also cause severe hypovolemic shock. Relevant investigations and specific treatment are available for such infections (see Section Fever and Acute Infections in a Critical Care Setting).

Profuse hemorrhage from the GI tract may produce profound collapse, and if the patient does not have hemetemesis or obvious bleeding per rectum, the source of bleeding may not be evident for as long as 24 hours. A rectal examination in these patients often reveals the presence of malaena by the jet black stools staining the examining finger. Hemorrhage from a leaking aneurysm may be missed if a careful clinical examination has not been performed.

Definitive therapy might first require diagnostic studies after the patient has been resuscitated and stabilized. Important diagnostic techniques to detect the site of the GI bleed are endoscopy and imaging techniques like arteriography. Definitive therapy might include surgical intervention, endoscopic therapeutic procedures like laser photocoagulation, variceal banding or injection of gastroesophageal varices by sclerosing agents, selective embolization of bleeding vessels, or mechanical balloon tamponade of bleeding varices.

Intravenous hydrocortisone is mandatory and lifesaving in hypovolemic shock of adrenocortical insufficiency. Hypovolemic shock in diabetic ketoacidosis cannot be fully reversed without the use of insulin.

CHAPTER 15

Cardiogenic Shock

INTRODUCTION

Cardiogenic shock (CS) is due to a failure of the pumping action of the heart (pump failure), resulting in a lowered cardiac output (CO) and an inadequate tissue perfusion. Progressive tissue hypoxia ultimately leads to irreversible shock and death. CS occurs in approximately 5–8% of patients hospitalized for ST elevation myocardial infarction (STEMI).[1] Left ventricular (LV) infarction is a far more frequent cause of CS compared to right ventricular infarction. Current research[1] shows that though shock is initiated by an impaired CO, neurohormonal factors, changes in the peripheral vascular system and elaboration of increased cytokines causing a systemic inflammatory response syndrome also play an important role in the perpetuation of shock. Early revascularization (ERV) has now been shown to significantly improve survival. More importantly, survivors have a good chance of long-term survival and can enjoy a good quality of life.

ETIOLOGY

Myocardial infarction (MI) with LV failure is the commonest cause of CS. It is important to exclude mechanical complications that can induce shock in patients with MI. These include ventricular septal rupture, contained free wall rupture, rupture of a papillary muscle. Mechanical complications should always be suspected in patients with CS with infarction not involving the anterior wall, particularly when it is a first MI.[1] Infection, bowel ischemia, an occult bleed may complicate MI. Diagnosis can only be made if there is a high degree of suspicion.

Any pathology which causes severe LV dysfunction or failure can cause CS. Acute mitral or aortic regurgitation typically caused by endocarditis or chordal rupture can cause CS. Very critical tight mitral stenosis as also very critical aortic stenosis can present with the clinical features of CS.

Acute myocarditis, congestive cardiomyopathy, hypertrophic obstructive cardiomyopathy may all present with ST elevation, raised cardiac enzymes and shock in the absence of coronary disease. Stress induced cardiomyopathy also called Takotsubo cardiomyopathy is characterized by acute LV dysfunction occurring after emotional stress or respiratory distress; it leads to CS in 4–5% of cases.[2] It is characterized by apical hypokinesia (leading to apical ballooning) and basal myocardial hyperkinesia and can lead to elevated ST segments, raised cardiac enzymes and in a small minority of patients to CS. Aortic dissection can lead to CS either by causing aortic incompetence or MI.

The picture of CS can also be observed in severe tachyarrhythmias, with poor myocardial preservation and myocardial dysfunction following open-heart surgery, massive pulmonary embolism and cardiac compression resulting in low output with shock. These are considered separately though the clinical picture may be indistinguishable from CS. The important causes of CS are listed in Box 1.

INCIDENCE AND RISK FACTORS

Cardiogenic shock complicates 5–8% of patients hospitalized for a STEMI[3,4] and 2.5% of non-STEMI.[5] In the West, there appears to be a decline in the incidence of CS, probably related to the increasing rates of primary percutaneous coronary intervention (PCI) in patients with MI.[6] Early reperfusion therapy in MI should reduce the incidence of CS. A randomized trial of in-ambulance thrombolysis versus primary PCI found no CS among patients assigned to prehospital thrombolysis.[6]

Box 1: Important causes of cardiogenic shock

- Acute myocardial infarction (commonest cause)
- Acute myocarditis
- Congestive cardiomyopathy—
  - Hypertrophic cardiomyopathy
  - Takotsubo cardiomyopathy
- Mechanical causes impairing myocardial function and contractility—
  - Critical aortic stenosis
  - Severe mitral and aortic valvular incompetence
  - Ruptured interventricular septum/ruptured free wall of ventricle/ruptured papillary muscle/ruptured chordae tendinae
- Severe tachyarrhythmias or bradyarrhythmias
- Patients with myocardial dysfunction following open heart surgery
- Myocardial contusion following trauma

Among PCI assigned patients 0.5% developed CS in the group randomized less than 2 hours after MI.

Risk factors for CS in patients with MI include older age diabetes, hypertension, anterior MI, STEMI, hypertension, left bundle branch block, multivessel coronary artery disease, prior MI and a prior diagnosis of heart failure.

PATHOPHYSIOLOGY

A low CO due to the various causes listed above is the primary reason for CS. However, other parts of the circulatory system also become deranged, contributing to the state of shock. Therefore, though the initiating factor is poor pump function, CS is the result of a temporary or permanent derangement of the entire circulatory system.

The onset and severity of shock are often but not always related to the quantitative damage and loss of functional myocardium. An infarction involving more than 40% of the wall of the left ventricle (as could happen following a block in the proximal left anterior descending artery) invariably spells fatal CS. Shock results from death of cardiac muscle leading to poor ventricular contractility and a low CO. There are several contributing factors which potentiate the low output state. These include poor contractility of ischemic muscle surrounding the infarcted zone, an early increase in the compliance of the infarcted area which bulges during systole, a dyssynergy of contraction in the peri-infarcted area and

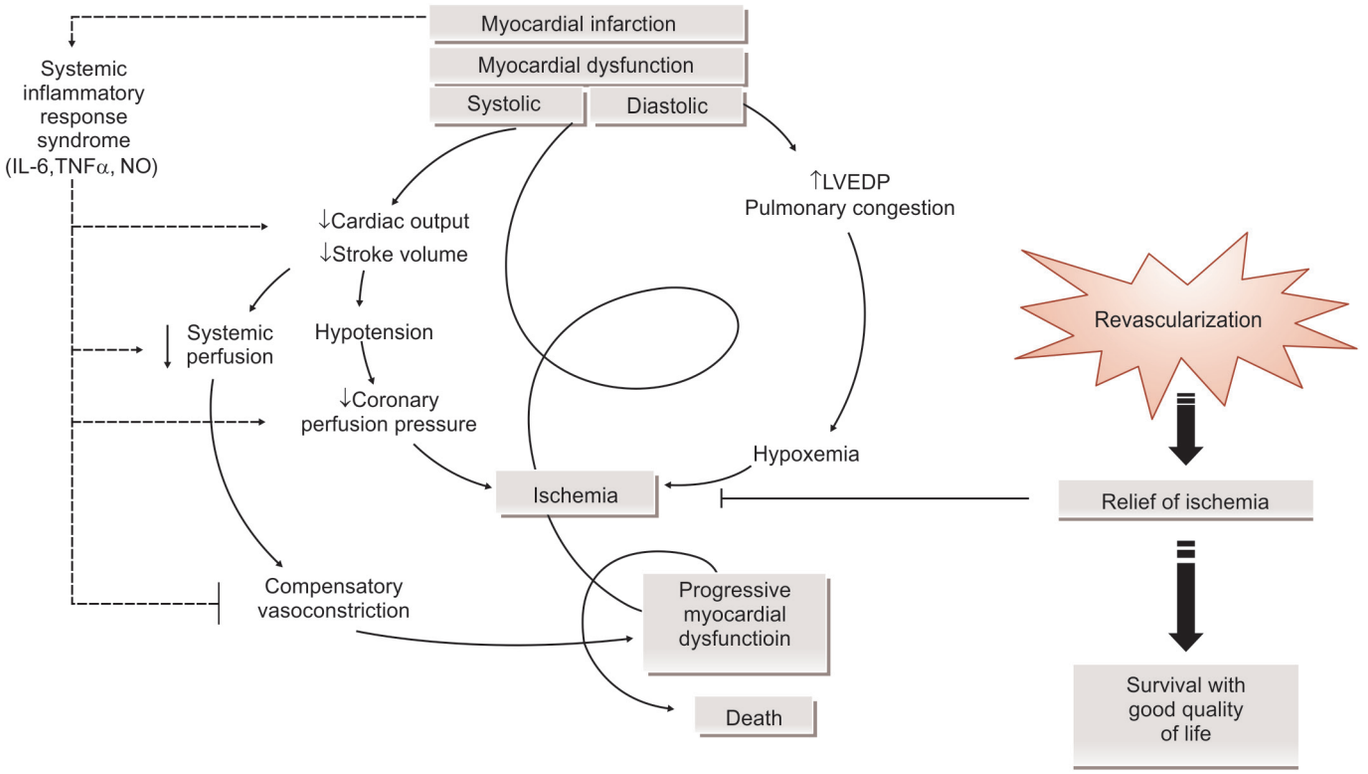

Fig. 1: Current concept of the pathophysiology of CS. The classic description of the pathogenesis is shown in black. Myocardial injury causes systolic and diastolic dysfunction. A decrease in CO leads to a decrease in systemic and coronary perfusion. This exacerbates ischemia and causes cell death in the infarct border zone and the remote zone of myocardium. Inadequate systemic perfusion triggers reflex vasoconstriction, which is usually insufficient. Systemic inflammation may play a role in limiting the peripheral vascular compensatory response and may contribute to myocardial dysfunction. Whether inflammation plays a causal role or is only an epiphenomenon remains unclear. Revascularization leads to relief of ischemia. It has not been possible to demonstrate an increase in CO or LVEF as the mechanism of benefit of revascularization; however, revascularization does significantly increase the likelihood of survival with good quality of life. IL-6 indicates interleukin-6; TNF-α, tumor necrosis factor-α; and LVEDP, LV end-diastolic pressure. Adapted from Hochman and Hollenberg et al. with permission of the publishers. Copyright© 2003, the American Heart Association, and copyright 1999©, the American College of Physicians

metabolic derangements not only within the infarcted region but in the myocardium at a distance from the infarcted zone.[7] As depicted in Figure 1, a diminished CO further diminishes coronary flow causing further ischemia and myocardial damage, with a possible further fall in CO and further hypoperfusion to tissues. A vicious cycle and a downward spiral are set into motion causing progressive myocardial dysfunction and increasing tissue hypoxia that leads to death.

Inotropes, vasopressors can improve both CO and tissue perfusion but do not generally break this vicious cycle and interrupt this downward spiral. The use of an intra-aortic balloon pump (IABP) temporarily supports and improves the circulatory state but this does not last and is no definitive therapy. Revascularization with reperfusion of the myocardium either through PCI, or bypass surgery can however, interrupt this vicious cycle and save lives.

The pathophysiology of CS is complex and cannot be solely attributed to myocardial damage following MI. In a number of patients severe impairment of contractility does not lead to shock; conversely the left ventricular ejection fraction (LVEF) in patients with CS may only be moderately depressed.[8] In the "Should We Emergently Revascularize Occluded Coronary Arteries for Cardiogenic Shock" (SHOCK) trial the mean LVEF was about 30% and the distribution of LVEF in patients in this trial overlaps with that of patients in many post MI trials who had low ejection fraction (EF) with or without heart failure and who were generally ambulatory out-patients.[9-11]

It therefore appears that the magnitude of myocardial damage in CS need not always be profound. However, among patients in shock, LVEF is an indicator of prognosis, the lower the EF, the worse the prognosis.[12] Interestingly, half of CS patients are noted to have small or normal LV size.[12,13] This shows that in these patients there is an absence of the adaptive mechanism allowing acute dilatation, which would have helped maintain a larger stroke volume in the early phase of MI. Systolic function is easy to assess (through echocardiography). Diastolic function is however not easily determined. It is probable that diastolic dysfunction brought about by a fall in ventricular compliance and by abnormalities in ventricular relaxation may contribute to CS in a number of patients.

Cardiogenic shock due to right ventricular infarction and dysfunction occurs in just about 5% of patients with CS due to MI.[14] Severe right ventricular failure results in a decreased right ventricular output (due to poor systolic function) and thereby sharply reduces LV filling and output. The marked increase in the right ventricular end-diastolic pressure (often >20 mm Hg) observed in these patients shifts the interventricular septum toward the LV cavity; this restricts LV filling and also raises left atrial pressure. The generally accepted practice of using a volume load in patients with severe right ventricular dysfunction, so as to maintain an adequate CO and an adequate LV preload may further increase right ventricular diastolic pressure. A marked rise in right ventricular end diastolic pressure caused by a volume load can be potentially harmful as it may worsen hemodynamic changes stated above. Inotropic support is indicated in these patients. An optimal right ventricular end-diastolic pressure of 10–15 mm Hg has been noted to be associated with a higher CO than end-diastolic pressures above or below this level.[15] There is however a fair degree of variability observed with regard to the relation between right ventricular end-diastolic pressure and CO in patients with CS due to right ventricular infarction. It is therefore best for filling pressures to be tailored to optimal CO in each patient.

Shock due to right ventricular dysfunction carries the same mortality as that due to LV dysfunction. In the SHOCK trial the benefit observed following revascularization was similar in patients with right ventricular dysfunction as with LV dysfunction.[9]

Role of Neurohormonal Factors and Systemic Inflammatory Response Syndrome in Cardiogenic Shock

Hypoperfusion due to a low CO triggers the release of catecholamines which constrict peripheral arterioles to maintain perfusion to vital organs. Vasopressin, angiotensin II improve coronary circulation and tissue perfusion, yet cause a significant increase in afterload with further impairment of ventricular dysfunction. Activation of the renin angiotensin system promotes salt and water retention that helps to improve perfusion and yet contributes to pulmonary edema.

Systemic Inflammatory Response Syndrome in Myocardial Infarction and Cardiogenic Shock

Myocardial infarction particularly when associated with CS can cause the SIRS. In spite of compensatory neurohormonal mechanisms, the systemic vascular resistance (SVR) is not always raised in CS. The variable SVR suggests that compensatory neurohormonal mechanisms are not always fully effective. In the SHOCK trial[16] the median SVR in CS was observed to be in the normal range, despite vasopressor therapy. In some patients the SVR is low, similar to septic shock. In fact culture positive bacterial infection develops in a number of patient with a low SVR.[16] These findings suggest the SIRS may play an important role in the pathophysiology of CS and that inappropriate vasodilatation as part of SIRS could result in impaired perfusion of the gastrointestinal (GI) tract, resulting in transmigration of bacteria and sepsis.[17] SIRS occurs more frequently with increased duration of shock.[17,18] Cytokine levels including interleukin-6 and tumor necrosis factor are noted to be elevated. Both these cytokines have a myocardial depressant action; tumor necrosis factor also induces endothelial dysfunction further impairing coronary flow. C reactive protein, procalcitonin, neopterin and other circulatory factors also perhaps contribute to SIRS.[1]

Excess nitric oxide (NO) may also contribute to SIRS. MI is associated with an increase in NO synthase.[1] The latter leads to an excess of NO which causes vasodilatation, myocardial depression and counters the effects of catecholamines. However, NO synthase inhibitors in a multicenter trial did not improve hemodynamics and outcome in CS.

Mechanical Factors

There are specific hemodynamic complications other than the loss of viable myocardium that can precipitate or worsen shock in MI. These include a ruptured interventricular septum, ruptured free wall of the ventricle or a ruptured papillary muscle.

Iatrogenic and Treatable Factors

There are some iatrogenic and/or treatable factors that can potentiate CS. These include—

- Hypovolemia due to the use of diuretics, sweating, restricted fluid intake and vomiting. Blood loss due to undetected bowel ischemia could also cause hypovolemia.
- Tachyarrhythmias or bradyarrhythmias.
- Depressant action of drugs. The use of propranolol in the setting of an evolving severe pump failure can be particularly disastrous. Depressant drugs may far outlast the biological half-life of the agent, since a positive feedback mechanism during the use of the drug may become self-perpetuating even when the drug is withdrawn. Over-sedation with narcotics and tranquillizers can also induce hypotension and worsen shock.
- Metabolic acidosis and electrolyte disturbances potentiate myocardial dysfunction.
- Unrelieved hypoxia.
- Severe prolonged unrelieved pain may worsen the shock state.
- Sepsis may complicate CS; it should be suspected in the presence of a low SVR. Blood cultures may be positive.
- Diuretics (particularly high doses) may cause or contribute to shock in patients with MI by diminishing circulatory volume.
- Pulmonary embolism.
- Excess volume loading in patients with right ventricular infarction can also contribute to shock.

Factors aggravating shock in acute MI are given in Box 2.

In summary, the pathophysiology of CS is initiated by pump failure but then involves other parts of the circulatory system. Compensatory neurohormonal mechanisms are often inadequate to counter CS. The SIRS has been shown to play an important role in the pathophysiology of CS. Finally, other factors, some treatable and some iatrogenic may contribute to CS.

Box 2: Factors aggravating cardiogenic shock in acute myocardial infarction

- Severe unrelieved pain
- Hypovolemia
- Tachyarrhythmias or bradyarrhythmias
- Depressant action of drugs, e.g. propranolol, overuse of narcotics and sedatives
- Metabolic acidosis and electrolyte disturbances
- Unrelieved hypoxia
- Pulmonary embolism
- Sepsis
- Diuretics in large doses
- Excess volume loading in patients with right ventricular infarction

CLINICAL FEATURES

The features of shock develop against the background of acute MI, or against the background of other severe low output states due to myocardial dysfunction, or to mechanical problems (as in severe valvular heart disease).

At least two of the five features listed below are present—

1. Hypotension with a systolic pressure below 90 mm Hg or a mean arterial pressure less than 55 mm Hg. There are a few points worthy of note in relation to hypotension. Blood pressure readings taken by the cuff method are unreliable in the presence of severe vasoconstriction. They are often much lower and often unobtainable by the cuff method under the above circumstances, even though pressure measurements via an intra-arterial cannula show satisfactory readings. It is equally important to remember that shock can exist with a systolic pressure higher than 90 mm Hg, particularly in the presence of compensatory vasoconstriction which raises the peripheral vascular resistance. Also, a patient may at times remain well perfused with a systolic blood pressure between 70 and 90 mm Hg. Tachycardia is frequently associated with hypotension but shock can exist with a bradyrhythm, or even with a normal heart rate.
2. Cold, pale, clammy or sweaty skin. The skin over the peripheries, forehead, nose, lips, face, first turns cold and clammy; the coldness then extends to the trunk.
3. A fall in urine output to less than 25 mL/hour with a sodium content less than 30 mEq/L.
4. Impaired cerebration—anxiety, restlessness, agitation, confusion and later, obtundation.
5. Metabolic acidosis due to lactic acid accumulation.

When life support systems keep a patient in severe CS alive for a few days, signs of increasing multiple organ dysfunctions are observed.

DIAGNOSIS[1]

The diagnosis of CS is evident when it evolves against the clinical features, electrocardiograph (ECG) and serial enzyme changes of an MI. When shock follows very soon after an MI, or if for any reason the history is unavailable, or the ECG changes are atypical, the diagnosis is more difficult. A patient in severe shock may never complain of chest pain pointing to an underlying MI, and yet a patient with hypovolemic shock due to a massive GI bleed may complain of ischemic cardiac pain and thus mislead the clinician into arriving at a wrong diagnosis.

The diagnosis of CS due to low-output states related to cardiomyopathy and severe valvular heart disease should be

evident on a clinical examination and relevant investigations. An etiology which is often missed is the low-output state due to a very tight aortic stenosis. The typical murmur may be absent in these patients because of the sharp reduction in the forward flow. An echocardiography is mandatory in all patients, and should aid in making a convincing diagnosis of aortic stenosis under the above circumstances. Acute aortic incompetence as a cause of a low-output state, may also be missed as the aortic diastolic murmur is short (due to high left ventricular end-diastolic pressures), and the left ventricle is not enlarged. The diagnosis is confirmed by echocardiography, and by catheter studies on the heart.

Cardiogenic shock can be mistaken for—

1. *Shock due to a severe internal bleed* A common site for an internal bleed is the GI tract. The bleed may not be evident for some hours, and blood loss for the first 6–12 hours is not manifested by an appreciable fall in the hemoglobin or the hematocrit. The diagnosis is particularly difficult when a large occult bleed in an elderly individual causes prolonged ischemic cardiac pain with ST-T changes in the ECG. The diagnosis is however obvious when there is malena or there is massive bleeding from the rectum or when the gastric aspirate through the nasogastric tube contains blood. A ruptured aortic aneurysm can also produce a rapidly evolving hypovolemic shock that may be mistaken for CS. A clinical examination however will always reveal collapsed neck veins in the former. Quick investigations should localize the source of bleeding. In difficult cases, a hemodynamic profile [low central venous pressure (CVP) and low pulmonary capillary wedge pressure (PCWP)] obtained through a Swan-Ganz catheter can confirm hypovolemia as the cause of shock.
2. *Massive pulmonary embolism* It produces the picture of CS. The ECG may simulate a myocardial infarct because of evidence of subendocardial injury. A S1Q3 pattern, right bundle branch block, a right ventricular strain pattern with a P pulmonale and clockwise rotation should point to a correct diagnosis. Pressure readings show a raised CVP, a high pulmonary artery (PA) end-diastolic pressure and a low to normal PCWP.
3. *Dissecting aneurysm of the aorta* A dissection of the thoracic aorta can result in pain indistinguishable from an acute MI and a picture of rapidly evolving shock. A suspicion of this diagnosis is aroused when the patient complains of excruciating pain chiefly in the back, and the ECG does not reveal the typical changes of infarction. An echocardiogram would help in the diagnosis; a computed tomography (CT) or magnetic resonance imaging (MRI) of the chest is a confirmatory test.
4. *Cardiac tamponade* It is characterized by an increasing heart rate, a rising CVP and a falling blood pressure. A PA catheter reveals an equilibration in the mean right atrial, PA diastolic and PCWPs.
5. Other conditions which mimic CS are hypotension following drugs, and septic shock, where the source of sepsis is not evident, and where there is an associated severe myocardial dysfunction. Shock following acute fulminant pancreatitis can also mimic CS, especially when the former is associated with grossly abnormal ST segment changes in the ECG. A full clinical examination and an evaluation of basic investigations point to the correct diagnosis.

The emphasis in the diagnosis of CS should be on the early recognition of signs of reduced tissue perfusion. Thus a patient with MI who has an unexplained change in the pulse rate, pulse volume, blood pressure, urine output or skin temperature is suspect as being in preshock, even though the clinical features do not fulfill the criteria listed above.

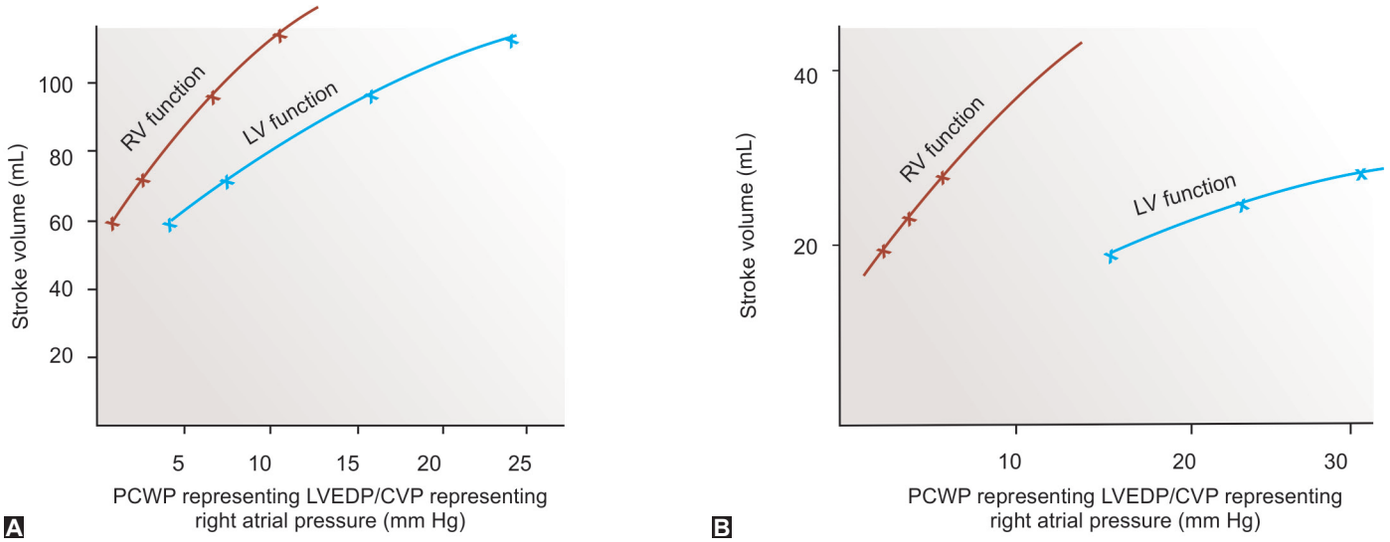
HEMODYNAMIC CHANGES AND HEMODYNAMIC PROFILE

A failure of pump function is followed by a failure of forward flow, resulting in poor perfusion and poor tissue oxygenation. This is the essence of CS. A failure of pump function of the left ventricle is also associated with increased LV end-diastolic pressure, increased left atrial pressure and increased PCWP. When the latter clearly exceeds the oncotic pressure exerted by the plasma proteins, pulmonary edema results. The picture of CS as has been explained below is associated with the following hemodynamic effects and profiles.

Hypoperfusion and Pulmonary Edema

Varying degrees of hypoperfusion ranging from moderate to very severe with varying degrees of pulmonary edema ranging from moderate to fulminant are observed (Figs 2A and B). The severest form of this situation is exemplified by a patient who is pulseless, pressureless, anuric, hypothermic with lactic acid acidosis and with evidence of failure of other vital organs due to very poor forward flow and perfusion; fulminant pulmonary edema is simultaneously present. Death in such instances is inevitable. However, as explained, varying gradations in both tissue hypoperfusion and in the degree of pulmonary edema are encountered. The hemodynamic profile shows the following—

- Normal or elevated CVP.
- Increase in PCWP greater than 18 mm Hg—the greater the rise in PCWP, the greater the degree of pulmonary edema. Fulminant edema is generally associated with a PCWP approaching or exceeding 30 mm Hg.
- A lowered CI less than 2.5 L/min/m^2—the lower the CI, the poorer the tissue perfusion. In very severe cases, the CI is less than 1.8 L/min/m^2 and terminally may even approach 1 L/min/m^2. In patients with early CS, the CI may only be slightly less than normal because of compensatory mechanisms.
- A systolic blood pressure often less than 90 mm Hg. In early or evolving shock, the blood pressure may be maintained at or above 100 mm Hg because of a raised SVR. In severe



Figs 2A and B: (A) Normal right and left ventricular function curves in a healthy volunteer as plotted by stroke volume against PCWP/CVP; (B) Right and left ventricular function curves in a patient with cardiogenic shock due to massive anterior wall infarction. Note (i) the wide separation of the RV and LV function curves resulting in a susceptibility to pulmonary edema; (ii) the marked flattening in the LV function curve resulting in poor forward flow with poor tissue perfusion and shock

shock with failure of forward flow, the systolic blood pressure is less than 70 mm Hg.

- A raised SVR—this is a compensatory mechanism to keep the blood pressure close to normal.

Isolated Hypoperfusion

It is very important to realize that pump failure should not necessarily be equated solely to increasing PCWP and pulmonary edema. In fact, pump failure may be solely characterized by poor flow of blood in the forward direction from the left ventricle causing severe shock, without a rise in the PCWP to an extent that leads to pulmonary edema. This was beautifully illustrated by Bradley, in his excellent small book on Studies in Acute Heart Failure.[19] Bradley showed through his hemodynamic studies, that when right ventricular function curves (representing stroke volume equations) were severely depressed and shifted to the right so that they overlapped the LV function curves, the lungs were protected from pulmonary edema, even though the patient was in shock. We were subsequently able to demonstrate this on our patients as well. The stroke volume equations of the right and left ventricles in these patients are illustrated in Figure 3.

The hemodynamic profile in patients with shock due to isolated hypoperfusion is as follows—

- Increase in mean atrial pressure or CVP.
- PCWP less than or equal to 15 mm Hg.
- Low CI less than 2.2 L/min/m^2 and often below 1.8 L/min/m^2.
- Hypotension with systolic BP less than 70–90 mm Hg.
- Increase in SVR.

The above hemodynamic effects and profile can be brought about in the following conditions—

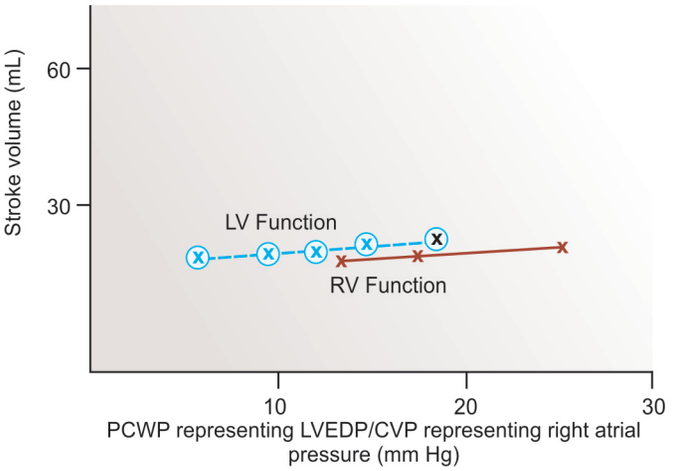


Fig. 3: Right and left ventricular function curves in a patient with myocardial infarction and cardiogenic shock with extremely poor perfusion and shock but no pulmonary edema. Note (i) The flattening of both right and left ventricular function curves resulting in poor perfusion and shock; (ii) The right ventricular function curve overlaps, and is below and to the right of the left ventricular function curve, in contrast to the normal curves. The relation between right and left atrial pressure is such that the patient is protected from pulmonary edema. This is observed in a global infarct (right and left ventricular wall involved), and in a massive anterior wall (LV) infarct with severely depressed right ventricular function

- A global infarct when the LV wall as well as the right ventricle are both infarcted and the right ventricular function curve is even below the LV function curve.
- An infarct of the LV wall where the overall pump function of not only the left ventricle but also of the right ventricle is grossly disturbed. This occurrence stresses the importance

6

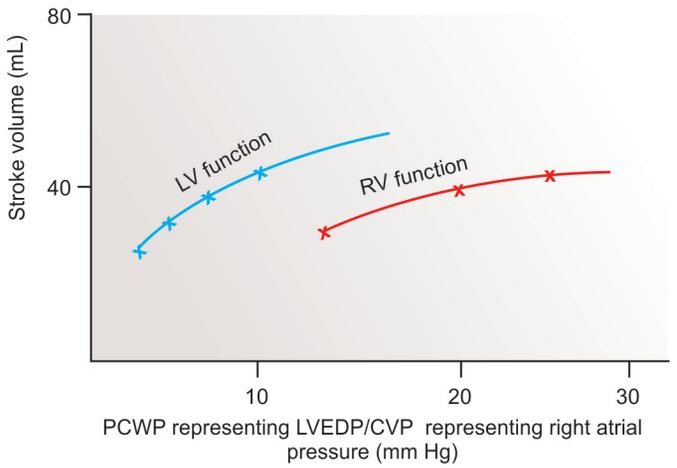

Fig. 4: Right and left ventricular function curves in a patient with inferior wall infarction and cardiogenic shock, but no pulmonary edema. Note right ventricular function curve is flattened and transposed below and to the right of the left ventricular function curve. Relation between right and left artial pressures is such that the patient is protected from pulmonary edema

of not always considering the heart to be consisting of two separate pumps (the right and the left), but as an overall, single, interdependent functioning unit so that gross disturbance in the left side can also affect the function of the right heart. Perhaps this is because of the septal wall which is common to the left and right ventricles; poor function consequent to a massive septal infarct would affect both ventricles. A further contributory factor is that even though the left ventricle may be infarcted, right ventricular function may be seriously prejudiced because of overall global ischemia. This is generally related to critical narrowing of the right coronary artery with poor collateral flow from the branches of a blocked left anterior descending artery to the right coronary vessels, and also to a falling aortic pressure leading to a poor circulation through the right coronary artery.

- In pure severe right ventricular infarction, the hemodynamic profile shows a marked increase in the CVP or in the mean right atrial pressure, a normal or low PCWP, a marked fall in the CI to less than 2 L/min/m^2, and severe hypotension with a rise in the SVR (Fig. 4).

Hypovolemia and Pump Failure

The association of hypovolemia with pump failure also adds a new dimension to the hemodynamic profile of pump failure. Typically hypovolemia in these patients as stated earlier, results from a combination of vomiting, very poor fluid intake or the use of diuretics. It could also be due to blood loss from a complicating bowel infarction.

The hemodynamic profile shows—

- A lowered CVP.
- A PCWP less than or equal to 15 mm Hg.
- Lowered CI of less than 2.5 or even less than 2.2 L/min/m^2.
- Hypotension, systolic pressure less than or equal to 90 mm Hg with an increased SVR.

A volume load enough to raise the PCWP greater than or equal to 18 mm Hg raises the CI significantly, yet the degree of rise is far less than what would be expected with normal pump function.

In fact poor pump function becomes unmasked when the volume load raises the PCWP to 15–18 mm Hg.

Special Hemodynamic Profiles

Complications of MI like a ruptured ventricular septum or a ruptured papillary muscle produce distinct hemodynamic profiles. Thus a ruptured ventricular septum is associated with—

- Rise in CVP and right atrial pressure.
- Rise in pulmonary systolic and diastolic pressures.
- A rise in PCWP greater than 18 mm Hg to often as high as 30 mm Hg.
- Fall in CI less than 2.2 L/min/m^2.
- Arterialization of blood sampled from the right ventricle and PA (i.e. a marked step-up of O_2 saturation of blood from the right ventricle and PA compared to blood in the superior vena cava or right atrium).

Papillary muscle dysfunction will show a high PCWP, a low CI, hypotension and prominent "v" waves with characteristic morphology in pressure tracings obtained from the PA and PA occlusive sites.

Various hemodynamic profiles described above are detailed in Table 1.

Treatment (Box 3)

Currently, the management of CS in acute MI is to improve the patient's hemodynamic profile so that prompt diagnostic testing and intervention, whenever possible, either through percutaneous intervention (percutaneous angioplasty and stenting) or in carefully selected cases through bypass surgery become feasible. Improvement in the hemodynamic profile and the general circulatory state is brought about by the immediate use of medical measures outlined in this section, and by using the support of the Intra Aortic Balloon Counterpulsation (IABP). The latter assist device should be used early and not late in the management of severe CS. In fact, in patients admitted to the intensive care unit (ICU) with severe CS, aortic balloon pump support must be used promptly, *pari passu* with other medical treatment outlined below. The above policy is only possible in an ideal set-up which has trained medical and paramedical personnel, good monitoring facilities, an intra-aortic balloon support and an infrastructure that provides for diagnostic angiography, PCI and coronary artery bypass surgery if so required, promptly or very soon after a patient's admission. There are perhaps very few centers in India and other developing countries which provide this perfect set-up. Yet as is explained later in this

Table 1: Hemodynamic (HD) profiles in cardiogenic shock

HD Profiles	*CVP (mm Hg)*	*SBP (mm Hg)*	*CI (L/min/m²)*	*PCWP (mm Hg)*	*SVR (dynes-sec/cm⁵)*
Hypoperfusion with pulmonary edema	Normal or↑	<90	< 2.2	20–30 or more	↑ to ↑↑↑
Isolated hypoperfusion (global infarct)	↑ or ↑↑	<70–90	< 2.2	≤15	↑ to ↑↑↑
Hypoperfusion with severe right ventricular infarction	↑↑	<70–90	< 2.2	<15	↑ to ↑↑↑
Hypovolemia with pump failure	Normal or low	<90	< 2.2	≤15	↑ to ↑↑↑
Ruptured ventricular septum or papillary muscle	↑↑	<90	< 2.2	>15; may be 20–30	↑ to ↑↑↑

Abbreviations: HD, hemodynamic; CVP, central venous pressure; SBP, systolic blood pressure; CI, cardiac input; PCWP, pulmonary capillary wedge pressure; SVR, systemic vascular resistance.

Box 3: Principles of management in cardiogenic shock

Objective

Improve hemodynamic profile to an acceptable state, through pharmacological measures + use of IABP so that diagnostic testing and intervention, whenever possible through angioplasty, or through surgery, become feasible

Pharmacological measures to improve hemodynamics—

a. Maximizing preload: Volume challenge if PCWP is less than 15 mm Hg—
   - Increase PCWP to 18–20 mm Hg or even more provided there is no pulmonary edema

b. Use of vasodilators—IV nitroglycerin in patients with high PCWP and well-marked pulmonary edema (reduce PCWP to 15–18 mm Hg)

c. Increasing cardiac contractility—
   - Dobutamine or dopamine by IV infusion or both
   - Digoxin; other inotropes in rare instances

d. Judiciously combine a, b and c

e. Use of noradrenaline if hypotension persists in spite of use of dopamine (>10 ug/kg/min)

f. IV furosemide combined with b and c if there is pulmonary edema

g. Maintain oxygenation—administer oxygen at flow rate of 6–8 L/min. If PaO_2 still less than 60 mm Hg, or if respiratory distress (rate >35/min), intubate and put on ventilator support

h. Correction of electrolyte and acid-base abnormalities

i. Correction of factors aggravating cardiogenic shock

Abbreviations: PCWP, pulmonary capillary wedge pressure; IABP, intra-aortic balloon pump; IV, intravenous.

section, though mortality increases as time to revascularize increases, *there is a survival benefit following revascularization as long as 48 hours after MI and 18 hours after the onset of CS.*[20]

Where facilities for interventional revascularization are unavailable or too delayed, pharmacological measures together with an intra-aortic balloon support offer the only chance for survival. Hemodynamic management through pharmacological measures instituted at the time of admission continues through interventional therapy, and well after, till recovery ensues.

This section first deals with monitoring procedures in CS, then with management of CS with emphasis on pharmacological measures complemented by the use of IABP device to help restore hemodynamic stability. It goes on to discuss reperfusion and revascularization in CS and the evidence to show that the earlier the reperfusion through interventional procedures, the better the outcome. There follows a brief description of ventricular assist devices and the management of CS due to mechanical complications following MI. The section ends with a brief description on long-term survival and quality of life after surviving CS.

MONITORING THE PATIENT IN CARDIOGENIC SHOCK[1]

Half-hourly pulse, and two to four hourly skin and rectal temperature, as well as hourly urine output through an indwelling Foley's catheter should be charted. The blood pressure may need to be checked very frequently and in patients with clinical evidence of peripheral vasoconstriction, it is important to cannulate the radial artery and connect the cannula or catheter to a pressure monitor so that correct pressure readings are obtained and recorded. The ECG is continuously monitored. The blood count, packed cell volume (PCV), serum electrolytes, blood urea, non protein nitrogen (NPN), creatinine, blood lactate levels, other blood chemistry, arterial pH and arterial blood gases are done on admission and repeated as and when necessary. A chest X-ray is mandatory, and follow-up X-rays are done to check in particular for radiological evidence of pulmonary edema. Both the CVP and the oxygen saturation of blood in the superior vena cava ($ScvO_2$) are continuously monitored through a central venous catheter; arterial oxygen saturation is also continuously monitored. In a number of patients detailed hemodynamic monitoring (often through the use of

Box 4: Monitoring patients in cardiogenic shock

- Half-hourly heart rate, blood pressure and respiratory rate
- Hourly skin and rectal temperature; clinical monitoring
- Hourly urine output through indwelling catheter
- Continuous ECG monitoring
- Blood count, serum biochemistry, arterial pH and arterial blood gases done on admission and repeated as and when necessary
- Chest X-ray
- Hemodynamic monitoring—
  - Central venous pressure
  - Pulmonary artery pressures—pulmonary artery end-diastolic pressure, pulmonary capillary wedge pressure
  - Cardiac output, cardiac index, stroke volume index, systemic vascular resistance, left and right ventricular stroke work indices
  - DO_2, $\dot{V}O_2$

PA catheter) is helpful (Box 4). Hemodynamic measurements should be done only by intensivists who are experienced both in noting correct measurements and in the assessment of values obtained.

Clinical monitoring is extremely important with particular reference to all signs of shock (see Clinical Features). These should include respiration, pulse volume and rate, CVP, mental state, respiratory rate and the degree of pulmonary congestion as judged by crackles on auscultation and by assessment of serial chest X-rays.

Central Venous Pressure

It is important to learn to gauge CVP on clinical examination. In fact, one should easily recognize a raised or normal jugular venous pressure (JVP); with a little practice one should also detect a low JVP. But for an accurate measurement of the CVP, a central venous line connected to a pressure monitor is necessary. If a pressure monitor is unavailable, the central line is connected through a bivalve to a water manometer. The zero level measurement is in the plane of the mid-axillary line, midway between the sternum and the back. Many units in the country cannot afford the use of PA catheters with the gadgetry to measure right-sided pressures, PCWP and CO; but a central venous line can be easily arranged with a bare minimum of facilities.

Left Ventricular Filling Pressure

The preload is ideally determined by measuring the end-diastolic volume. This is difficult in an ICU setting in a patient with MI. A practical method of gauging the preload is by measuring the PA end-diastolic pressure, which in MI approximates the pulmonary occlusive or the PCWP. The latter in turn, corresponds reasonably with the LV filling pressure. The compliance of the ventricular wall in MI may be decreased so that the relation between the filling pressure and the end-diastolic volume is altered (see Chapter Overview of Shock Syndromes). Even so, measurement of the PA diastolic pressure or the PCWP remains the most readily available method of gauging preload in these patients. Serial measurements are of greater value than isolated readings. It is important to stress that the CVP cannot be relied upon to give an idea of the LV filling pressure in CS. The CVP may in fact be perfectly normal in some patients even though the left ventricular filling pressures are markedly raised.

Cardiac Output

Ideally all patients with CS should have their CO measured and monitored. Serial measurements of CO are made through the Swan-Ganz (S-G) catheter using the thermodilution technique. Samples of mixed venous blood from the PA are also serially obtained through the S-G catheter. A lowered pressure of mixed venous oxygen (PvO_2) or a lowered mixed venous oxygen saturation ($S\dot{v}O_2$) points to a lowered CO. Serial values of $ScvO_2$ help to indicate the trend in changing CO (see Chapter Hypovolemic and Hemorrhagic Shock). Filling pressures of the left ventricle, CO, SVR, stroke volume, stroke work, are often measured through a PA catheter or S-G catheter. The use of the PA catheter has declined significantly following a prospective observational study that its use was associated with a poor outcome.[21] However, no such association has been shown in CS.[22] Many units continue to use the PA catheter in CS with severe hypotension. Clinical echocardiography is a reasonable alternative as both PA systolic and wedge pressure can be accurately measured by this modality. In particular, the finding of a short mitral decelerating time is highly predictive of PCWP greater than 20 mm Hg in CS.[23]

There are comparatively few centers in developing countries including India, that can afford the luxury of measuring CO. When facilities are lacking, changes in the CO should be clinically gauged by observing changes in tissue perfusion, blood pressure, urine output and changes in the function of other vital organs. Clinical examination and chest radiographs help in roughly assessing PCWP in about 70% of patients with CS.

Management[1]

General Measures

Antithrombotic therapy with aspirin and heparin should be given in patients with CS as is routinely recommended for MI. Clopidogrel is indicated in all patients who undergo PCI. The patient is given high flow oxygen, is closely monitored, while at the same time preparations are made to promptly insert an intra-aortic balloon counterpulsation device (IABP) in all hypotensive patients. Blood sugars are brought under tight control (<140 mg/dL) with the use of insulin.

Pharmacological Treatment to Restore Hemodynamic Stability

Increasing CO and improving tissue perfusion This is the basic principle and forms the essence of therapy. Factors which determine CO are—

- End-diastolic fiber length, i.e. end-diastolic volume or preload. Roughly in clinical practice (with the exceptions stated above), this is equated to the filling pressure of the ventricles, which in turn (with regard to the left ventricle) is equated to the measured PA end-diastolic pressure or the measured PCWP.
- Contractility of the ventricular muscles.
- Heart rate and rhythm.
- Afterload. In MI this is clinically related (again roughly) to the outflow resistance offered by the constricted peripheral vessels.

Management should be directed to the skillful manipulation of the factors stated above so that CO and perfusion improve.

Maximizing Preload

It has been shown that the optimal filling pressures of the left ventricle in shock following MI, range between 15–24 mm Hg.[4] If therefore in a hypotensive shocked patient the PCWP is normal to low (< 15 mm Hg), and the CVP is also low or on the lower side of normal, the patient is hypovolemic for some reason and needs a volume load. Boluses of 300 mL of dextrose saline or Ringer Lactate are rapidly infused over 30 minutes till such time as the low blood pressure and other signs of shock improve. One should aim to maintain a pulmonary artery end-diastolic pressure (PAEDP) or PCWP between 18–20 mm Hg. The degree to which CO, blood pressure and signs of shock improve will depend on the underlying myocardial dysfunction. If hypovolemia is a significant contributory factor in shock, then increasing the preload (PCWP or PAEDP) will produce a significant improvement in the CO, blood pressure and the clinical features of shock. If on the other hand, hypovolemia is a minor or incidental finding, then raising the PCWP to 18–20 mm Hg may produce only a slight improvement in the CO and blood pressure, thus unmasking the severity of underlying myocardial dysfunction.

If to start with the PAEDP or the PCWP is less than 20 mm Hg, one may still maximize the preload by judiciously pushing IV fluids so that the PAEDP increases to around 20 mm Hg. The patient should however be under constant clinical and frequent radiological monitoring, to determine increasing crackles within the lungs and increasing radiological evidence of pulmonary edema. Some degree of pulmonary edema may be acceptable if improvement in CO and tissue perfusion is obviously manifest. In our experience in Mumbai, India, in most patients with CS the optimum PAEDP is between 15 and 20 mm Hg, these values being a little lower than those reported from the West. However, the relation of optimal filling pressure to optimal CO should be individualized as this relationship may vary from patient to patient. If during the process of maximizing the preload frank pulmonary edema ensues, the volume challenge is stopped and 40–100 mg IV furosemide administered intravenously.

If an increase in the PAEDP to above 20 mm Hg brings no improvement in either the CO or tissue perfusion (ideally gauged both clinically and by sequential CO measurements), then further management consists of the manipulation of the afterload and cardiac contractility. Also, if to start with the PAEDP is very high (well above 20 mm Hg), volume infusion is pointless and will only add to the existing pulmonary edema, without increasing the CO or tissue perfusion. In such cases, measures to reduce a very high preload to optimal levels, and measures to improve cardiac contractility, should immediately be resorted to. IV furosemide should also be given to decrease preload and reduce pulmonary edema.

Use of Vasodilators

If the hemodynamic profile shows a raised PAEDP (> 18–20 mm Hg), a systolic blood pressure greater than or equal to 90 mm Hg, a lowered cardiac index and systemic hypoperfusion, vasodilator therapy is indicated.

Vasodilators reduce the abnormally high preload and afterload, thereby improving pump function. The fall in peripheral resistance improves CO (as the outflow impedance is significantly reduced), and therefore in many patients there is no significant fall in blood pressure. Even when there is a slight fall in arterial blood pressure, the tissue perfusion may well improve, as judged clinically. Nitrites chiefly reduce the preload and have a much smaller effect on the afterload. With a marked increase in PAEDP and frank pulmonary edema, IV nitroglycerin (0.3–4 µg/kg per minutes) is the drug of choice. The initial dose of nitroglycerin should be 10 µg/minute given through a microdrip. This is gradually increased till the optimal effects are achieved. The end-point here is a PAEDP of about 15–18 mm Hg. The infusion may have to be stopped or sharply reduced if there is a significant reduction in the systolic blood pressure. Tachycardia and severe headache are important side effects of nitroglycerin. Unfortunately, tolerance to nitroglycerin is observed within 24–72 hours. Once the patient's hemodynamic profile has improved, the patient is switched to oral nitrites.

Sodium nitroprusside is no longer used as a vasodilator in CS. It can cause a disastrous crash in the blood pressure even in carefully titrated doses. The drug causes marked arterial vasodilatation at the level of the resistance vessels. This can result in a coronary steal syndrome with further ischemic insult to the already damaged myocardium.[24] Use of sodium nitroprusside can also cause cyanide poisoning with metabolic acidosis. The toxic effect is not as uncommon as was previously thought.

Use of vasodilator therapy is difficult without adequate monitoring facilities—an arterial cannula in the radial artery, an S-G catheter to monitor PAEDP or PCWP, and if possible the CO. It is also imperative to control and monitor the infusion rate if disaster is to be avoided.

Increasing cardiac contractibility When the hemodynamic profile of a patient in CS shows hypotension (systolic BP between 70 and 90 mm Hg or even lower) a reduced CI, a raised PCWP (well >20 mm Hg) with increased SVR and poor tissue perfusion, inotropic drugs must be used to improve

cardiac contractility. As far as possible it is unwise to use inotropic drugs before first determining the CVP and the PAEDP which means that it is wrong to use inotropic drugs without first determining whether volume loading by IV infusion would be helpful or not (except of course in patients who have frank pulmonary edema). Inotropic drugs often produce both central and venous constriction (by increasing venous tone) thereby raising the CVP, and also at times pulmonary venous constriction, thereby raising the PAEDP. A wrong picture of iatrogenically induced high filling pressure may then be obtained after the use of inotropic drugs, and the major therapeutic intervention of increasing effective circulatory volume is CS may not be availed of.

Use of inotropes and vasopressors[25] The inotropic drugs most frequently used to augment cardiac contractility are dopamine and dobutamine.

1. *Dopamine* is perhaps the drug most frequently used to start with. Dopamine combines powerful inotropic properties with vasopressor properties (due to stimulation of alpha receptors) and effectively raises perfusion pressure. It is started with a dose of 5 ug/kg per minute and the dose is progressively increased every 10–15 minutes (to a maximum of 20–30 ug/kg per minute) till the systemic arterial blood pressure rises to acceptable levels (mean arterial blood pressure 65–70 mm Hg) for a reasonable perfusion to the brain and myocardium. Cerebral and renal perfusion necessitate a systolic perfusion pressure of more than 75–80 mm Hg; adequate coronary perfusion necessitates a systemic diastolic pressure of 65 mm Hg with a LV filling pressure of 15 mm Hg. An unfortunate side-effect of dopamine and other inotropes observed in some patients is tachycardia and arrhythmias which prevent the administration of an appropriate dose.

2. *Dobutamine* When hypotension is not marked (between 80 and 100 mm Hg) some units prefer to start with dobutamine given at an infusion rate of 2–15 ug/kg per minute. Dobutamine improves stroke volume, CO and ventricular performance. The overall improvement in ventricular performance and function leads to decreased ventricular filling pressures. Dobutamine increases systolic blood pressure through its effect on the stroke volume and pulse pressure, thereby, improving peripheral tissue perfusion. At the same time it directly reduces ventricular afterload and wall stress by a direct reduction in systemic and pulmonary vascular resistances, ventricular systolic volume and ventricular filling pressures.[26] Dobutamine increases diastolic time (through a reduced systolic time), and increases perfusion pressure through the coronaries thereby leading to increased myocardial oxygen supply, when this is vitally necessary.[26] These effects have been proven in animal experiments and in humans with ischemic heart disease.[26] Dobutamine should be started at an infusion rate of 2–3 µg/kg per minute and the rate progressively increased till the patient improves hemodynamically and remains stable.

A combination of dopamine and dobutamine is often necessary to help improve the hemodynamic state.

If, however, dopamine alone or even a combination of dopamine and dobutamine fail to raise the pressure and improve the hemodynamic state, noradrenaline is added in an IV infusion at the rate of 2–5 µg per minute, slowly increasing the dose to obtain a satisfactory systolic pressure. Both dopamine in a dose greater than 10 ug/kg per minute and noradrenaline are strong vasoconstrictors; large doses of these vasopressors may worsen tissue perfusion and aggravate shock. Large doses can also markedly increase the afterload and thereby further compromise cardiac function. An absent or poor response to inotropes and vasopressors is associated with a mortality greater than 90%. Dopamine in doses greater than 30 ug/kg per minute and noradrenaline in a dose greater than 30 µg per minute are likely to do more harm than good.

3. *Digoxin* is probably of little value in the management of CS except for the control of a rapid ventricular rate resulting from atrial fibrillation. It may also be used when LV failure is chiefly characterized by pulmonary edema rather than by poor tissue perfusion. A dose of 0.25 mg is given intravenously and repeated 6 hourly till a digitalizing dose of 0.75 mg to a maximum of 1 mg is reached.

4. *Other Inotropes* Amrinone is a far weaker inotrope as compared to dopamine or dobutamine. It increases cardiac contractility independently of catechol pathways. It is believed to act by increasing cAMP and calcium concentrations. The increased cAMP in smooth muscles decreases peripheral and pulmonary vascular resistances as also resistance in the coronary circulation. It increases stroke volume without producing a tachycardia. The initial dose is 0.75 mg/kg given over 5 minutes, followed by an infusion of the drug at 5–10 µg/kg per minute. The total daily dose should not exceed 10 mg/kg. A combination of dobutamine plus amrinone is often employed immediately after bypass surgery to counter myocardial depression in patients who to start with have a poor ejection fraction.

Glucagon is an inotrope which increases cardiac contractility and decreases peripheral resistance. The dose is 4–6 mg intravenously in a bolus followed by an infusion of the drug at a rate of 4–12 mg/hour. It could be used when dopamine or dobutamine fails to change the hemodynamic effects of severe CS or when dysrhythmias develop. Glucagon may be particularly useful when depressed LV function is related to the previous use of beta-blockers. Glucagon could induce well-marked hyperglycemia as a side effect.

A list of commonly used inotropic drugs with their doses and site of action is given in Table 2 (Box 5).

Combination of Inotropic Drugs and Vasodilator Therapy

Vasodilator therapy comprising of IV nitroglycerin can be combined with dopamine or dobutamine in a dose sufficient to allow of the benefits of vasodilatation and yet maintain an adequate systolic perfusion pressure of 90–100 mm Hg. Close monitoring of the PAEDP, arterial blood pressure, CO, tissue perfusion and the infusion rates of drugs is mandatory.

Table 2: Commonly used inotropic drugs with their doses and site of action

	Dopamine	*Dobutamine*	*Norepinephrine*	*Vasopressin*
Clinical indication	Cardiogenic shock, Vasodilatory shock, HF, Symptomatic bradycardia unresponsive to atropine or pacing	Low CO (decompensated HF, cardiogenic shock, sepsis induced myocardial dysfunction) Symptomatic bradycardia unresponsive to atropine or pacing	Shock (vasodilatory, cardiogenic)	Shock (vasodilatory, cardiogenic) Cardiac arrest
Dose range	2.0 to 20 µg/kg/min (max 50 µg)	2.0 to 20 µg/kg/min (max 40 µg)	8–30 µg/min	Infusion: 0.01 to 0.1 U/min (common fixed dose 0.04 U/min) Bolus: 40-U IV
Receptor Binding				
α_1	+ + +	+	+ + + + +	N/A
β_1	+ + + +	+ + + + +	+ + +	N/A
β_2	+ +	+ + +	+ +	N/A
DA	+ + + + +	N/A	N/A	N/A
V_1	N/A	N/A	N/A	+
V_2	N/A	N/A	N/A	+
Major side effects	Severe hypertension (especially in patients taking nonselective β-blockers), ventricular arrhythmias, cardiac ischemia, tissue ischemia/gangrene (high doses or due to tissue extravasation	Tachycardia, increased ventricular response rate in patients with atrial fibrillation, ventricular arrhythmias cardiac ischemia, hypertension (especially nonselective β- blocked patients) hypotension	Arrhythmias, bradycardia, peripheral (digital) ischemia, hypertension (especially nonselective β- blocked patients)	Arrhythmias, hypertension, decreased CO (at doses > 0.4 U/min), cardiac ischemia. Severe peripheral vasoconstriction causing ischemia (especially skin) Splanchnic vasoconstriction

V_1, receptors (vascular smooth muscle); V_2, receptors (renal collecting duct system); DA, Dopamine receptors
Abbreviations: CO, cardiac output; HF, heart failure.

Box 5: Management of fulminant pulmonary edema in cardiogenic shock

- Morphine 2–5 mg IV
- Reduce preload with IV nitroglycerin
- Increase cardiac contractility with inotropic support (dopamine, dobutamine)
- IV furosemide 100–250 mg, repeated if necessary or titrated IV infusion
- Combat hypotension with a titrated dose of noradrenaline (if necessary)
- Intubate and put on ventilator support with a high FiO_2

Abbreviation: IV, intravenous.

Use of Diuretics

Pulmonary edema warrants the use of an appropriate dose of furosemide either given as a bolus dose or a titrated IV infusion at the rate of 10–40 mg/hour. It is important to realize that following diuresis, the filling pressures of the left ventricle may fall to a point where the CO is further lowered, with a further drop in tissue perfusion. The filling pressure of the left ventricle should not be allowed to fall below 15–18 mm Hg.

Intra-aortic Balloon Counterpulsation (IABP)[1]

Severe CS characterized by marked hypotension, a very low CO and poor tissue perfusion is unlikely to respond to pharmacological measures described. Mechanical support with IABP should always complement and supplement these pharmacological measures.

Intra-aortic balloon counterpulsation should be instituted as quickly as possible *pari passu* with pharmacological measures, if possible even before transfer for diagnostic and therapeutic intervention to establish reperfusion. In the large National Registry of Myocardial Infraction, IABP was independently associated with survival at centers with higher rates of IABP use, whether PCI, fibrinolytic therapy or no reperfusion had been used.[27] Major complications occurred in 2.8%;[28] risk factors for complications include female sex, small body size, peripheral vascular disease.

Maintaining Oxygenation

It is important to ensure proper oxygenation by administering oxygen at a flow rate of 6–8 L/minute. A PaO_2 of less than 60 mm Hg, or respiratory distress, respiratory rate greater than 35/minute are clear indications for intubation and ventilator support. In fact, severe shock itself is an indication for respiratory support. Mechanical ventilation rests respiratory

muscles and reduces the oxygen cost of breathing, thus enabling oxygen to be used by the vital organs of the body. It also ensures adequate oxygenation and helps combat severe pulmonary edema. The FiO_2 should be set to allow oxygen saturation over 95%. Positive end-expiratory pressure (PEEP) should, if possible, be gradually increased, provided there is no marked hypotension, watching its effect on the blood pressure.

Correction of Electrolytes and Acid-Base Balance

Metabolic acidosis (lactic acidosis) is frequently observed and is due to poor tissue perfusion. Acidosis improves when tissue perfusion improves. If the pH is less than 7.25, it may need correction with an appropriate dose of IV sodium bicarbonate. A PaO_2 greater than 70 mm Hg should be maintained through the use of ventilator support using a high FiO_2 and PEEP. Increasing metabolic acidosis leads to cellular injury and further impairs myocardial function. Hypokalemia predisposes to ventricular dysrhythmias including ventricular tachycardia and fibrillation.

Correction of Factors that Aggravate Shock

Hypotension in MI may be potentiated by severe unrelieved pain, or it could also be partly related to the overuse of IV morphine or pethidine, sedatives and tranquillizers. Excessive use of diuretics can cause hypovolemia and hypokalemia leading to hypotension and weakness. Both supraventricular and in particular ventricular arrhythmias with fast ventricular rates need to be recognized and treated with drugs or if the need arises, by electroversion. Arrhythmias can cause a serious deterioration in the hemodynamic profile of such individuals. Bradyarrhythmias due to inferior wall infarction when marked, cause a sharp fall in CO and need to be corrected by IV atropine or by pacing. Persistent mild hypoxia can aggravate the dangers of hypotension as it is associated with decreased oxygen transport to tissues. The oxygen saturation must be maintained well over 90%. The danger of nosocomial infection is always present in a shock state particularly in patients with pulmonary edema who are on ventilator support. Such infections can tilt the balance against a patient who could have otherwise recovered. Finally, the deleterious hemodynamic changes produced by dysfunction and death of the myocardial wall can worsen into an irreversible state following a complicating pulmonary embolism. This may be difficult to diagnose against the background of CS. Pulmonary embolism if sufficiently severe is characterized by a high CVP, a high PAEDP and a PCWP which is significantly lower than the PAEDP. These are some of the contributory factors which singly or in combination can worsen the severity of shock in MI.

A great deal of attention continues to be paid over the last many years at attempts at myocardial preservation, i.e. providing better blood supply to ischemic muscle surrounding an area of infarction and thereby preventing ischemic muscle from undergoing further damage or death. Improvement of blood supply to ischemic muscle should improve pump function and help in relieving the state of shock. This in principle is theoretically sound, but is difficult to translate into practice. There are a number of unknown factors in relation to anatomy, collateral circulation, local blood flow within the coronaries, and metabolic requirements of ischemic or damaged myocardium, that operate in a given individual with MI. The best known method of helping to increase coronary blood flow is by administering an IV nitroglycerin drip which can reduce the work-load of the heart and which directly dilates the coronary vessels. The presence of marked hypotension prevents its use as is often the case. Some units continue to use IV glucose-potassium-insulin infusions (500 mL of 20% dextrose, 20 units insulin, 40 mEq KCl) in the hope that this may improve myocardial function. Short of interventional procedures like angioplasty which opens a culprit lesion within a coronary artery and directly improves blood supply, other methods of myocardial preservation are of dubious value.

Box 6: Monitoring of patients with cardiogenic shock in absence of invasive monitoring facilities

- Measure CVP via central line
- Monitor ECG, BP, heart rate, rhythm, temperature, O_2 saturation, arterial pH and blood gases
- High PAEDP or PCWP evidenced by—
  - CXR showing pulmonary edema
  - Clinically crepitations over lung bases, left ventricular diastolic gallop (audible third heart sound)
- Estimate CO and tissue perfusion clinically by noting—
  - Blood pressure
  - Skin temperature
  - Degree of sweating
  - Volume of peripheral pulse
  - Hourly urine output
  - General sensorium, and absence or presence of lactic acidosis
- Blood lactate level

Abbreviations: CVP, central venous pressure; PAEDP, pulmonary artery end-diastolic pressure; PCWP, pulmonary capillary wedge pressure; CXR, chest X-ray; CO, cardiac output.

Management of Cardiogenic Shock in the Absence of Invasive Monitoring Procedures

Many ICUs or coronary care units in the country lack the facilities to monitor intra-arterial pressure through an intra-arterial cannula, or the PAEDP via the S-G catheter. Facilities for CO measurements are scarce. Fortunately, both gadgetry and technical expertise have improved significantly over the last decade, particularly in the large metropolitan cities. Even so, they are still in short supply (Box 6).

Almost all units can measure the CVP through a central line connected to a water manometer. The JVP can also be gauged clinically from the upper limit of pulsations of the internal jugular vein (with the head and neck elevated to an angle of about 45° from the horizontal). It is good clinical practice to tally the clinical measurement of the JVP with the actual

measurement of the CVP through a central line connected to a pressure gauge or to a manometer. Unfortunately, the CVP does not predict the PAEDP, a normal CVP being invariably associated with a high PAEDP in cases of CS.

A high PAEDP or PCWP is indirectly confirmed thus—

- *Clinically*, by noting the presence or absence of crepitations over the bases.
  If present, the degree and extent of crackles are noted. A LV diastolic gallop is always related to a raised LV filling pressure. An audible third heart sound generally indicates a PAEDP greater than 18 mm Hg.
- *Radiologically*, by a chest X-ray which can diagnose both interstitial and alveolar pulmonary edema. The chest X-ray is vital because on occasions (in about 30% of cases), the radiograph shows clear pulmonary congestion and even pulmonary edema which is not evident on auscultation. Gross pulmonary edema generally signifies a PAEDP greater than 30 mm Hg; varying but gradually increasing degrees of pulmonary edema are observed as the PAEDP rises above 20 mm Hg.

The arterial blood pressure by the cuff method is quite unreliable in the presence of severe vasoconstriction. Pressures may be unobtainable by the cuff method, but on monitoring via an intra-arterial catheter may be shown to be greater than 90 mm Hg. Impalpable radials or even brachials do not therefore signify irreversible shock in these individuals, but if the femorals are impalpable, or are barely felt, it always points to severe hypotensive shock. The CO and tissue perfusion can be judged clinically as best as possible by noting the skin temperature, the degree of sweating, the urine output, volume of peripheral pulses, general sensorium, the presence or absence of lactic acidosis and the overall clinical picture.

In the absence of invasive monitoring facilities, the following approach is recommended for the management of CS—

- Administer oxygen through high flow mask; monitor heat rate, rhythm, ECG tracing, CVP, blood pressure, O_2 saturation, X-ray chest, skin temperature, urine output, serum lactate. Frequent examination of the cardiorespiratory system.
- If there is no clinical and radiological evidence of pulmonary edema, use a volume load to raise the blood pressure and improve tissue perfusion. Stop the volume load when signs of pulmonary congestion become apparent clinically and/or radiologically. Then start on inotropic support and if needs be vasopressor support. If pulmonary congestion progresses to edema, use in addition a titrated dose of furosemide and a titrated dose of IV nitroglycerin.
- If definite well-marked pulmonary edema is already present, use inotropes and vasopressors. A titrated dose of IV nitroglycerin and IV furosemide will help to reduce preload. Fulminant pulmonary edema warrants intubation and mechanical ventilator support. Lesser degree of pulmonary edema may warrant the use of non-invasive ventilator support.

With increasing experience, we have been able to predict the hemodynamic profile on clinical and radiological examination, and by the clinical response to therapeutic measures in 70% of cases. This is a fairly satisfactory correlation with the actual measurement of pressures and CO, and should encourage good patient care in units lacking the monitoring facilities outlined earlier.

Reperfusion through Revascularization

The survival benefit of Early Revascularization (ERV) in CS has been convincingly demonstrated in the randomized SHOCK (Should We Emergently Revascularize Occluded Coronary Arteries for Cardiogenic Shock) trial.[9,20] In this trial, 302 patients with acute myocardial infarct and CS due to predominant LV failure were randomly assigned to an initial medical stabilization (IMS, n = 150) group, which included thrombolysis (63% of patients), intra-aortic balloon counterpulsation (80%) and subsequent revascularization (25%) or to an early revascularization group (ERV) (n = 152) which mandated revascularization within 6 hours of randomization and included angioplasty (55%) and coronary artery bypass graft surgery (35%). Results showed an increased benefit in survival at 1 year in the ERV group. The survival was 46.7% in the ERV group compared to 33.6% in the IMS group. The benefit was however apparent only in patients under 75 years.

Timing of Percutaneous Coronary Intervention

As in MI without shock, earlier revascularization in CS gives better results. Presentation 0–6 hours after symptom onset was associated with a lower mortality among CS patients in which door to angiography time was less than 90 minutes in about three quarter of patients.[29] In the SHOCK trial[9] there was an increase in the long-term mortality as time to revascularization increased from 0–8 hours. *However, as mentioned earlier there is a survival benefit as long as 48 hours after MI and 18 hours after shock onset.*

Stenting and Glycoprotein IIb/IIIa Inhibitors[30]

Stenting and Glycoprotein IIb/IIIa inhibitors have been shown to be independently associated with improved outcome in patients undergoing PCI for CS.

Percutaneous Coronary Intervention or Coronary Artery Bypass Graft Surgery

In the SHOCK trial,[9] 35% of patients in the ERV group underwent CABG at a median of 6 hours after randomization. Survival and quality of life was similar to those who underwent PCI even though the CABG group had a higher triple prevalence of left main disease, triple vessel disease and diabetes compared to the PCI group.

The American College of Cardiology (ACC)/American Heart Association (AHA) guidelines[25] suggest that CABG is

the preferred method of revascularization in left main disease, severe triple vessel disease or in the presence of ventricular septal rupture or severe mitral regurgitation. PCI of the infarct related vessel is recommended in single or double vessel disease or in moderate triple vessel disease or when CABG is not possible for more extensive disease.

In perfect ICU and hospital set-ups, where prompt revascularization is offered to patients with CS following myocardial infarct, the mortality in the modern era is about 25%, far lower than older figure of 80–90%. Among CS patients undergoing PCI, age, time from symptom onset to PCI, post PCI, thrombolysis in myocardial infarction (TIMI) flow grade are independent predictors of mortality. Though ERV is increasingly practiced in Europe and America, developing world figures range from just 27% to 54%.[4]

How do these results in the West apply to conditions in India and other developing countries?

- Early revascularization as described in the SHOCK study is for logistic, economic and other reasons possible in very few units.
- In the present scenario the best possible approach for CS in MI is—
  - To thrombolyze the patient provided he is admitted to the Emergency unit within the first 6– 8 hours.
  - Stabilize the circulation with an aortic-balloon counterpulsation device and by pharmacological measures and then opt for revascularization, either a PCI or a CABG depending on the findings at coronary angiography.

Ventricular Assist Device and Extracorporeal Life Support[1]

Left ventricular assist device (VAD) supports circulation by drawing oxygenated blood from the left side of the heart and returning blood to the systemic arteries with either a pulsatile or continuous flow. This device may allow for recovering of stunned and hibernating myocardium and halt or reverse neurohormonal derangements.

Extracorporeal life support and VAD have been used sequentially as a bridge to cardiac transplant. To what degree these life support systems (even in expert hands) influence outcome is yet uncertain.

Treatment of Cardiogenic Shock due to Mechanical Complications[1]

Mechanical complications of MI in the form of a ruptured ventricular septum, ruptured papillary muscle, ruptured free wall are responsible for 12% of patients who present with or develop CS. Ventricular septal rupture has the worst prognosis, with a mortality of 87%.[31] The risk of these complications is higher with thrombolysis than primary PCI. The above mentioned mechanical complications should be strongly suspected in patients with a small infarct and shock. Both echocardiography and hemodynamic measurements can confirm the diagnosis.

Open heart surgery is advised in patients with mechanical complications. The use of an intra-aortic balloon counterpulsation together with pharmacological measures should help stabilize the circulation at least to some extent. *The sooner these patients are taken up for open heart surgery the better*. Waiting invariably ultimately results in a deteriorating circulatory state with multiple organ failure and a hopeless prognosis. There is a subgroup of patients with ventricular septal defect (VSD) where surgery is avoided because mortality is near 100%; this includes patients more than 75 years of age and those with a poor right ventricular function. Right ventricular function is an even more important determinant of outcome in ventricular septal rupture than LV function.[32,33]

Cardiogenic Shock in Pathologies Caused by Obstruction to Left Ventricular Outflow

Perhaps the commonest of these is tight aortic stenosis where the patient presents with cardiomegaly, absent or a faint systolic murmur in the aortic area and severe failure. The diagnosis can be clinically missed but is evident on an echocardiography. Emergency bypass surgery though carrying a considerable risk may be life saving if successful.

Hypertrophic obstructive cardiomyopathy can present with CS. The recognition of LV outflow obstruction is critical as hypotension in these patients is worsened by the use of diuretics or inotropes since both these agents will worsen obstruction. Treatment of CS due to hypertrophic obstructive cardiomyopathy consists of volume expansion and β-blockers. Pure agonists may be used to increase afterload, thereby increasing LV cavity size and decreasing obstruction.

Outflow obstruction at times causing CS is also observed in a rare condition termed Takotsubo cardiomyopathy which is characterized by extensive akinesia of apical zones with hyperkinesia of the rest of the myocardium, particularly the base. Alpha agonists may be helpful for their vasopressor effect and in severe cases an aortic balloon support device may tide the patient over a crisis. Low dose inotropes with careful monitoring of their effects have also been used.

Long-Term Survival and Quality of Life after Surviving Cardiogenic Shock

Result of the SHOCK trial reveals that 3 year and 6 year survival rates in the ERV group were 41.4% and 32.8% with persistence of treatment benefit.[20]

The quality of life importantly was far better than clinicians would ordinarily suppose. In patients with CS treated with ERV, 80% of survivors were asymptomatic at 18 months and all were in the New York Heart Association Functional Class I and II.

CHAPTER 16

Sepsis and Septic Shock

GENERAL CONSIDERATIONS

Septic shock is the result of overwhelming infection. It can evolve with frightening, suddenness and severity and is frequently lethal. Severe sepsis is the second most important cause of death in intensive care units all over the world. However, sepsis and septic shock occurring from community-acquired infections outnumber sepsis and septic shock due to nosocomial infections. The epidemiological data from our country is lacking, but a recent study showed that 6% of all deaths in the United States from 1999 to 2005 were sepsis related and the age-adjusted rate of sepsis-associated mortality was 50.37 deaths per 100,000.[1] Some idea of the burden of sepsis in low and middle income countries (incidence per 1,000 patients-days) is given below in Table 1.

The mortality in septic shock even in good centers ranges from 40% to 60% despite the advances in antimicrobial treatment, and despite the intensive care provided to these patients.

The incidence of sepsis and septic shock appears to be increasing all over the world. Inadequate immune responses to infection due to underlying comorbid states, such as malignancy, lymphomas, leukemias, HIV infection, chronic hepatic or renal failure, diabetes, predispose to sepsis and septic shock. Infections in the aged and in the malnourished are also frequently followed by severe sepsis, septic shock and death. Iatrogenic infections induced by procedures or their complications in critical care units can also cause septic shock.

Table 1: Burden of sepsis in low and middle income countries (Incidence per 1000 patients-days). The Brazilian sepsis epidemiological study

Syndrome	*Incidence*	*Mortality (%)*
Sepsis	61.4	34.7
Severe sepsis	35.6	47.3
Septic shock	30.3	52.2
Zambia–30% of patients in a rural hospital had signs of sepsis		

Source: Brazilian Sepsis Epidemiological Study (BASES study). Critical Care 2004.

Septic shock chiefly follows Gram-negative bacterial infections. There is however, an increasing incidence of Gram-positive infections producing septic shock. The use of broad-spectrum antibiotics over prolonged periods of time, and organ transplantation, have brought in their wake fungal and viral infections which can also produce severe sepsis and septic shock. Important causes of severe sepsis associated with multiple organ failure in the tropics, in our experience, include fulminant tetanus, severe infections produced by *P. falciparum*, hemorrhagic dengue fever, typhoid, fulminant amoebic infections and acute disseminated hematogenous tuberculosis. These have been discussed at length in other sections of the book.

The important factors predisposing to the development of septic shock are listed in Box 1.

DEFINITIONS[2]

Definitions are a matter of semantics but it is important that clarity is introduced into the terminology used to describe various clinical profiles associated with sepsis. This would certainly help evaluate the results of management protocols in septic states. It has been increasingly realized over the last several years that the clinical features observed in sepsis, together with complications of shock and multiple organ failure can occur in other widely different conditions, which are unrelated to infection. An American College of Chest

Box 1: Important predisposing factors and causes of septic shock

- Infections in the aged, or malnourished
- Inadequate immune responses to infection due to underlying background disease, e.g. hepatic or renal failure, diabetes mellitus, malignancy, antimitotic drugs, HIV infection, lymphoma
- Iatrogenic infections induced by procedures in critical care units
- Virulent Gram-negative and Gram-positive infections
- Opportunistic infections (including fungal, viral) after prolonged antibiotic therapy, or following organ transplants, or in other immunocompromised patients, such as those with HIV infection and lymphoma
- Fulminant tetanus
- Hemorrhagic dengue fever
- Severe *P. falciparum* infections
- Disseminated hematogenous tuberculosis
- Fulminant *B. typhosus*, salmonella and amebic infections

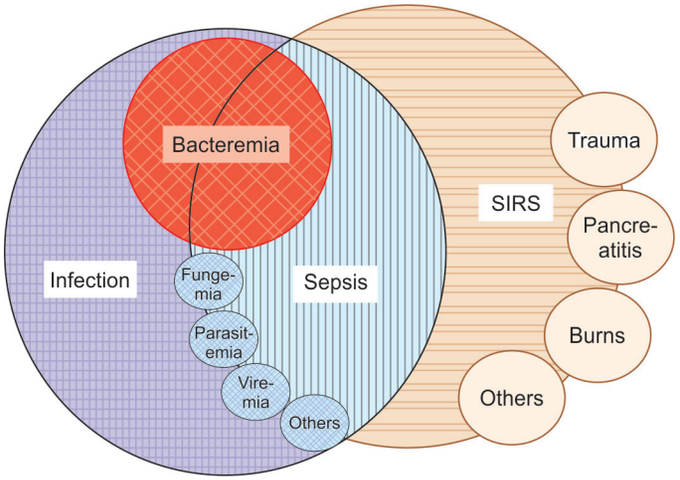

Fig. 1: The interrelationship between systemic inflammatory response syndrome (SIRS), sepsis and infection

Source: Bone RC, Balk RA, Cerra FB, et al. Definitions for sepsis and organ failure and guidelines for the use of innovative therapies in sepsis. The ACCP-SCCM Consensus Conference Committee. American College of Chest Physicians/Society of Critical Care Medicine. Chest. 1992:101:1644-55.

Physicians-Society of Critical Care Medicine (ACCP-SCCM) consensus conference held in 1991, proposed semantic terms that attempt to clearly define sepsis, and sepsis-related clinical states. This conference also proposed the use of the term systemic inflammatory response syndrome (SIRS) to include patients in whom the clinical features resembled sepsis, even though the etiology was due to noninfective causes. The proposed semantic definitions at this consensus conference are briefly described below.[3]

The SIRS is characterized by two or more of the following features: (1) body temperature greater than 38°C or less than 36°C; (2) heart rate greater than 90/minute; (3) hyperventilation greater than 20/minute or a $PaCO_2$ less than 32 mm Hg; or a white blood cell (WBC) count greater than 12,000/mm^3 or less than 4,000/mm^3 or greater than 10% band forms. A SIRS can occur following noninfectious causes, e.g. trauma, crush injuries, pancreatitis and burns. Also, SIRS even when primarily unrelated to infection can lead to hypotension, shock and to multiple organ failure. The consensus conference suggested that the term sepsis be used exclusively when a SIRS is due to infection. The interrelationship between SIRS, sepsis and infection is illustrated in Figure 1.

Severe sepsis is defined as sepsis associated with organ dysfunction, hypoperfusion or hypotension. Septic shock is defined as severe sepsis with hypotension that does not respond to adequate fluid replacement. It is associated with evidence of hypoperfusion and/or organ dysfunction.

These groupings, though arbitary, are useful and have been globally adopted both by clinicians and investigators. Their chief value lies in the evaluation and comparison of studies in patients with sepsis. The pathophysiological significance of these groupings remains to be established. Though the concept of the SIRS is excellent in that it can arise as an innate immune response to noninfectious causes and to infections, the criteria used to define SIRS are both nonspecific and mild in degree. Judging by the above mentioned criteria, most patients in a large teaching hospital in our country would not only have SIRS but would be dubbed as septic. Also the use of SIRS criteria to define septic shock is unrealistic. Shock from any noninfectious cause can also be associated with tachypnea, tachycardia and an increased WBC count. Again, the body temperature is often normal in septic shock. The SIRS criteria cannot therefore separate septic shock from other forms of shock. We have always maintained ever since the deliberations of the ACCP-SCCM consensus were published that the concept of SIRS should be retained but its criteria either changed or abandoned.

Several North American and European Intensive Care Societies agreed in 2001 to take a relook at the definitions of sepsis and sepsis related conditions.[4] This consensus conference came to the following conclusions—

- Current concepts of sepsis, severe sepsis and septic shock should remain unchanged.
- Current definitions do not allow for precise staging of the host response to infections.
- Signs and symptoms of sepsis are more varied than the initial criteria stated in 1991; the consensus included in the clinical features of sepsis, subtle changes involving one or more organ systems either detected clinically (Box 2), or on relevant laboratory tests.
- The future, according to this consensus conference, lies in developing a staging system that will characterize progression of sepsis. They suggest the PIRO concept of staging sepsis. This concept stratifies patients on the basis of their **P**redisposing conditions, the nature and extent of the **I**nsult (Infection), the nature and magnitude of the host **R**esponse, and the degree of concomitant **O**rgan dysfunction.

Box 2: Comparison between 1991 SIRS criteria to expanded list of signs and symptoms in 2001 Sepsis Definitions Conference

SIRS Criteria (1991)—

- Fever or hypothermia
- Tachycardia
- Tachypnea
- Altered white blood cell count

Sepsis Definitions Conference (2001)—

- General signs and symptoms include fever/hypothermia, tachypnea /respiratory alkalosis, positive fluid balance or edema—
  - General inflammatory reactions include altered white blood cell count, increased biomarker (C-reactive protein, IL-6, PCT) concentrations
  - Hemodynamic alterations include arterial hypotension, tachycardia, increased cardiac output or low systemic vascular resistance (SVR), altered skin perfusion, decreased urine output, hyperlactatemia (increased base deficit)
  - Signs of organ dysfunction include hypoxemia, coagulation abnormalities, altered mental status, hyperglycemia, thrombocytopenia, disseminated intravascular coagulopathy, altered liver function (hyperbilirubinemia), intolerance to feeding (altered gastrointestinal motility)

Abbreviations: SIRS, systemic inflammatory response syndrome; IL, interleukin; PCT, procalcitonin.

It has been proposed that the PIRO system could be used to stratify patients at or shortly after ICU admission. In fact the PIRO system has already been used to study ICU mortality in ventilator-associated pneumonia and in critically ill patients who had community acquired pneumonia.[5] Rubulotta and colleagues[6] used two large sepsis databases to validate a PIRO staging model risk stratification in severe sepsis. Clearly the system has the potential not only to stratify patients with sepsis with regard to prognosis, but would perhaps help to target specific therapy to specifically characterized subgroups. More studies are needed before this approach is widely accepted.

The consensus arrived at in 2001 noted the relative nonspecificity of the clinical features decided under SIRS. SIRS is often associated with increased levels of inflammatory markers in the blood—notably, the circulating concentrations of IL (interleukin)-6, procalcitonin (PCT), and C-reactive protein (CRP) are increased (Box 2). Perhaps, it may be possible in the future to use purely biochemical and/or immunological markers rather than clinical criteria to identify the inflammatory response. However, as yet, no large prospective studies lend support to such a hypothesis.

All the above-mentioned features listed in the Sepsis Definition Conference of 2001 (Box 2), could be subtle and mild, and need to be carefully searched for.

CLINICAL FEATURES

The clinical features of severe sepsis and septic shock include the following—

- Features of a SIRS due to an infection. These features include fever (or rarely hypothermia), tachycardia, tachypnea, and leucocytosis (or leucopenia <4000/mm^3).
- Systolic arterial blood pressure (BP) less than 90 mm Hg, or a mean arterial BP (MAP) less than 60 mm Hg. In hypertensive individuals, a fall of systolic arterial BP greater than 40 mm Hg below baseline is significant.
- Evidence of poor tissue perfusion as judged by a lactic metabolic acidosis or a sharp fall in urine output, and/or evidence of dysfunction of one or more organs or organ systems, either detected clinically or through laboratory tests.

The circulatory state is generally hyperdynamic, so that in addition to tachycardia, the pulse is bounding and of good volume, and the peripheries are warm.

There are certain important clinical pointers to impending severe sepsis and shock that need to be considered in a patient with infection or sepsis. These include the onset of unexplained tachypnea, the presence of a mild icterus, a subtle change in the mental state generally due to cerebral hypoperfusion and to metabolic changes, a fall in the urine output (< 50 mL/hour), mild metabolic acidosis, or the presence of a few purpuric spots. These all point to early organ dysfunction and may precede hypotension.

LABORATORY FEATURES

Besides showing leucocytosis or leucopenia, a coagulation profile may show evidence of an early disseminated intravascular coagulopathy (DIC). This includes an elevated prothrombin time, a decreased platelet count, decreased fibrinogen, increased fibrin degradation products, and increased thrombin index. Thrombocytopenia may often occur without evidence of DIC.

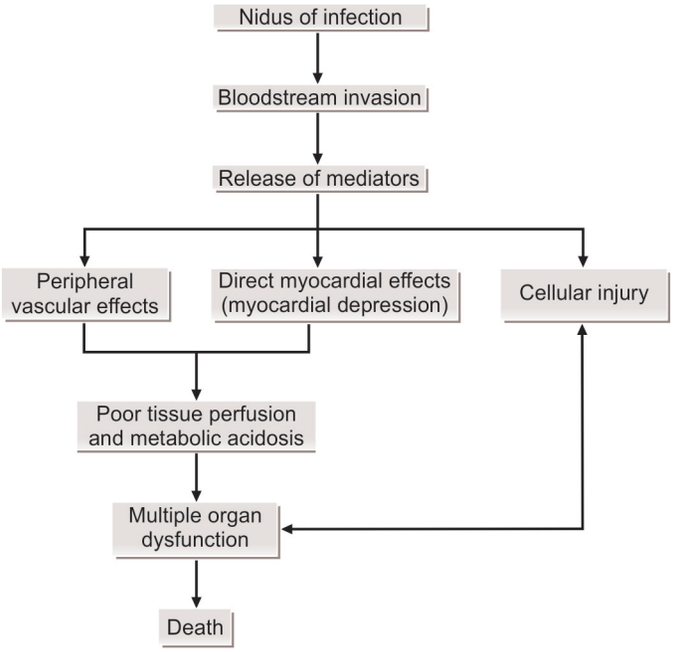
Hyperglycemia is common. Sudden marked elevations of serum glucose levels in patients on hyperalimentation may be the first indication of severe impending sepsis. Hypoglycemia is observed in the preterminal or terminal state of septic shock and signifies severe hepatic dysfunction. A rise in serum bilirubin, serum aminotransferases, and in the alkaline phosphatase, occurs very frequently and points to hepatic dysfunction.

The hypermetabolic state is evinced by a marked increase in the urinary urea or urinary nitrogen over 24 hours, and a negative nitrogen balance.

The arterial pH may be low in the presence of metabolic acidosis and early involvement of the lung is manifested by a mild to moderate hypoxia with hypocapnia.

Cytokines (especially IL-6 and IL-8), CRP , and PCT levels have been noted to rise significantly in sepsis. Literature review[7] indicates that there are many biomarkers that can be used in sepsis, but none have sufficient specificity or

Flowchart 1: Pathogenesis of severe sepsis and septic shock



sensitivity to be routinely employed in clinical practice. PCT and CRP have been most widely used, but even these have limited abilities to distinguish sepsis from other inflammatory conditions or to predict outcome. In view of the complexity of the sepsis response, it is unlikely that a single ideal biomarker will ever be found. A combination of several sepsis biomarkers may be more effective, but this requires further evaluation.[7]

PATHOPHYSIOLOGY[8-11]

A description of current research on this subject would fill a volume. This section merely gives a basic brief description of the pathophysiology of septic shock to enable a better comprehension of sepsis and its complications; difficulties in management would then be more easily appreciated (Flowchart 1).

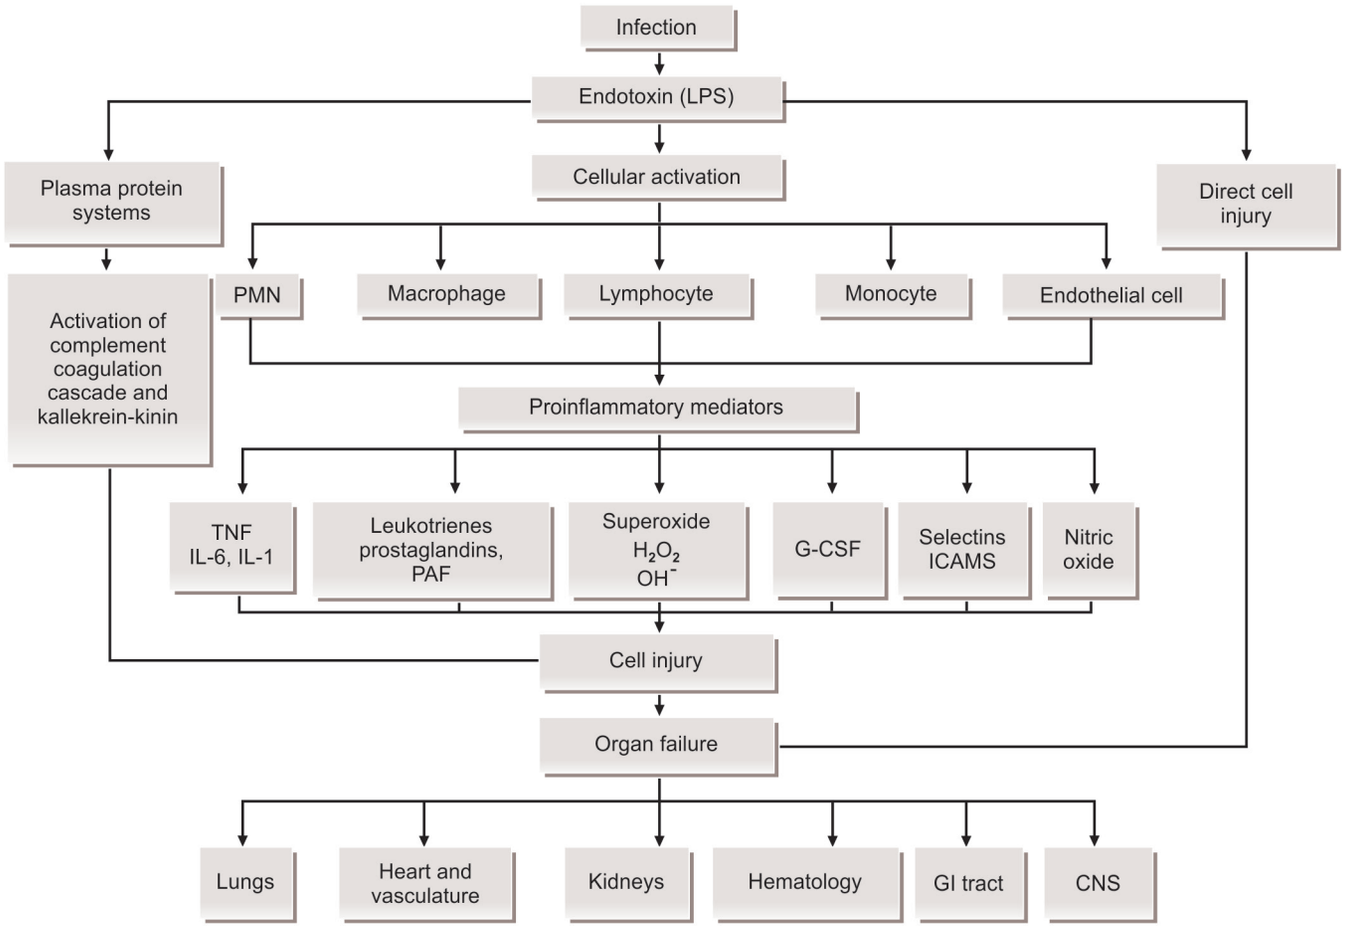
Classically septic shock is due to endotoxins released by Gram-negative bacteria. Recent investigations have implicated cell wall components of both Gram-negative and Gram-positive organisms. Septic shock can also occur with fungal infections, viral infections, as well as protozoal infections, notably *P. falciparum* infections, or for that matter can result from any pathogenic microorganism. Studies on septic shock have however been chiefly in relation to endotoxin produced by Gram-negative bacteria. Endotoxin is a lipopolysaccharide component of the outer membrane of the bacterial cell. It consists of oligosaccharide side chains, a core polysaccharide and lipid A, the latter being highly antigenic and believed to be responsible for the features of clinical sepsis. Endotoxin is directly toxic to endothelium and tissue cells, contributing to diffuse endothelial and tissue injury that characterizes the sepsis syndrome. Endotoxin interacts with normal host defenses and triggers the release of numerous mediators—IL-1, granulocyte monocyte-colony stimulating factor, tumor necrosis factor (TNF-α) and procoagulant activity factor. Endotoxin initiates the release of cytokines from mononuclear cells, in particular of TNF-α which is responsible for a number of features of the sepsis syndrome. Endotoxin also activates neutrophils with the subsequent release of proteases and oxidants which promote endothelial and tissue cell damage, degrade matrix and generate other proinflammatory mediators. A degradation of arachidonic acid is observed in cell walls through phospholipase. The mobilized arachidonic acid from the leucocyte cell can follow two pathways—the cyclo-oxygenase pathway leading to the formation of thromboxanes and prostaglandins, and the lipo-oxygenase pathway leading to the formation of leukotrienes. These mediators have various actions, some of them deleterious to tissue integrity and function. Phospholipase A2 also releases membrane bound phospholipids which are converted to the platelet activating factor (PAF). The latter is known to increase vascular permeability, increase production of toxic oxygen free radicals, and activate platelets and phagocytes.

Recent attention has been focused on the role of toxic oxygen metabolites, in particular nitrous oxide (NO). Activated phagocytes produce oxygen radicals that kill bacteria. A leakage of these products from the cell can cause tissue damage. Endothelial derived relaxing factor (EDRF) is another toxic free radical which chemically is NO. While small quantities of NO can improve blood flow in the microcirculation, larger quantities can produce vasodilatation and hypotension. NO can be produced from several cell lines including vascular endothelium and polymorphonuclear cells. NO synthetase is induced by endotoxin and TNF-α; it produces NO from L-arginine.

Endotoxin also activates factors within the serum. It thus activates and stimulates the coagulation pathway. This can occur at multiple sites. Research has focused increasing attention on the roles of endothelial injury and coagulation in sepsis.[8] Sepsis can be conceptualized as a loss of homeostasis, caused by an imbalance of opposing mechanisms that normally maintain this homeostasis. On one side are coagulation and inflammation, actively promoted by endothelial injury, thrombin production, tissue factor expression and proinflammatory mediators. On the opposite side is fibrinolysis. Fibrinolysis normally counters the procoagulant factors, but is suppressed in sepsis. The suppression of fibrinolysis is perhaps related to several factors, notably increased levels of plasminogen activator inhibitor-1 (PAI–1), thrombin-activable fibrinolysis inhibitor (TAF-Ia) and decreased levels of Protein C. The homeostatic imbalance prevailing in sepsis is believed to lead to microvascular thrombi in various organ systems. This could be the driving force that culminates in increasing multiple organ dysfunction and death.

In summary, invasive infection of the body by microorganisms and their products or toxins elicits a strong response

Flowchart 2: The role of mediators in severe sepsis and septic shock



from the host defenses.[11] The response is characterized by activation of cellular elements and of the plasma protein systems. The cells activated include the mononuclear cells, lymphocytes, macrophages, neutrophils and endothelial cells. The activated cells produce numerous cytokines and mediators, some of which are proinflammatory and some anti-inflammatory. The host defense mechanisms also activate complement, the coagulation cascades and the kallikrein-kinin systems. Current thinking conceptualizes sepsis as a loss of homeostasis in which procoagulant forces predominate over fibrinolysis.

If the host defense response is disorganized, unorchestrated, unbalanced and unchecked it fails to defend the host and paradoxically enough inflicts injury on the host. This injury is widespread because of the toxic effect of numerous mediators, and also because of endothelial damage and the dominance of procoagulant factors leading to microvascular thrombi in various organ systems. The clinical features of severe sepsis, septic shock, and the evolution of multiple organ dysfunction and failure are a consequence of the changes described above. Flowchart 2 illustrates the role of mediators in severe sepsis and septic shock. Figure 2 illustrates the loss of homeostasis in severe sepsis.

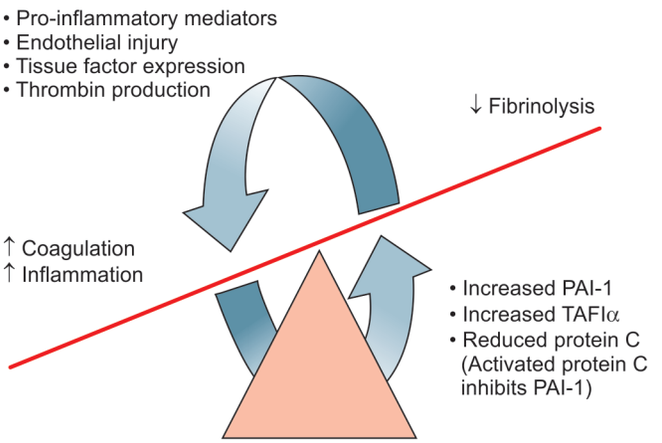


Fig. 2: Loss of homeostasis in severe sepsis

HEMODYNAMIC EFFECTS

The hemodynamic effects of severe sepsis typically result in a high output hyperdynamic circulatory state with tachycardia and hypotension. Septic shock in addition to the

above is characterized by systolic BP less than or equal to 90 mm Hg not responding to fluid replenishment. It is associated with evidence of hypoperfusion and/or organ dysfunction. The hemodynamic state outlined holds not only for bacterial infections, but severe infections caused by other microorganisms, including fungal and viral infections, as also fulminant infections peculiar to the tropical and developing countries of the world.

The high cardiac output and the hyperdynamic circulatory state in severe sepsis and septic shock could well be a compensatory response to increased tissue metabolism.[12] This is certainly true for the hemodynamic profile of severe tetanus where a hyperdynamic circulatory state is observed even in paralyzed patients on ventilator support.[13,14]

The hemodynamic effects of severe sepsis and septic shock can be considered under the following heads—

Peripheral Vascular System

- There is a marked decrease in the arterial and venous tone resulting in venous and arteriolar dilatation with a fall in peripheral vascular resistance, and therefore a fall in the systemic arterial BP. The smaller arterioles are chiefly affected whereas venous tone is most reduced in the larger capacitance vessels. These changes are greatest in the areas of active infection and inflammation. Hypotension in septic shock is associated with complement activation and with increased TNF-α, IL-1 levels. Other vasodilating substances include nitric oxide, endothelial relaxing factor and PAF. Bernard et al.[15] have provided further insight into the mechanism of sepsis induced vasodilatation and hyporesponsiveness to vasoconstrictor drugs. Their study implicates macrophage derived mediators that affect smooth muscle contractility via nitric oxide synthesis. Catecholamine alpha-receptor downregulation has been experimentally reported, and if applicable to humans, may account for the poor vasoconstrictor response to vasopressors.

  The microvascular circulation has been shown to be adversely affected, contributing thereby to tissue hypoxemia and the frequent evolution of multiple organ failure. De Becker and colleagues[16] noted that the density of the microvasculature was markedly reduced in severe sepsis, with a sharp reduction in the proportion of perfused small vessels. A new technique, termed orthogonal polarization spectral imaging was used to measure sublingual microcirculation, as representative of the vascular bed. This new technique may help to elucidate the mechanisms involved in reduced microvascular blood flow in severe sepsis and septic shock.
- A generalized increase in vascular permeability is also noticed in septic shock with increase in interstitial fluid and tissue edema. A peripheral pooling, hepatosplanchnic pooling, and at times fluid loss from the gastrointestinal tract is responsible for a fall in effective circulatory volume.
- The combined effect of the above two factors leads to hypovolemia which may not be overt; this can at times mask the underlying hyperdynamic state, which becomes evident on fluid repletion.
- There is a change in the pattern of blood flow distribution in septic shock. Some organs receive a supranormal supply of oxygen, whereas others are rendered ischemic. This is of particular importance in the splanchnic circulation. Hepatovenous desaturation has been reported in septic patients.[17]
- Changes in oxygen delivery, oxygen uptake and oxygen use or consumption by tissues are dealt with later.

Heart[18]

Myocardial depression is present in almost all patients with septic shock. Decreased compliance with decreased left ventricular diastolic function is observed. Left ventricular systolic function is also reduced as evinced by a dilated cardiomyopathy with a low ejection fraction and a reduced ventricular stroke work index. Cardiac output is usually increased because of marked tachycardia. Myocardial depressant factors include TNF-α, low molecular weight soluble molecules and lipid soluble substances. There is no evidence of myocardial ischemia, the coronary blood flow being well maintained. There is evidence of beta-receptor downgrading and this may be responsible for the poor response to inotropic drugs which is often observed in these patients. In the absence of severe hypovolemia, the net result is a hyperdynamic circulation with increased cardiac output due to increased heart rate.

Pulmonary Hypertension

Pulmonary hypertension due to increased pulmonary vascular resistance is frequently present particularly when septic shock produces the acute respiratory distress syndrome (ARDS). When significant pulmonary hypertension develops, right ventricular function may be markedly affected due to an increased afterload.

Tissue Oxygenation

Tissue oxygenation eventually always suffers in septic shock. There is an increase in lactic acid production with metabolic acidosis.

Hemodynamic Profiles in Septic Shock[19]

The hemodynamic profile is dependent on the stage of shock—early or late, on the compensatory mechanisms present, on the presence and degree of myocardial dysfunction in the septic state, on the presence and degree of associated hypovolemia, and the therapy the patient may have received prior to admission to the ICU.

- The most characteristic pattern in the early stage is a hyperdynamic circulation characterized by a high cardiac index (CI at times as high as 7 L/m^2) with tachycardia, a low systemic vascular resistance (SVR), a low pulmonary capillary wedge pressure (PCWP) and hypotension. The early stage of severe sepsis and septic shock is characterized by peripheral vasodilatation so that the pulse is

bounding and the peripheries warm. The high CI is due to tachycardia and not to increased contractility. In fact, as has been discussed already under Hemodynamic Effects, both systolic and diastolic functions of the heart are depressed in spite of the high cardiac output. The left ventricular ejection fraction (LVEF) typically falls to as low as 20–30% in the first 24–48 hours. During this period the left ventricle dilates and abnormalities in both systolic and diastolic function are observed. The left ventricle responds abnormally to a volume load, in that the reduced left ventricular stroke work increases marginally or to a very small extent. In survivors, a reversal of this abnormal function is observed over 7–10 days.

- In the late stage of severe sepsis and septic shock, particularly in patients who are likely to succumb, the cardiac function remains poor or continues to deteriorate. The profile likely to be observed is a normal or a slightly low CI, an increasing PCWP, a normal SVR or a SVR showing a trend towards a slow increase. Persistent or increasing hypotension poorly responsive or unresponsive to therapy is observed.
- The preterminal stage of septic shock is often associated with a low CI, a high PCWP and an increased systemic vascular resistance. Marked tachycardia, with hypotension unresponsive to all therapy is observed.

Though the last profile is preterminal or in the late stages of septic shock, some patients with fulminant septic shock may have a very low CI with a high SVR soon after its onset. At times, hypovolemia may strongly contribute to this profile and this is recognized by low filling pressures. However, in a few individuals the PCWP is high, so that the hemodynamic profile is similar to that seen in severe cardiogenic shock.

The various hemodynamic profiles in septic shock are shown in Box 3.

Frequently observed left heart pressures and cardiac output in septic shock vis-à-vis the values in cardiogenic, cardiac compressive, hypovolemic shock and anaphylactic shock are detailed in Table 2.

Box 3: Various hemodynamic profiles in septic shock

Early stage—tachycardia, hypotension, low PCWP, high CI, and low SVR

With progression of the syndrome and deteriorating cardiac function—hypotension, increasing PCWP, normal or slightly low CI, normal to rising SVR

Late (preterminal) stage—hypotension, high PCWP, low and progressively decreasing CI, and increased SVR

Rarely, very low CI, high PCWP and high SVR is seen at the start in fulminant septic shock (profile resembles cardiogenic shock)

Abbreviations: CI, cardiac index; PCWP, pulmonary capillary wedge pressure; SVR, systemic vascular resistance.

Table 2: Frequently observed left heart pressures and CO in septic shock, cardiogenic shock, cardiac compressive shock, hypovolemic shock and anaphylactic shock

Types of Shock	*PCWP (mm Hg)*	*CO (mL/min)*
Septic shock	↓ or Normal	↑↑ or Normal
Cardiogenic shock (following acute MI)	↑↑	↓↓
Cardiac compressive shock (Cardiac tamponade)	↑↑	↓ or ↓↓
Hypovolemic shock	↓↓	↓↓
Anaphylactic shock	↓ or Normal	↑ or Normal

Oxygen Delivery (DO_2) and Oxygen Uptake ($\dot{V}O_2$) in Severe Sepsis and Septic Shock[20]

In the early and evolving phase of severe sepsis and septic shock, there is an increase both in DO_2 and in $\dot{V}O_2$. Even though there is an increase in oxygen consumption it may not be enough for the increased tissue need for oxygen, so that tissue hypoxia can still occur. Oxygen extraction ratios may be increased at this stage. Shoemaker[21] in a large prospective study of patients in septic shock, reported that survivors had a higher CI, a higher DO_2 and a higher $\dot{V}O_2$ than nonsurvivors. In the late phase of septic shock, oxygen consumption may fall sharply even though DO_2 is satisfactory, resulting in a low oxygen extraction ratio. Decreased oxygen extraction and consumption could well be related to the presence of the microcirculatory mitochondrial dysfunction syndrome (MMDS). MMDS as the name suggests is due to an impaired microcirculation which prevents adequate oxygen from reaching tissue cells and/or disturbed mitochondrial function within tissue cells, so that oxygen cannot be utilized by the cells. The MMDS is discussed later in this chapter.

Relation between Oxygen Uptake ($\dot{V}O_2$) and Oxygen Delivery (DO_2) in Septic Shock

In normal individuals (normal physiology), the oxygen consumption ($\dot{V}O_2$) is dependant on tissue demands and is independent of oxygen delivery. Once oxygen delivery falls below a critical level, DO_2 critical, the $\dot{V}O_2$ becomes linearly dependant on DO_2. Anaerobic metabolism then sets in resulting in lactic acidosis. In severe sepsis, septic shock, the $\dot{V}O_2$-DO_2 relationship shifts upwards and to the right. This is due to alterations in distribution of blood flow which impairs the ability of the tissues to extract oxygen from the perfusing blood. The dependency of $\dot{V}O_2$ on supply (DO_2) is thus observed over a wider range of oxygen delivery values than usual, in patients with septic shock. See Figures 3 and 4.

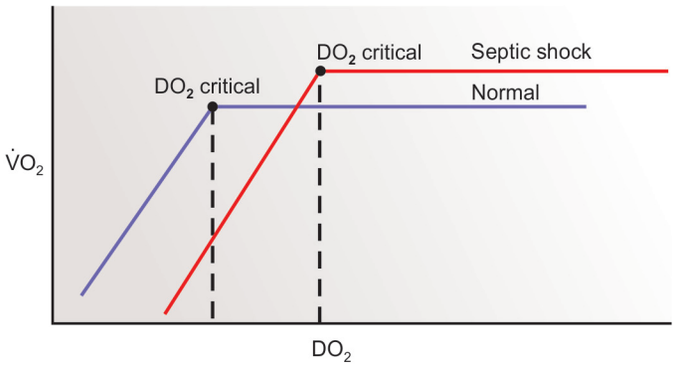

Fig. 3: In severe sepsis and septic shock, the relation between DO_2 and $\dot{V}O_2$ shifts to the right and upwards of the normal physiological DO_2-$\dot{V}O_2$ relation

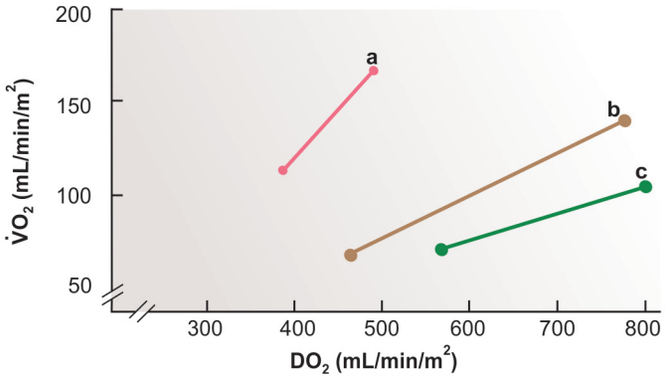

Fig. 4: Oxygen consumption ($\dot{V}O_2$) plotted against oxygen availability (DO_2) in normals (a), and in patients with septic shock (b and c). Note that as the severity of septic shock increases (b and c), the slope of the $\dot{V}O_2$-Oxygen availability relationship decreases, pointing to an inability of the tissues to utilize oxygen in spite of adequate oxygen availability

MANAGEMENT[22,23]

Severe sepsis has been divided into two stages: (1) early and (2) late with reference to its management. The first 0–6 hours is the early stage of sepsis—the golden hours during which a quick diagnosis is made and goal directed therapy instituted according to the seminal work of Rivers and colleagues[22] and the subsequent international guidelines laid down in the Surviving Sepsis Campaign (SCC).[23] In sepsis, the transition to an increasingly serious illness occurs during these 'golden' six hours when quick diagnosis and prompt management can lead to better outcome. The onset and progression of severe sepsis and septic shock is characterized by an imbalance between oxygen delivery and oxygen demand resulting in global tissue hypoxia and ultimately in multiorgan dysfunction and failure. The purpose of early goal directed therapy (EGDT) is to try and rectify this imbalance thereby reducing morbidity and mortality.

The priority tasks which should be performed within 6 hours of severe sepsis and septic shock are—

- Hemodynamic stabilization or resuscitation.
- Restoring tissue oxygenation.
- Use of lung protective ventilation if ventilatory support is deemed necessary.[24]
- Infection identification and infection control (antibiotic therapy and source control).[25]

It is crucial to commence resuscitative measures to restore hemodynamic stability promptly as soon as the diagnosis is made—at home if this is feasible before awaiting transfer to the hospital, in the ambulance, in the emergency department (ED), in the ward or on admission to the ICU. In India, though treatment is often first initiated in the ED, patients are quickly shifted to the ICU where better trained personnel, better monitoring and better facilities are available.

Initial Assessment

The first priority in a patient with severe sepsis or septic shock is to stabilize the airway, administer oxygen through a high flow mask and if there is significant respiratory distress or hypoxia to initiate ventilatory support. Of equal importance comes an assessment of perfusion—the heart rate and rhythm, the blood pressure, skin temperature, capillary refill, mental state and the urine output over the last 4–6 hours, if this information is available. On admission to the ED or the ICU, the heart rate, respiratory rate, temperature, electrocardiogram (ECG) and oxygen saturation are continuously monitored. As soon as this initial assessment is made, restoration of tissue perfusion through improvement of the circulatory state is promptly begun. Other measures, in particular identification of the nature of infection and measures to control infection (antibiotic therapy and source control) should be taken *pari passu* or soon after efforts to restore hemodynamics of the circulation have begun.

Hemodynamic Stabilization and Improvement of Tissue Oxygenation

The goals of initial resuscitation[22,23] in severe sepsis, septic shock are—

- Central venous pressure (CVP) of 8–12 mm Hg. If a patient is mechanically ventilated, a higher central venous target 12–15 mm Hg is recommended.[26]
- Mean arterial blood pressure 65 mm Hg or greater.
- Urine output 0.5 mL/kg per hours or preferably more.
- Central venous or mixed venous oxygen saturation greater than or equal to 70% or greater than or equal to 65%, respectively.
- No base deficit, a normal pH and normal or reduced lactate level in the blood.

Achievement of the above goals during hemodynamic resuscitation necessitates the insertion of a central venous catheter to measure CVP. Though the initial BP is measured by a sphygmomanometer, an arterial line is preferable particularly in patients who are hypotensive as in many hypotensive patients, the BP readings recorded by a sphygmomanometer are much lower than what they actually are. Hourly urine output through a Foley's catheter is essential.

The central venous oxygen saturation measured via the central venous catheter is currently felt to be a fairly good substitute for the mixed venous oxygen saturation as measured through the pulmonary artery catheter.

Volume Resuscitation

The initial measure towards achieving the goals stated above is volume resuscitation. Volume resuscitation should commence promptly through a 14F gauge catheter inserted into a peripheral vein. It should not await the insertion of a central venous catheter (see Chapter Hypovolemic and Hemorrhagic Shock) for fluid infusion, or the insertion of an arterial line for accurate measurement of BP. In the ED, or in the ICU the central venous line and an arterial line can be inserted by one intensivist, while another intensivist starts volume resuscitation.

Initial volume resuscitation should be performed with either 1,000 mL of a crystalloid solution (0.9% normal saline or a Ringer lactate solution) or 300 of a colloid (5% albumin) over 30 minutes. The saline versus albumin fluid evaluation (SAFE) study[27] concluded that in patients in the ICU use of 5 % albumin or normal saline for fluid resuscitation resulted in similar outcomes at 28 days. Even so, for quick resuscitation in severely hypotensive patients both colloids and crystalloid can be infused together, or the initial infusion of a colloid solution is followed by an ongoing infusion of crystalloids (see Chapter Hypovolemic and Hemorrhagic Shock). Volume status, tissue perfusion and BP are monitored on an ongoing basis. Further infusion of fluids is continued till hemodynamic improvement continues and the goals of hemodynamic resuscitation are met. The central venous pressure should not be pushed beyond 12 mm Hg or beyond 15 mm Hg if the patient is on mechanical ventilation support. Patients in severe septic shock have large volume deficits and many require as much as 8–10 L of crystalloids or 2–4 L of colloids in the first 24 hours.[22]

Use of Vasoactive Drugs and Inotropes

If after volume infusions have raised the CVP to 12 mm Hg, the MAP is less than 65 mm Hg, vasopressors and/or inotropes are indicated. Norepinephrine is generally recommended as the first line drug starting with 2–4 μg/minute and progressively increasing the dose so as to obtain a MAP greater than 65 mm Hg.[22] It is wise not to exceed a dose greater than 30 μg/minute as larger doses are not only infructuous but may well do harm. According to the SSC guidelines,[23] epinephrine (added to and potentially substituted for norepinephrine) can be used as an additional agent to maintain adequate BP. Vasopressin in a dose of 0.03 units/minute (according to the SSC guidelines) can be added to norepinephrine with intent of either raising MAP or decreasing norepinephrine dosage. Low dose vasopressin is not recommended as the single initial vasopressor for treatment of sepsis-induced hypotension. Vasopressin in doses higher than 0.03–0.04 units/minute should be reserved for salvage therapy. According to the guidelines, dopamine is best used only in highly selected patients (e.g. patients with low-risk of tachyarrhythmias and absolute or relative bradycardia). Even so, in many critical care units, dopamine remains the drug of choice after norepinephrine in patients with septic shock. When administered in a dose greater than 10 μg/kg per minute, dopamine has both a strong vasopressor effect plus an inotropic action. The latter is particularly useful in patients with septic shock who have myocardial dysfunction. Dopamine is often combined with dobutamine in these patients. The dose of dopamine should not exceed a maximum of 30 μg/kg per minute—further increase is not likely to help and in all probability does more harm and may have to be omitted in patients with marked tachycardia or arrhythmias. Low-dose dopamine is no longer recommended for renal protection.[23]

Rivers and associates[22] mention in their protocol for Early Goal Directed Therapy that if the MAP is greater than 90 mm Hg, vasodilators are given until it is brought down to 90 mm Hg or below.

Vasopressors can unquestionably increase the arterial BP but their powerful vasoconstrictor properties could produce increasing organ ischemia and adversely affect cardiac output by markedly increasing the afterload. In patients with septic shock who have sepsis induced myocardial dysfunction this could do more harm than good to the circulatory state and to tissue perfusion.

Vasopressors and inotropes should always be given through a central line. Sinus tachycardia and tachyarrhythmias are important complications of these drugs and may prevent the use of an appropriate dose. A rare but feared complication particularly with dopamine administration is ischemic limb necrosis. Phentolamine in an intravenous (IV) bolus dose 5 mg followed by an infusion of 1 mg/minute should be given at the earliest sign of limb ischemia. Phenylephrine though recommended in selected situations is barely used in most critical care units except perhaps as salvage therapy.

Use of Dobutamine

If after a volume load has pushed the CVP to the required level and if in spite of the use of vasopressor support the central venous oxygen saturation ($ScvO_2$) is less than 65%, dobutamine is administered as an IV infusion starting with 5 μg/kg per minute, going up to 20 μg/kg per minute. Dobutamine is particularly useful in the presence of sepsis induced myocardial dysfunction.

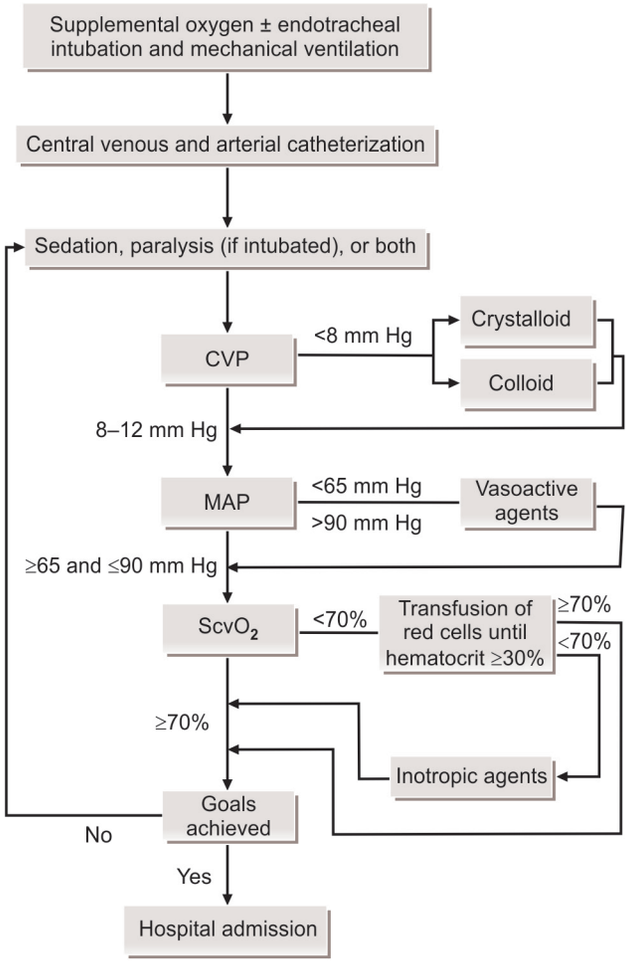
Packed Red Blood Cell (RBC) Infusion

Rivers and colleagues[22] in their work on EGDT recommend that the packed cell volume (PCV) if low is raised to 30% by infusion of packed RBCs in order to improve the oxygen carrying capacity of blood and thereby help in the relief of tissue hypoxia. The steps in EGDT are illustrated in Flowchart 3.

Laboratory and Other Investigations in 0–6 hours

A laboratory evaluation should include a complete blood count with white blood cell differentiation, blood culture,

Flowchart 3: Components of EGDT as per Rivers E, Nguyen B, Havstad S, et al. Early goal-directed therapy in the treatment of severe sepsis and septic shock. N Engl J Med. 2001;345:1368-77.



Abbreviations: EGDT, early goal-directed therapy; CVP, central venous pressure; MAP, mean arterial pressure; $ScvO_2$, central venous oxygen saturation.

PCT, erythrocyte sedimentation rate (ESR), CRP, blood chemistry, arterial pH and blood gas values and arterial blood lactate. Laboratory tests to evaluate organ function should be done on admission. These include an assessment of renal function—electrolytes, blood urea nitrogen (BUN) and creatinine and an assessment of hepatic function which includes serum bilirubin, aspartate aminotransferase (AST), alkaline phosphatase and serum proteins. The coagulation profile including prothrombin time (PT), international normalized ratio (INR), partial thromboplastin time (PTT) and platelets should be tested. Blood for the above tests and blood cultures should be sent to the lab as soon as a peripheral vein has been secured. Urine culture, culture from wounds, discharges and other body fluids if relevant should also be asked for. An appropriate antibiotic or a combination of antibiotics is administered intravenously in an appropriate dose as soon as those cultures have been sent. Evaluation of the above laboratory investigations should be on an on-going basis, being repeated at appropriate intervals.

Table 3: Techniques for measuring blood flow and tissue oxygenation

Technique	*Arterial or venous access required?*	*Suitable for all patients?*
External Doppler	No	Yes
Esophageal Doppler	No	No, the patient must be sedated
Thoracic bioimpedance	No	No, the patient must have normal anatomy and access to the neck
Exhaled CO_2 Fick method	No	No, the patient must be on a ventilator
Pulse contour	Yes	No, the patient must have at least an arterial line in place
Pulmonary artery catheter	Yes	No, the patient must have a central line in place

Source: Modified from Ahrens T. Hemodynamics in sepsis. AACN Adv Crit Care. 2006;17(4):435-45.

Other investigations include—

- An X-ray chest (portable in the ICU or ED).
- USG of the abdomen and pelvis.
- Further imaging [e.g. computed tomography (CT), magnetic resonance imaging (MRI)] should be organized after the patient is stabilized and that too if appropriate and necessary.
- Tests to identify the source of sepsis—
  - Blood cultures have already been mentioned.
  - Sputum examination—smear, culture and sensitivity.
  - Urine routine, culture and sensitivity.
  - Examination of other fluids or discharge from wounds, secretions.
  - Examination of cerebrospinal fluid (CSF), if necessary.

Monitoring Hemodynamic Perfusion and Tissue Oxygenation during Resuscitation

Monitoring CVP and MAP is easy. However, even when resuscitation goals for CVP and MAP are achieved, poor tissue perfusion and tissue hypoxia may persist. This is indicated by raised lactate levels and lowered $ScvO_2$ levels, both of which require to be monitored. An increased lactate level and a lowered $ScvO_2$ point to the need for renewed resuscitative efforts. The ultimate goal of resuscitation in septic shock is the abolition of tissue hypoxia through an adequate oxygen supply to meet tissue requirement. Ideally, measurements of tissue perfusion and oxygenation are necessary to determine if this has been achieved.

Blood flow measurements are not frequently done because of the difficulties associated with the use of available invasive techniques.[28] Newer less invasive techniques such as external and esophageal Doppler, thoracic impedance are being increasingly employed by clinicians in the West (Table 3).[28,29] Except for the external Doppler, these noninvasive techniques

Table 4: Techniques for measuring tissue oxygenation

Measure	*Method*	*Variables*	*Global or regional*	*Invasive or noninvasive*
Established techniques—				
Systemic oxygenation	PAC	$\dot{V}O_2/DO_2/ERO_2$	Global	Invasive
Mixed venous O_2 saturation	PAC–blood gas analyses	$S\dot{v}O_2$	Global	Invasive
Central venous O_2 saturation	CVC (right atrium)–fiber optic cable	$ScvO_2$	Global	Invasive
Lactate	Laboratory–enzymatic testing	Lactate	Global	Invasive
Emerging techniques—				
Gastrointestinal tonometry and sublingual capnography	Measurement of pCO_2 in an air-filled or saline-filled balloon; use of sublingual probe	$prCO_2/pCO_2$ gap, pHi, sublingual pCO_2	Regional	Minimally invasive
Near-infrared spectroscopy	Near-infrared absorbance analysis	Hb/O_2Hb, cytochrome aa_3	Regional	Noninvasive
Tissue oxygen tension	Polarographic probes	pO_2	Regional	Minimally invasive

Abbreviations: PAC, pulmonary artery catheter; CVC, central venous catheter; $\dot{V}O_2$; oxygen consumption; DO_2, oxygen delivery; ERO_2, systemic O_2 extraction ratio, Hb, hemoglobin; $S\dot{v}O_2$, mixed venous oxygen saturation; $ScvO_2$, central venous oxygen saturation; pHi, gastric intramucosal pH.

are not suitable for all patients. Also very few units in India and other developing countries have sufficient experience in their use.

Tissue oxygenation is commonly assessed by measuring arterial lactate levels, $ScvO_2$ or mixed venous oxygen saturation ($S\dot{v}O_2$) (Table 4). All these three are global indirect measures of tissue oxygenation. Decreased $ScvO_2$, $S\dot{v}O_2$ levels point to increased oxygen extraction by tissues experiencing an oxygen deficit. Increased lactate levels signify anaerobic metabolism because of insufficient oxygen supply to satisfy tissue requirements. The $S\dot{v}O_2$ requires the use of a pulmonary artery catheter (PAC). However, the $ScvO_2$ is generally regarded as a reliable substitute for the $S\dot{v}O_2$. The outcome impact of the PAC in hemodynamic stabilization has been controversial. Studies and these include meta-analysis have revealed conflicting outcomes—decreased morbidity, improved mortality following surgery, no benefit in the ICU, increased mortality associated with the use of the PAC.[30]

In a study on patients with established acute lung injury (ALI), PAC and central venous catheter (CVC) directed therapy revealed no differences in outcomes such as mortality, ICU free days and the number of ventilator free days.[31] Currently the SSC guidelines indicate that the $S\dot{v}O_2$ and $ScvO_2$ are equivalent for monitoring resuscitation.[23] The routine monitoring of patients with the PAC in patients with septic shock is not recommended. Yet many units use the PAC for guidance in the management of very critically ill septic patients who require large volume infusions, large doses of vasopressors and/or inotropes, particularly in the presence of ARDS. Management of patients in whom severe sepsis is complicated by cardiogenic shock or is associated with severe sepsis induced myocardial dysfunction, or is combined with hemorrhagic shock is also helped by the use of the PAC. In the above mentioned seriously complicated situations, the PAC allows a detailed hemodynamic analysis, allowing a measurement of the CI, stroke volume, stroke work index, pulmonary artery pressure, PCWP, systemic and pulmonary vascular resistances, DO_2 and $\dot{V}O_2$. It helps the intensivist to adjust these variables through appropriate therapeutic interventions aimed at improving tissue perfusion and supplying adequate oxygen for tissue needs. In conclusion, though the PAC is not indicated for use in every patient with septic shock, in special situations and in selected patients it may help better management, notwithstanding the statistical evidence quoted against its use.

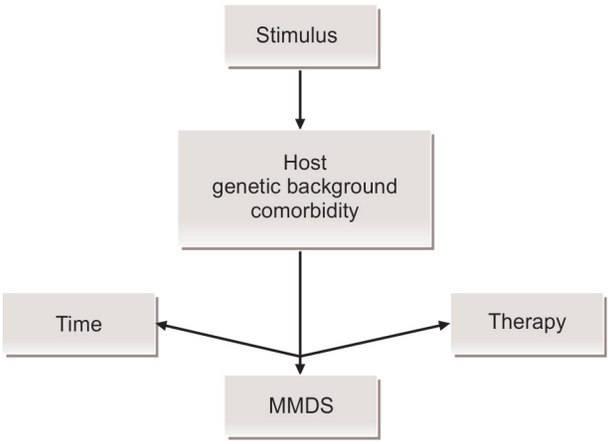
Outcome of EGDT in Severe Sepsis and Septic Shock

The genesis of EGDT and its proven outcome benefit arose from the seminal study by Rivers and colleagues.[22] Participants in the study by Rivers and colleagues were randomly assigned to receive goal-directed or standard resuscitation therapy. Patients in the goal-directed therapy group were resuscitated according to the EGDT protocol for at least 6 hours following arrival in the ED. In-hospital, 28 days and 60 days mortality rates for patients in the EGDT group were 30.5%, 31.3% and 44.3% respectively compared with 40%, 49.2% and 50.94% in the standard therapy group.[22] In addition, Acute Physiology and Chronic Health Evaluation (APACHE) II scores, Simplified Acute Physiology Scores (SAPS) , multiple organ dysfunction scores were significantly better in the EGDT group 7–72 hours after protocol entry. An analysis of the literature by Otero and colleagues.[32] showed that these outcomes are reproducible, generalizable and have external validity. The importance of early recognition of sepsis and septic shock is self evident, as rapid and appropriate treatment benefit outcome.

MICROCIRCULATORY MITOCHONDRIAL DYSFUNCTION SYNDROME[33]

Death in septic shock is due to increasing tissue hypoxia leading to multiorgan dysfunction and failure. The question

Flowchart 4: Microcirculatory mitochondrial dysfunction syndrome (MMDS)



Source: Adapted from Spronk P, Kanoore-Edul V, Ince C. Microcirculatory and mitochondrial distress syndrome (MMDS): a new look at sepsis. In: Pinsky MR, Payen D (Eds). Functional Hemodynamic Monitoring, Update in Intensive Care and Emergency Medicine. Germany: Springer; 2005. pp. 47-67.

arises as to why in spite of goal directed therapy restoring hemodynamic stability, patients with septic shock still have a significant mortality. Current thoughts in many centers are directed to the MMDS (Flowchart 4) where DO_2 is more than adequate but oxygen does not reach the tissue cells, because of abnormalities in the microcirculation. Abnormalities in microcirculation include capillary spasm, capillary thrombi, a reduced capillary bed, poor blood flow in capillaries, increased permeability leading to edema, shunting of blood within small arterioles directly to the veins so that blood bypasses tissue cells. Impaired mitochondrial function prevents oxygen that reaches tissues from being utilized by tissue cells. As mentioned in Chapter Overview of Shock Syndromes, mitochondrial dysfunction may be due to oxygen deprivation caused by microcirculatory dysfunction, or may occur independently of disturbances in the microcirculation. Mitochondrial function could be adversely affected by the direct action on cell metabolism by cytokines and other noxious stimuli.

The microcirculatory mitochondrial dysfunction syndrome is being particularly researched upon in septic shock. Measures to determine abnormalities in microcirculatory flow have been touched upon in Chapter Overview of Shock Syndromes. A persistent increase in serum lactate and reduced $\dot{V}O_2$ in spite of normal or even more than normal DO_2 lends suspicion to the diagnosis of MMDS. Measures to counter this syndrome are being studied. These include further volume infusions—to further increase DO_2, a titrated infusion of nitroglycerine to increase microcirculatory blood flow and counter capillary spasm, provided there is no existing hypotension. Multiple action therapy in the form of fluid resuscitation plus vasoactive and inotropic support is reported to be effective in recruiting the microcirculation. The use of a NO donor agent can open the microcirculation thereby perfusing weak microcirculatory units. Also conceivably the use of an inducible nitric oxide synthase (INOS) inhibitor can reduce pathological shunting and recruit poorly functioning microcirculatory units. Whether the measures stated above are likely to help outcome is yet unknown.

Stabilizing the Airway and Breathing

Stabilizing the airway and breathing has been mentioned as an early prime concern in a patient admitted with severe sepsis and septic shock. If these basic functions are in question—due to excessive airway secretions, very low O_2 saturation, respiratory distress or an evolving ARDS, ventilator support should be prompt. ARDS usually develops later in the natural history of septic shock but may well be the first manifestation of severe sepsis. Ventilator support should follow the now clearly accepted lung protection strategies using relatively low tidal volumes (6 mL/kg of predicted body weight) with the upper limit of the plateau pressure being not more than 30 cm H_2O. Permissive hypercapnia may be allowed to minimize tidal volumes and plateau pressures (see Chapter Acute Lung Injury and Acute Respiratory Distress Syndrome).

Antibiotic Therapy

A number of studies have demonstrated the crucial importance of early administration of appropriate broad-spectrum antibiotics in reducing mortality in septic shock.[34-36] Kumar and colleagues[37] in a retrospective cohort study in patients with septic shock showed that increasing delay in the initiation of antimicrobial therapy after the onset of hypotension was associated with an increasing risk for death. These workers also showed that the median time to initiation of antibiotic therapy was a reliable and significant predictor of mortality. The recent SCC guidelines recommend starting IV antibiotic therapy as early as possible (within the first hour) as each hour's delay is associated with a progressive measurable increase in mortality.[23,34,37]

Antibiotic therapy should be prompt but as mentioned earlier should as far as possible be preceded by blood culture, culture of urine, Gram staining and culture of sputum, other body secretion (if indicated), wounds, bed sores, if present. Therapy should on no account await results of these tests. If cultures for any reason are delayed, antibiotic therapy should start forthwith.

The following features in relation to antibiotic therapy need consideration—

- The initial selection of an antibiotic or antibiotics against severe sepsis and septic shock should cover all likely pathogens and should take into consideration their ability to penetrate in adequate concentration the suspected source of sepsis.
- Patient factors such as pre-existing comorbid conditions, immune suppressed states, recent antibiotic administration, risk factors for multiple drug resistant (MDR) colonization, a history of drug allergies and intolerance play an important role in antibiotic selection.
- In case of nosocomial infections causing septic shock, a knowledge of the prevalence of various pathogens in the

hospital or in an ICU and the sensitivity of these organisms to antibiotics is another crucial factor in selection. (Also see Chapter Nosocomial Infections).

- There is a frighteningly increased prevalence of highly resistant Gram-negative infections in many critical care units in India. An increasing prevalence of resistant Gram-negative infections causing sepsis and septic shock is also being observed in the community. A combination of a carbapenam plus an aminoglycoside or a piperacillin-tazobactum with an aminoglycoside in full appropriate dosage would be justified to start with in severe sepsis or septic shock. In units with a very high prevalence of resistant pathogens like pan-resistant Pseudomonas aeruginosa or ESBL organisms, antibiotic treatment with alternative regimens such as colistin or polymyxin should be considered.
- Methicillin resistant staphylococcal infections are comparatively rare in most critical care units in India. If suspected, vancomycin or linezolid should be added to the antibiotic regime. The latter would also help to cover vancomycin resistant enterococci. Fulminant sepsis or sepsis where Gram-positive infection is possible or suspect, requires the use of a Gram-positive cover in addition to a Gram-negative cover.
- Severe sepsis and septic shock due to a community acquired pneumonia should be covered with amoxicillin or amoxicillin-clavulanate in addition to antibiotics that cover other likely organisms. The incidence of penicillin-resistant pneumococcal infection is low in India.
- In areas with a high prevalence of Candida species or in situations where fungal infection seems likely (as in neutropenia or immunocompromised patients) fluconozole, or echinocandins to cover fluconazole resistant *Candida glabrata* or *C. krusei* should be included in the antimicrobial regime.
- In neutropenic patients with sepsis or septic shock, a powerful combination of antibiotics is mandatory, e.g. piperacillin-tazobactum plus an aminoglycoside. Vancomycin may need to be added if there is a possibility of a staphylococcal infection. If there is no improvement and if fever persists over 24 hours amphotericin B or fluconazole is added to cover a fungal infection. This blunderbuss therapy in neutropenic patients with severe sepsis or septic shock of unknown etiology is unfortunate but usually unavoidable.[38]
- The possibility of fulminant disseminated hematogenous tuberculosis causing the picture of severe sepsis and septic shock in immunocompromised patients and rarely even in immunocompetent patients should always be kept in mind in our country and in other poor countries where tuberculosis is rampant.
- In tropical countries, fulminant *P. falciparum* infections, leptospiral infections, rickettsial infections and dengue can result in severe sepsis and MOF. If source of infection is not apparent, and if the clinical picture is compatible with any one of the above diseases, appropriate treatment is specifically given, even if convincing proof of these disease is not present.
- Observational studies indicate that outcome of sepsis[35] and septic shock is worse if the causative microorganisms are not sensitive to the initial antibiotic regimen. The importance of hitting early and hitting hard cannot be over emphasized.

How Long Should Antibiotics Be Given in Severe Sepsis or Septic Shock?

- Once the causative organism is identified on culture and the microbial sensitivity to antibiotics is available, further antibiotic therapy should be directed solely against the identified pathogen. Unnecessary antibiotics should be promptly discontinued to avoid nosocomial superinfections, fungal infections and drug toxicity. The single most effective antibiotic as judged from minimum inhibitory concentration (MIC) results suffices. Most units however still prefer to treat *P. pyocyaneus* infection and perhaps even klebsiella infection with a combination of antibiotics though evidence for this approach has been disputed.
- The de-escalation of antibiotics in patients who have severe sepsis or septic shock has been shown to result in better outcomes.[39] Current recommendations are to continue therapy for 7–10 days.[41] Longer duration may be justified in patients who respond slowly in severe *P. pyocyaneus* infection, in neutropenic patients and in patients with immunologic deficiencies.
- It is unfortunate but true that in many patients with severe sepsis and septic shock, cultures are negative. The decision to continue, taper, stop antibiotic therapy depends on overall clinical assessment of the patients.

If in patients with the clinical picture of severe sepsis or septic shock, the source of sepsis is underdetermined, it is important to look for noninfectious etiologies known to give rise to a similar clinical picture. These include acute pancreatitis, multiple blood transfusions, poisoning, severe vasculitis, acute connective tissue disorders, thrombotic thrombocytopenic purpura, cholesterol embolic syndrome and the hemophagocytic syndrome.

Identifying the Source of Infection and Source Control

After sending the requisite cultures and then starting an empirical antibiotic regime, an intensive search for possible sources of infection should be made. This should include an extremely thorough clinical examination, laboratory tests, and the use of current imaging techniques. Any localized collection of pus within the body should be promptly drained. Intra-abdominal abscess, an empyema of the gall bladder, paracolic abscess, pelvic abscess, an appendicular abscess, an empyema tucked away in the paravertebral space are some localized collections of pus that should be avidly searched for (Box 4). The common sources of infection are the chest and

Box 4: Common sources of severe sepsis/septic shock requiring urgent source control

- Pneumonia, Empyema
- Intra-abdominal abscess
- Gangrenous cholecystitis
- Necrotizing pancreatitis with infection
- Ascending cholangitis
- Amebic liver abscess
- Perforated viscus
- Ischemic bowel
- Obstructive uropathy
- Complicated pyelonephritis or perinephric abscess
- Necrotizing soft tissue infections (necrotizing fasciitis)
- Clostridial myonecrosis
- Iatrogenically induced sepsis

Note: In the tropics and poor developing countries—sources include falciparum malaria, dengue, leptospiral infection, and amebic infection.

the abdomen. Investigations should therefore always include a CT scan of the chest, abdomen and the pelvis. No amount of antibiotics can salvage a situation if a localized abscess is left undrained—the sooner it is drained the better. The possibility of iatrogenic hematogenous sepsis arising from contaminated central lines should always be kept in mind. Suspect central lines should be removed and the tips sent for culture. Cultures from central and peripheral lines should always be done. Laboratory tests for tropical infections listed earlier should be done as and when necessary.

In close to 30% of patients, no source of infection can be definitely identified. The frequency of positive blood cultures varies with different clinical situations, and with different microbiological laboratories. In our set-up, the incidence of positive blood cultures is about 30%. Again patients who have already received, or are receiving antibiotics, are less likely to have positive cultures. It is to be remembered that death from septic shock can result from an undetected focus of sepsis or from a focus of sepsis which for many reasons need not yield positive blood cultures—this is particularly true in patients with abdominal sepsis.

Difficulties in the diagnosis and location of a source of sepsis may be immense in critically ill individuals, particularly if modern diagnostic and imaging facilities are unavailable, as is to be expected in many third world countries. These difficulties need special emphasis in the following situations.

In Pregnancy and Parturition During pregnancy and soon after delivery the source of sepsis can be easily missed. An acute appendicular abscess in a patient with advanced pregnancy often produces discomfort in the right hypochondrium, and in the tropics can be mistaken for an amoebic hepatitis or cholecystitis. A pelvic abscess can also be easily missed during pregnancy if not specifically looked for. Diagnosis is doubly difficult because of constraints on imaging procedures.

Perforation of the gut due to any etiology soon after a caesarean delivery, is a disaster which is often missed. The subject has been discussed under Intra-abdominal Sepsis in the Section Surgical Infections in the Intensive Care Unit.

In the Aged and the Infirm Problems of identifying the source of sepsis in the aged are invariably extremely difficult. The body responses to sepsis are blunted, and this is one reason why the diagnosis is delayed. Localizing signs are few and sometimes ill-defined and indeterminate. For example, perforation of the large bowel may produce very few signs, and may therefore be missed till too late. Pneumonia or an empyema tucked away in the paravertebral space may also remain undiagnosed for a period of time in the old and the infirm.

In Neutropenic and Immunocompromised Patients The problems in these patients are often impossibly difficult. In fact, neutropenic patients with sepsis, often have no identifiable source of infection. In these patients, the source of infection is believed to be a small or even microscopic focus in the bowel or perhaps in some other organ system.

Late Stage (Preferably Termed the Later Stage) of Sepsis

The late stage (preferably termed the later stage) of sepsis commences after the first 6 hours are over. The late stage merits what is sometimes termed a second line treatment in contrast to the first line treatment already described during the first 6 golden hours. Unquestionably it is the first line treatment in the early stage which chiefly influences outcome. Even after the first 6 hours it is vital to continue to maintain hemodynamic stability and maintain tissue perfusion so as to counter tissue hypoxia. This might entail titrated volume replacement as also vasopressor and/or inotropic support for several hours and in some patients for several days.

Ventilator Support

Almost all patients with severe sepsis and septic shock need more than just supplemental oxygen. They need ventilator support—some may need this in the early phase or stage, others often require it later. These patients generally have a low partial pressure of oxygen (PaO_2) because of ventilation-perfusion inequalities within the lung, and in hemodynamically unstable patients because of a low partial pressure of oxygen in mixed venous blood (PvO_2) which contributes to a low PaO_2. Even otherwise, these patients are generally tachypneic with respiratory rates ranging from 30–45 breaths/minute. Ventilator support rests the muscles of respiration, sharply lowers the oxygen cost of breathing, enabling more oxygen to be delivered to the vital organs of the body. ARDS is an important complication of sepsis necessitating ventilator support using lung protective measures (see Chapter Acute Lung Injury and Acute Respiratory Distress Syndrome).

Support to Other Organ Systems

Septic shock often leads to multiorgan failure. Each organ system requires adequate support. Renal replacement therapy to counter acute renal failure is often necessary and

should not be unduly delayed. The mortality in patients with more than three organ failure is horrendous in several bacterial sepsis but is not so forbidding in severe sepsis due to tropical infections.[41]

Use of Recombinant Human Activated Protein C in Severe Sepsis

Activated Protein C (APC) has now been shown to be of no use in severe sepsis and septic shock. The drug has been withdrawn from the market and is no longer available.

The story of APC is indeed a blow to evidence based medicine and for that alone it needs to be briefly reported. In 2001, after the Prowess Trial[40] this drug was acclaimed as the one and only drug which had a direct salutary action on severe sepsis and septic shock. The medical profession was exhorted to use it. Then came the Enhance Trial and the Address Trial,[42] the latter noting an increase in mortality in patients with sepsis who had a single organ failure and who were administered this drug. Following this, came the Surviving Sepsis Guidelines (2008) which advocated its use only in patients with severe sepsis with a high APACHE score (>25) and multiorgan failure. And then at last came the recent Prowess Shock trial and the latest 2011 Cochrane Database System Review.[43] This review included in its database a review of five randomized control trials involving 5,101 participants. The review reported that APC did not reduce the risk of death in adult participants with severe sepsis and therefore should not be used in treating patients with severe sepsis and septic shock. Additionally APC was associated with a higher risk of bleeding. They concluded, "unless additional randomized controlled trials (RCT) provide evidence of a good treatment effect, policy makers, clinicians and academicians should not promote the use of APC". At last, the story of APC which in 2001 began with a bang ended in 2012 with a whimper!! Perhaps this review may lead to further debate, and (who knows!) even more RCTs with further questionable results—an example of evidence based medicine enjoying an internecine quarrel!

Use of Corticosteroids

There have been a number of trials and a number of reports with conflicting evidence with regard to the use of corticosteroids in severe sepsis and septic shock—a state of affairs confusing and disturbing to the intensivist engaged in the management of this critical problem. Among the various studies is the Corticus Study group—Hydrocortisone therapy for patients with septic shock.[44] This study concluded that hydrocortisone did not improve survival or show reversal of shock in patients with septic shock or in patients who did not have a response to adrenocorticotropic hormone (ACTH). Current recommendations[23] suggest that hydrocortisone should not be used to treat adult septic shock patients if adequate fluid resuscitation and vasopressor therapy are able to restore hemodynamic stability. In case this is not achievable, IV hydrocortisone in a dose of 200 mg/day can be used. When used, the risk of superinfection should limit its use preferably to not more than 7 days. However, corticosteroids should not be administered for the treatment of sepsis in the absence of shock.

What does one do in clinical practice? To use, or not to use—that is the question! Evidence seems to change again and again. Even so, and in spite of current evidence, there will probably be as many using this drug as those not using it!

Perhaps hydrocortisone in small doses of 50 mg 6–8 hourly may have a role in early shock, in those patients who remain hypotensive despite a volume load and the use of vasopressors.[44].

Blood Product Administration

- The recent surviving sepsis guidelines recommend that RBC transfusions should be given only when hemoglobin (Hb) falls less than 7 g/dL so as to target a Hb of 7–9 g/dL. This recommendation is based on Transfusion Requirements in Critical Care Trial which suggested that a Hb of 7–9 g/dL when compared to 10–12 g/dL was not associated with an increased mortality in adults.[45] This trial suggests that red blood cell transfusion in sepsis increases oxygen delivery but does not necessarily increase oxygen consumption.[46-48] Not withstanding evidence (which of course could change!) this recommendation goes against clinical judgment. For one, it goes against the goal directed resuscitative protocol that advises a PCV of 30 % in patients with a low $ScvO_2$; for another it is impossible to predict blood flow and DO_2 to vital organs such as the heart, the brain, the kidneys and the gut in critically ill individuals. Nor is it possible to predict the extent and degree of vessel wall disease particularly in severely ill elderly individuals. It is a well accepted fact that myocardial ischemia and/or a poor cerebrovascular circulation can exist without being clinically manifest. For example, critically ill patients with well-marked coronary artery disease may have a normal ECG tracing. An increase in oxygen content should benefit such patients. Whatever the present evidence, there are many who would aim at an Hb close to 10 g/dL.
- Fresh frozen plasma should not be used to correct laboratory clotting abnormalities in the absence of bleeding or planned invasive procedures.[23]
- The guidelines for the SCC[23] recommend that platelets should be prophylactically transfused only in patients with severe sepsis when counts are less than 10,000/mm^3 in the absence of apparent bleeding, and also when counts are less than 20,000/mm^3 if the patient has a significant risk of bleeding. Higher platelet counts greater than or equal to 50,000/mm^3 are advised for active bleeding, surgery, or invasive procedures. Major surgical procedures require platelets of more than 100,000/mm^3.

METABOLIC SUPPORT

Glycemic Control

A randomized multicentric trial in cardiac surgery patients compared a conservative glycemic control to a tight glycemic control (blood sugar <120 mg/dL) through the use of IV insulin.[49] Patients who had tight glycemic control had a significant reduction in morbidity and mortality at the end of 1-year vis-à-vis patients who were offered the usual conservative control. Other advantages of tight control were a reduced intensive care stay, a reduced incidence of renal failure and of critical illness polyneuropathy.[49] However, a recent study by the same group in medical critically ill patients showed no significant difference.[50] In view of the danger of hypoglycemia particularly in developing countries where nursing supervision and resources are limited, it is much safer to use a titrated dose of insulin so as to keep the blood glucose levels around 150 mg/dL.

Use of Bicarbonate

The use of bicarbonate in the treatment of sepsis induced lactic acidosis is controversial.[51,52] In fact, there is no evidence to support its use.[51] However, in the presence of severe acidosis with a pH of less than 7.15, IV bicarbonate is used by many units. Possibly its use is unlikely to improve the ultimate outcome. At times the use of bicarbonate in patients with a low pH has a salutary effect on myocardial function and blood pressure.

The use of bicarbonate can have adverse effects. The release of CO_2 following its use can cause an intracellular acidosis; detrimental to cell function. It can also lead to a fall in the ionized calcium which theoretically could reduce myocardial contractility. Repeated use of IV bicarbonate can result in an acute volume overload. Adverse effects of bicarbonate can be reduced by using slow IV infusions instead of rapidly administered boluses. In summary, sepsis induced lactic acidosis is best corrected by improving the underlying primary disorders by measures outlined earlier.

Nutritional Support

This is vital for survival in the hypercatabolic state that characterizes sepsis and septic shock. Hyperalimentation is frequently necessary if the gut function is poor and does not allow adequate intake of calories, proteins, carbohydrates, minerals and vitamins (see Chapter Nutrition Support in the Critically Ill Adult).

Prophylaxis for Deep Vein Thrombosis and Stress Ulcers

Patients with severe sepsis need prophylaxis against deep vein thrombosis either with low molecular weight heparin, or if this is inappropriate, with the use of a mechanical protective device (intermittent compression device or compression stockings). Prophylaxis for stress ulcers in severe sepsis is provided by the use of H_2 receptor-antagonists or proton pump inhibitors. Patients without risk factors do not need prophylaxis.[23] Most intensivists prefer the use of sucralfate. If a GI bleed has already occurred or if the patient is at high risk for a GI bleed, use of a proton pump inhibitor is advocated.

Immunotherapy—Neutralization of Toxic Mediators, Cytokines, in Sepsis

Septic shock is mediated by numerous interacting endogenously produced mediators and cytokines, triggered by the action of bacterial toxins, chiefly endotoxins derived from Gram-negative bacteria. A search is on for pharmaceutical agents that can directly counter these harmful endogenous mediators, or their noxious effects on tissues. Agents tried include nonsteroidal anti-inflammatory drugs, nalaxone, pentoxiphylline, antitumour necrosis factor, surfactant (to replace depleted surfactant in ARDS). The use of antibodies against proinflammatory ILs or of monoclonal antibodies to the core antigen of the J-5 strain of *E. coli* has yielded unsatisfactory results. High dose corticosteroids and the use of a number of agents to inhibit activity of nitric oxide synthetase have proved futile. It is unlikely that a single inhibitor or antagonist to the numerous interacting mediators in severe sepsis is ever likely to succeed. Perhaps a multipronged attack on the important proinflammatory cytokines and mediators that inflict damage on the host seems a more rational approach.

PROBLEMS IN MANAGING SEVERE SEPSIS AND SEPTIC SHOCK IN INDIA AND OTHER DEVELOPING COUNTRIES

The major problem is the very late admission of patients with severe sepsis to the ED or the ICU. Patients admitted often have advanced multiorgan failure with refractory hypotension. They have reached a point of no return. The reason for the delay is a lack of awareness of the clinical features of sepsis and severe sepsis among general practitioners and the lack of urgency among doctors in hospitals who look after these patients. Continuing medical education is the only answer to mitigate this problem.

Another problem is the poverty of resources and of trained personnel in ICUs outside the larger metropolitan centers of poor countries. To a lesser extent this problem is also valid in the larger cities of India and other poor countries. Lack of resources includes absence of modern microbiological, imaging and monetary facilities and the unavailability in many units in the country of powerful antibiotics to counter infection. Lack of resources should also include lack of information technology in poor countries, or lack of awareness of the importance of its use.

The problems in the management of severe sepsis and septic shock in rural and semi-rural India where hospitals are poorly staffed and equipped can be impossibly difficult.

Box 5: Sepsis Bundle for poor tropical countries having poorly equipped ICUs

- Awareness and clinical recognition
- Basic laboratory tests—CBC, urine, relevant cultures, HIV rapid test, malaria- thick and thin smears, IgM dengue, tests for other tropical infections (before starting antimicrobials)
- Fluid resuscitation followed wherever necessary by vasopressors and inotropes
- Assessment of end-points (treatment response)—
  - CVP of 8–12 mm Hg
  - Urine output ≥0.5 mL/kg/hour
  - Blood pressure (MAP ≥65–70 mm Hg)
  - Skin perfusion (improved with better capillary refill)
  - Tests for different organ functions should be normal or show improvement
- Antimicrobials—antibiotics, antimalarials , others (depending on the locale and clinical features—to be started within the first hour)
- Source identification and control

Box 6: Programming priorities for sepsis in poor countries

- Education
- Laboratory facilities
- Developing sepsis management guidelines in hospitals with limited resources
- Simple diagnostic tests to identify end-points of resuscitation
- Antimicrobials (antibiotics, antimalarials etc) – their appropriate and prompt use.
- Improving critical care facilities
- Use of information technology to help in treatment

Box 5 suggests the sepsis bundle for poor tropical countries in hospitals with meagre facilities and resources.

Box 6 suggests programming priorities for the management of severe sepsis in poor countries.

CHAPTER 17

Cardiac Compressive Shock

INTRODUCTION

Compression of the heart and the great veins opening into the right heart can restrict and sharply reduce diastolic filling of the ventricles. This results in a low output state with inadequate tissue perfusion akin to the picture of cardiogenic shock. The classical cause of acute cardiac compression resulting in shock is cardiac tamponade due to accumulation of fluid within the pericardial sac. This chapter is devoted to the description of cardiac tamponade. Before we give the description, it should be noted that acute severe cardiac compression resulting in a shock-like low output state can also result from a tension pneumothorax. The problems here are further compounded by disturbances in pulmonary function and respiratory exchange due to acute compression collapse of one lung, with a marked shift of the mediastinum to the opposite side and by mediastinal flutter during inspiration and expiration. Acute cardiac compression can also occur in mechanical ventilation with positive end-expiratory pressure (PEEP). In the presence of very high intrathoracic pressure, the large veins opening into the right heart and the heart chambers are sufficiently compressed to sharply restrict diastolic filling and produce a low output state. A major contributory factor in this situation is the strain imposed on the right ventricle by increased vascular resistance within the pulmonary capillaries, and perhaps a further impairment of filling of the left ventricle by a septal shift that encroaches on the left ventricular volume.

CARDIAC TAMPONADE[1,2]

General Considerations

The pericardium has very little elasticity when acutely stretched. Therefore, a very rapid accumulation, as little as 300–500 mL of fluid within the pericardial sac can result in a sharp rise in the intrapericardial pressure, and cause compression or tamponade of the chambers of the heart. Fluid with a higher specific gravity, like blood or thick pus, will cause greater compression and greater tamponade. As little as 300 mL of thick pus formed acutely within the pericardial sac can lead to death from tamponade in children. On the other hand, a slow accumulation of fluid within the pericardial sac allows the pericardium to stretch maximally so that intrapericardial pressure may not be sufficiently raised to produce a serious tamponade even with an effusion of one liter or more.

Cardiac tamponade can result from pericardial effusions due to any cause. The important medical causes include acute viral (idiopathic) pericarditis, pericarditis secondary to metastatic neoplastic disease, uremic pericarditis, purulent pericarditis, tuberculous pericarditis, pericarditis occurring in patients with myocardial infarction who have been anticoagulated, and occasionally in systemic lupus erythematosis. In tropical countries, a left lobe amebic liver abscess rupturing into the pericardium, is a rare but important cause of tamponade.

In an emergency setting, unquestionably the most important cause is hemopericardium resulting from trauma and accidents. A dissection of the aorta which ruptures into the pericardial sac can also result in immediate tamponade and quick death.

In the intensive care unit, postoperative bleeding following open heart or cardiothoracic surgery, and hemopericardium in sepsis and septic shock are important causes.

Diagnostic and therapeutic procedures performed in a critical care unit can sometimes be complicated by acute cardiac tamponade. Perforation of the right atrium by a central venous line, particularly when the line is used to administer fluids or is used for parenteral alimentation, is an important

Box 1: Iatrogenic causes of cardiac tamponade

- Postoperative hemorrhage following cardiac surgery
- Use of anticoagulants
- Barotrauma during mechanical ventilation
- Upper gastrointestinal (GI) endoscopy or sclerotherapy resulting in esophageal perforation
- Internal jugular or subclavian vein puncture
- Perforation of the heart by indwelling catheter (used for hemodynamic monitoring, pacing), or during angiography
- Perforation of the heart or coronary artery during balloon angioplasty

cause of acute cardiac tamponade. Perforation of the heart by a pacing catheter, or tear of the coronary artery during balloon angioplasty, or of the heart by catheters used for balloon valvuloplasty, can all cause hemopericardium, resulting in cardiac tamponade and death (Box 1).

Pathophysiology[1,3]

A rapid accumulation of fluid within the pericardial sac leads to an acute increase in intrapericardial pressure. When this intrapericardial pressure rises to equal the atrial and the right ventricular diastolic pressure, the transmural pressure distending these chambers declines to about zero. A further accumulation of pericardial fluid leads to a further increase in the intrapericardial pressure and the right ventricular diastolic pressure, so that they now equal the left ventricular diastolic pressure. Cardiac tamponade thus occurs on equalization of the intrapericardial and ventricular filling pressures. This results in a marked fall in the distending pressure and therefore in the diastolic volumes of both ventricles, resulting in a fall in the stroke volume. The reduction in stroke volume is initially compensated for by an increased adrenergic drive that causes tachycardia and an increase in the ejection fraction. To a lesser extent, it is also compensated for by an increase in circulatory volume due to salt and water retention induced by a decreased urinary excretion of sodium. A fall in sodium excretion is related to the reflex inhibition of the release of the atrial natriuretic factor produced by a rise in intrapericardial pressure. With severe cardiac tamponade, the compensatory mechanisms do not suffice to prevent a sharp fall in cardiac output and in the systemic blood pressure, so that perfusion of vital organs is impaired. Reduced coronary perfusion results in subendocardial ischemia. Sinus tachycardia is usually present, but sinus bradycardia may also occur through a reflex mediated by the cardiac depressor branches of the vagus nerve or through nonvagal mechanisms. Severe bradyrhythms foreshadow electromechanical dissociation and death in patients who are almost pressureless because of severe tamponade.

Hemodynamic Profile[1]

The hemodynamic profile in cardiac tamponade is characterized by a marked rise in the central venous and right atrial pressure, and by equalization of the right atrial, right ventricular diastolic and the pulmonary capillary wedge pressures (PCWP). The PCWP is an index of the left ventricular diastolic pressure. If the intrapericardial pressure were to be measured, it would be found to be equivalent to the right atrial pressure, the right ventricular diastolic pressure and the PCWP. Tachycardia, hypotension and a raised systemic vascular resistance with poor tissue perfusion characterize the clinical hemodynamic profile.

It should be noted that the rise in the right atrial (and intrapericardial) pressure is less marked in the presence of hypovolemia, so that cardiac tamponade unless very severe, may be masked in hypovolemic states.

Another point of note is that if the left ventricular diastolic pressure is elevated to start with because of left ventricular disease, then cardiac tamponade occurs when the intrapericardial, right atrial and right ventricular diastolic pressures become equal, but these pressures will be lower than the left ventricular diastolic pressure as gauged by the PCWP.

Clinical Features[2,4]

The clinical features of acute cardiac tamponade are—

- A progressive rise in the central venous pressure (CVP) as gauged by a clinical estimation of the jugular venous pressure, to +15 to +20 mm Hg. When hypovolemia is associated with cardiac tamponade (as after trauma or accidental injuries), the CVP may not show the degree of rise normally expected. Such a low pressure tamponade may pose difficulties in diagnosis. The liver is not usually enlarged in acute cardiac tamponade.
- A falling arterial pressure. There is a progressive fall (initially in the systolic pressure), with an increasing inadequacy in tissue perfusion. This is characterized by oliguria, cold, sweating peripheries, restlessness, together with all the features of a rapidly evolving shock state.
- A small quiet heart. The apex is not felt and the heart sounds are faint or inaudible. Clearly audible sounds do not however negate the diagnosis of cardiac tamponade.
- A pulsus paradoxus. The volume of the pulse falls perceptibly during inspiration and increases during expiration and this can be best elicited by a sphygmomanometer. The cuff pressure is raised well above the systolic pressure, and is then very slowly lowered till Korotkoff's sounds are first heard only in expiration. The cuff is slowly further deflated so that the sounds are equally well heard both during inspiration and expiration. The difference between these pressures gives the magnitude of pulsus paradoxus; it exceeds 10 mm Hg in cardiac tamponade.

Complete disappearance of the pulse on inspiration can occur in severe tamponade. A pulsus paradoxus on palpation is often better appreciated in the carotids or femorals rather than in the radials, particularly when the volume of the pulse is low. At times, a pulsus paradoxus not appreciated clinically or with a sphygmomanometer can be demonstrated on recording the arterial pressure via an intra-arterial cannula. The degree of paradoxus in the arterial pulse is often significantly greater

in direct arterial pressure recordings as compared with a clinical estimation using the sphygmomanometer.

A pulsus paradoxus in cardiac tamponade is merely an exaggeration of the normal physiology during inspiration which is characterized by a slight decrease in the left ventricular stroke volume and in the systolic arterial pressure. In cardiac tamponade, inspiration causes a decrease in the intrapericardial and right atrial pressures, with increased blood flow to the right ventricle. This increase in venous flow to the right ventricle during inspiration results in an increase in the dimensions and size of the right ventricle, the septum being straightened and pushed to the left. There is a resulting decrease in the left ventricular volume and size, with decrease in left atrial and left ventricular diastolic pressures. This leads to a fall in aortic flow and in systolic arterial pressure. Pulsus paradoxus in cardiac tamponade is thus chiefly related to increased inspiratory venous return and increasing flow into the right ventricle. Inspiratory pooling of blood within the lungs may result in a reduced gradient between the pulmonary venous circulation and the left heart, and this may be a minor contributory factor toward the observed inspiratory fall in left ventricular stroke volume and systolic arterial pressure.

- Tachycardia with a feeble pulse volume is invariably present. Bradycardia is often a preterminal event and precedes electromechanical dissociation and death.
- Inspiratory swelling of the neck veins may be noted. Cardiac dullness may be increased on percussion, if there is a sufficiently large collection of fluid in the pericardial sac.
- Patients with acute cardiac tamponade are tachypneic, restless, in shock, and may complain of precordial discomfort. A pericardial or a pleuropericardial rub may be heard. If hypotension is marked, the patient is generally obtunded.

Diagnosis[2,5] (Box 2)

A well-marked rise in the CVP is a requisite for the diagnosis of cardiac tamponade, except in rare instances where hypovolemia is associated with tamponade. In the latter situation, diagnosis is difficult and can only be arrived at if the background factors (trauma, injury) are kept in mind, and further relevant investigations done. It is important to recognize cardiac tamponade at a point in time when the chief physical finding is a rising CVP. A rise in CVP to +15 mm Hg in the presence of a moderate sized pericardial effusion suffices for a diagnosis of cardiac tamponade. The diagnosis can be made with a lesser degree of rise in CVP if pulsus paradoxus above 10 mm Hg is present or if the atrial and the right- and left-sided diastolic filling pressures are equalized. It is obviously unwise to wait for a falling blood pressure before making a correct diagnosis. Unfortunately, a rise in the CVP in a critical care setting can be due to several factors, notably over-infusion of intravenous fluids and myocardial dysfunction.

Acute right heart failure, due to right ventricular infarction, or massive pulmonary embolism may on clinical examination mimic acute cardiac tamponade as these produce a rise in the CVP. Acute increase in the heart size with clear lung fields may further confuse the issue. However, the other clinical features of acute myocardial infarction and the presence of background features against which pulmonary embolism occurs should help in the diagnosis. Pulsus paradoxus in the presence of a rising CVP always points to cardiac tamponade. Pulsus paradoxus is not observed in acute congestive heart failure, but may rarely be observed with massive pulmonary embolism. Other conditions causing pulsus paradoxus include profound hemorrhagic shock, other forms of severe hypotension and obstructive lung disease.

The diagnosis of acute cardiac tamponade is frequently missed in acute bacterial pericarditis complicating acute pneumonias or sepsis. This is because a rapid accumulation of 250 mL of pus will demonstrate no clinical signs of fluid within the pericardial sac. A sudden clinical deterioration in a patient with lobar pneumonia or sepsis in the presence of a raised jugular venous pressure, should always suggest the correct diagnosis.

Box 2: Diagnosis of cardiac tamponade

Marked rise in CVP, tachycardia, hypotension
Pulsus paradoxus >10 mm Hg
Chest X-ray: rapidly increasing cardiac silhouette with clear lung fields; increasing size of mediastinum after open heart surgery
ECG: electrical alternans of P, QRS and T waves; sudden fall in voltage of tracing
Echocardiography: collapse of the right atrium and the right ventricle in diastole is a very sensitive sign of pericardial effusion causing hemodynamic compromise
Hemodynamic profile: raised atrial pressure; equalization of atrial, right and left ventricular diastolic pressures

Abbreviations: CVP, central venous pressure; ECG, electrocardiography.

Chest X-Ray

A normal heart size does not rule out cardiac tamponade. A rapidly increasing cardiac silhouette with clear lung fields is however a feature of cardiac tamponade. Following open heart surgery, the presence of hypotension, raised CVP, and enlarged mediastinal shadow on an X-ray of the chest, strongly suggest cardiac tamponade.

Electrocardiography

The electrocardiography (ECG) may show features of electrical alternans of P, QRS and T waves but this is not commonly observed. A sudden fall in voltage in the ECG tracing should also suggest the development of pericardial effusion. A myocardial rupture following infarction is often associated with a slow junctional rhythm, promptly followed by electromechanical dissociation.

Doppler Echocardiography[6]

Doppler echocardiography is the best diagnostic tool for the diagnosis of pericardial effusion and cardiac tamponade. Echocardiography not uncommonly underestimates the

quantity of fluid in the pericardial sac which is better revealed on a computed tomography (CT) or magnetic resonance imaging (MRI) study. The presence of tamponade is however best brought out by a Doppler echo which shows the following characteristic features—

- Circumferential pericardial fluid layer and compressed cardiac chambers with high ventricular ejection fractions.
- Doppler study shows marked respiratory variations in transvalvular flow; both atrial and ventricular septa move sharply leftward on inspiration, reversing on expiration.
- During early diastole the right ventricle wall collapses (invaginates) and in late diastole the right atrial wall invaginates. The ventricular wall collapse is a less sensitive but more specific finding; whereas right atrial wall collapse is more specific if the inward movement lasts more than 30% of the cardiac cycle.
- Left ventricular wall collapse usually occurs under specific conditions, as in patients with localized postsurgical tamponade.

These wall changes occur when respective chamber pressures temporarily fall below the pericardial pressure.

Hemodynamic Profile

In an intensive care setting, provided that time is available, a hemodynamic study would show a raised atrial pressure and equalization of the atrial, right ventricular diastolic and left ventricular diastolic pressures. Equalization should always be measured at the end-expiratory phase, and it should be noted that the equalization need not be exact or perfect, particularly if the PCWP or pulmonary artery end-diastolic pressure is used (as it invariably is) as a measure of the left ventricular diastolic pressure.

Variant Forms of Cardiac Tamponade[2]

- Low-pressure tamponade[7] occurs at diastolic pressure of 6–12 mm Hg and is chiefly observed in patients with hypovolemia , hemorrhage, or after a diuretic-induced volume depleted circulation. Patients are generally normotensive and pulsus paradoxus is absent; characteristic fluctuations in transvalvular diastolic Doppler flows are observed. A fluid challenge with a liter of warm saline can result in the typical tamponade dynamics.
- Hypertensive cardiac tamponade has all the classic features of tamponade but occurs at high arterial pressures (even often >200 mm Hg). It has been ascribed to an excessive alpha-adrenergic drive. There is invariably a history of hypertension present.
- Regional cardiac tamponade occurs when any area over the heart is compressed by a loculated effusion. This is observed especially after cardiac surgery and is more frequent after postoperative anticoagulant therapy. Postoperative myocardial stiffness, hemorrhage, and fluid electrolyte disturbances generally preclude the presence of classical signs such as pulsus paradoxus. Doppler echocardiography, a widened mediastinal shadow on imaging, hypotension, tachycardia and a raised CVP, all considered in their entirety allow diagnosis.
- After right ventricular infarction, a loculated effusion can cause selective right-heart tamponade in which right atrial pressure is higher than left atrial pressure. Diagnosis is difficult as there is no pulsus paradoxus.
- Effusoconstrictive pericarditis shows the hemodynamic changes of a cardiac tamponade. The changes persists (because of the underlying constriction) even after the pericardial fluid has been drained.

Management[1,2,5]

Pericardiocentesis[8]

Acute cardiac tamponade particularly when due to hemopericardium as a result of trauma or injury should be dealt with on an emergency basis. An immediate pericardiocentesis is mandatory. The technique of this procedure is described in a separate chapter.

Cardiac tamponade after open heart surgery necessitates re-surgery to remove blood clots and fluid causing tamponade. Most surgeons prefer to relieve tamponade from other causes by a surgical procedure, wherein a pericardial window is fashioned surgically and a drain left within the pericardial sac. The drain is removed when it stops draining. An antibiotic cover is generally necessary for a few days.

Supportive Treatment

Supportive treatment perhaps buys time. The use of inotropic support with or without vasodilator therapy (to reduce systemic vascular resistance) is controversial. Dobutamine is the preferred inotropic drug as it also has a vasodilator effect.

Volume infusions are also used to counter hypotension. They would help if there is hypovolemia but may be otherwise counterproductive as they could increase intracardiac pressure and heart size, which in turn would increase intrapericardial pressure thereby further reducing the transmural pressure supporting the circulation.

Supportive treatment is never a substitute for removal of the tamponade by drainage of the fluid compressing the chambers of the heart.

Mechanical ventilation with positive pressure breathing should be avoided in patients with tamponade because this further decreases cardiac output.[4]

It is important to keep a close clinical watch after pericardiocentesis has been done to determine if tamponade recurs. A rising CVP is again an ominous sign. If a Swan-Ganz catheter is *in situ*, demonstration of an equalization of the atrial, right ventricular diastolic and PCWP should point to a recurrence of the tamponade.

CHAPTER 18

Anaphylactic Shock

GENERAL CONSIDERATIONS[1]

The incidence of anaphylactic shock in hospitalized patients is around 1 in 10,000, and the fatality rate is as high as 10–20%. Anaphylactic shock is an anamnestic response in which a sensitized individual comes in contact with an antigen. The antigen combines with specific immunoglobulin E (IgE) antibodies on mast cells and basophils, and induces the release of mediators such as histamine, platelet activating factor and other mediators that mediate the anaphylactic response. The latter is characterized by severe vasodilatation, bronchoconstriction, pruritus and increased vascular permeability. The common precipitating agents for anaphylaxis include drugs, particularly penicillin. Other antibiotics can also give rise to anaphylaxis. Contrast material and blood products are important causes of anaphylaxis. In fact, almost any and every drug including steroids has been shown to cause an acute anaphylactic reaction at one time or another.[2]

Anaphylactoid reactions are different from anaphylactic shock. The former are related to the direct release of mediators by the offending agent from mast cells and basophils without IgE antibodies coming into play. This direct release of mediators may be brought about by complement-mediated reactions or by nonimmunological activation of mast cells. Products of arachidonic acid breakdown include leukotrienes which increase vascular permeability and induce bronchoconstriction, as also thromboxanes and prostaglandins. Prostaglandin D2 can further cause bronchoconstriction. Common etiological agents that result in anaphylactic shock and anaphylactoid reactions are listed in Box 1.

Box 1: Commonly used agents implicated in anaphylactic and anaphylactoid reactions

- Antibiotics—
  - Penicillin and analogs
  - Sulfonamides
  - Tetracyclines
  - Streptomycin
- Local anesthetics—
  - Lidocaine
- General anesthetics and muscle relaxants—
  - Thiopental
  - Tubocurarine
- Non-steroidal anti-inflammatory agents
- Blood products and vaccines—
  - Red blood cell, white blood cell and platelet transfusions
  - Gamma globulin
  - Rabies vaccine
  - Tetanus antitoxin, toxoid
  - Diphtheria antitoxin
  - Snake and spider antivenin
- Diagnostic agents—
  - Iodinated radiocontrast agents
- Venoms—
  - Bees, wasps, spiders, jellyfish
- Hormones—
  - Insulin
  - Hydrocortisone
  - Pituitary extracts
  - Vasopressin

Contd...

Contd...

- Extracts of allergens used for desensitization
- Foods—
  - Eggs
  - Milk and milk products
  - Legumes (peanuts, soybeans, kidney beans, chickpeas)
  - Nuts
  - Shellfish
  - Citrus fruits
- Other drugs—
  - Protamine
  - Parenteral iron
  - Dextrans

Box 2: Conditions in the intensive care unit (ICU) to be distinguished from severe anaphylaxis

- Cardiac problems in the ICU—acute myocardial infarction
- Shock from any other cause—septic shock, hypovolemic shock
- Bronchoconstriction due to aspiration, asthmatic attack, pulmonary edema from other causes
- Pulmonary embolism
- Cerebrovascular accident—causing seizures, hypotension
- Vasovagal syncope

Box 3: Management of anaphylactic shock

- Intubate and administer oxygen at high flow rates. If intubation not possible, emergency tracheostomy or puncture of cricothyroid membrane
- Epinephrine 0.5–1 mL of 1:1,000 solution subcutaneously; this can be repeated every 10 minutes, and is followed by a maintenance infusion of epinephrine
- If no response to subcutaneous epinephrine, or if laryngospasm or cardiovascular collapse present, 5–10 mL of 1:10,000 solution of epinephrine given intravenously (IV)
- If IV access unavailable, 0.5–1 mL of 1:1,000 solution of epinephrine given intramuscularly (IM), or 10 mL of 1:10,000 solution instilled through endotracheal tube
- Administer volume load
- Use antihistaminic, e.g. diphenhydramine 1 mg/kg IV, and repeat 6 hourly
- Relief of bronchospasm by IV aminophylline 250 mg in 20 mL dextrose
- Hydrocortisone 300 mg IV stat, followed by 100 mg IV 6 hourly
- If hypotension persists despite epinephrine, volume load and antihistaminics, start dopamine infusion. If this also does not raise the blood pressure (BP), start epinephrine infusion
- Ventilatory support with high fraction of inspired oxygen (FiO_2) may be required in critically ill patients

CLINICAL FEATURES

Symptoms may occur instantaneously or within a few minutes after an intravenous injection of the offending agent. At times the reaction may develop after 0.5–1 hour of the exposure. Anaphylaxis to oral drugs may take 1–2 hours, but in many patients can be instantaneous.

The major features of anaphylactic shock include hypotension and circulatory collapse due to widespread peripheral vascular dilatation. Severe laryngeal edema and obstruction, angioedema, overwhelming bronchoconstriction and fulminant pulmonary edema may also occur either singly or in combination. Tachycardia, arrhythmias, syncope and seizures at times constitute the predominant clinical features. Diaphoresis, abdominal pain with cramps and diarrhea may occur if death does not ensue following the sinister picture described above. Urticaria is often observed but may be totally absent in patients with fatal anaphylactic shock.

An increased hematocrit is often found due to hemoconcentration resulting from increased vascular permeability.

DIFFERENTIAL DIAGNOSIS (BOX 2)

In a critical care setting, anaphylactic shock in a seriously ill patient may be mistaken for myocardial infarction, hypovolemic or septic shock or pulmonary embolism. Bronchoconstriction due to anaphylaxis may be wrongly imputed to aspiration of gastric contents. A sudden seizure with hypotension may be mistaken for a cerebrovascular accident. A temporal relationship to the administration of intravenous fluids, drugs or blood products should always arouse suspicion of the correct diagnosis.

TREATMENT[3,4] (BOX 3)

The two immediate emergency measures to be instituted in anaphylactic shock are—

1. Intubation to secure the airway before it is blocked by laryngeal edema. Oxygen at high flow rates should be administered. Intubation may be extremely difficult even for an expert. If expert help is unavailable, or intubation fails and there is danger of asphyxia, an emergency airway must be secured (however inadequate this be), by puncturing the cricothyroid membrane by a large bore needle. A tracheostomy should be performed if intubation is impossible, as soon as surgical help is available. An infusion of norepinephrine may also be necessary in patients with persistent hypotension.
2. *Epinephrine which is the first drug to be administered should be promptly given to every patient with anaphylaxis.* We prefer to give it subcutaneously 0.5–1 mL of a 1 in 1,000 solution. This may be repeated every 5–10 minutes,

if necessary. If the patient does not respond to the initial dose, or if laryngospasm or frank cardiovascular collapse is present, 5–10 mL of 1 in 10,000 solution of epinephrine is given intravenously. If intravenous access is not possible, 0.5–1 mL of a 1 in 1,000 solution is given intramuscularly, or 10 mL of a 1 in 10,000 solution of epinephrine may be instilled through the endotracheal tube. A maintenance intravenous infusion of epinephrine may be necessary after the initial bolus dose.

3. Volume load This is the next most important aspect of therapy. In a critical care setting, a venous line is generally already present. We prefer to use crystalloids, though colloids produce quicker volume expansion, for fear of inducing further allergic reactions to colloidal solutions. Short, wide peripheral catheters permit quicker fluid infusions than long, thin central venous lines. Again, collapse of large veins due to circulatory shock increases the risk of iatrogenic complications associated with the insertion of central lines. An iatrogenic pneumothorax, for example, in such a patient would compound difficulties in management.

After the above management protocol has been instituted, one can use an antihistaminic like diphenhydramine 1 mg/kg intravenously, and repeat the dose 6 hourly, if necessary. Aminophylline 250 mg intravenously in 20 mL dextrose helps reduce the bronchospasm. Hydrocortisone 300 mg intravenously, followed by 100 mg 6 hourly may prevent the late manifestations of anaphylaxis. Steroids have little or no role in the immediate alleviation of anaphylactic shock.

If hypotension persists after the use of epinephrine, volume load and antihistaminics, a dopamine infusion starting with 5 μg/kg per minute and titrated if so required to 10–20 μg/kg per minute is infused to increase the blood pressure (BP). If dopamine proves ineffective, then an infusion of epinephrine in a concentration of 3–4 μg per minute is started and slowly increased till a rise in BP is observed. Patients receiving beta-blockers at the time of acute anaphylaxis may fail to respond adequately to epinephrine. Intravenous atropine and glucagon are useful aids to reverse circulatory shock in such patients. Critically ill patients may need both cardiovascular support and ventilatory support with a high fraction of inspired oxygen (FiO_2) till such time as recovery slowly ensues.

Cardiovascular Problems Requiring Critical Care

- Acute Coronary Syndromes
- Unstable Angina
- Acute Myocardial Infarction
- Acute Left Ventricular Failure with Pulmonary Edema
- Tachyarrhythmias in the Intensive Care Unit
- Bradyrhythms and Heart Block in the ICU
- Antiarrhythmic Drugs Used in the ICU
- Hypertensive Emergencies and Aortic Dissection in the ICU
- Pulmonary Embolism

CHAPTER 19

Acute Coronary Syndromes

GENERAL CONSIDERATIONS

Acute coronary syndromes are due to an acute disturbance in coronary artery circulation resulting in myocardial ischemia, which if severe or prolonged, could progress to myocardial infarction (MI). The syndrome includes the classical triad of unstable angina, ST segment elevation myocardial infarction (STEMI) and non-ST elevation myocardial infarction (NSTEMI). The ST elevation myocardial infarction may also have a pathological Q-wave in the anterior chest leads in an anterior myocardial infarction, and in the inferior leads in an inferior myocardial infarction. The NSTEMI may occasionally also have pathological Q-waves over the area of the infarction. These are not separate entities but form a related continuum of the same disease process. Even so, each of these three acute coronary syndromes has a differing prognosis and specific strategies in management.

Critical care, therefore, demands that patients presenting with ischemic cardiac pain be placed into one of these three syndromes. This can be achieved by integrating the history and clinical findings with the evolution in time of the twelve lead electrocardiograms and the quantification over time of the biological markers of myocardial cell necrosis. Since acute coronary syndromes form a dynamic continuum, patients diagnosed to start with as unstable angina, during observation and investigation over time, may ultimately develop into a STEMI or NSTEMI. The dividing line between unstable angina and myocardial infarction may at times be tenuous. Microinfarction detected by a slight rise in the newer sensitive biological cardiac markers may well be an additional event between unstable angina and classical MI.[1]

Acute myocardial ischemia, besides producing unstable angina, STEMI and NSTEMI (the classic triad of acute coronary syndromes), can also result in other clinical presentations. These include sudden death, cardiac arrhythmias causing palpitation, presyncope or syncope, acute pulmonary edema due to severe left ventricular failure. These presentations of myocardial ischemia should logically also be included under acute coronary syndromes. They may present without anginal pain and without ECG or biochemical evidence of MI.

PATHOPHYSIOLOGY

Most patients with acute coronary syndromes have significant obstructive atherosclerotic lesions in the coronary arteries. Acute myocardial ischemia can be precipitated either by a sharp reduction in supply of oxygen (e.g. a thrombus obstructing the coronary lumen or vasospasm), or a significant increase in oxygen demand (e.g. an acute rise in the blood pressure or tachycardia). Both a reduction in oxygen supply and an increase in oxygen demand may operate in the same patient.

The major precipitants of the acute coronary syndrome are briefly described below[2]—

- *Rupture or erosion of an atherosclerotic plaque* with a resulting thrombus obstructing the lumen of a coronary artery. This is the most frequent and important pathogenic mechanism. Remarkably enough, the vulnerable plaques (i.e. plaques prone to rupture) are not the tightly stenotic lesions but lesions with usually less than 50% stenosis.[3] These lesions may not be visualized by coronary angiography.

Plaque rupture or erosion is precipitated by biochemical causes. These include liquid lipid content within the plaque, inflammation with erosion of a thin fibrous cap overlying the

plaque and local shear stress forces. A ruptured atherosclerotic plaque exposes the underlying subendocardial matrix to the circulating blood. Initially, this leads to platelet adhesion followed by platelet activation. The latter results in the release of thromboxane A_2, serotonin and other chemotactic agents, which are strong vasoconstrictors. Platelet activation also results in expression and activation of glycoprotein IIB/IIIA receptors on the platelet surface so that it can bind fibrinogen. The final step is platelet aggregation with the formation of a platelet plug over the plaque rupture site. Together with the formation of a platelet plug, there is activation of the coagulation system within the plasma initiated through the release of tissue factor. Activation of factor X to factor Xa leads to the generation of thrombin, which converts fibrinogen to fibrin. Thrombin once formed acts as a powerful stimulus for platelet aggregation; thrombin also activates factor XIII which leads to stabilization of the fibrin clot. The pivotal role of a thrombus partially or completely occluding a coronary artery in the pathogenesis of acute coronary syndromes is supported by substantial evidence.[4]

- *Inflammation and infection* Inflammation may well play an important role in the formation of atherosclerotic lesions and in the erosion or rupture of vulnerable plaques.[5] The role of infectious agents, in particular Chlamydia pneumoniae in causing such inflammation is the subject of current research.[6]
- *Coronary vasoconstriction* Coronary vasoconstriction reduces coronary blood flow and occurs in the following situations—
  - In the presence of coronary atherosclerotic lesions, particularly with plaques.
  - In microcirculatory angina, caused by spasm of intramural vessels.
  - In *Prinzmetal's angina* The latter is associated with severe focal spasm either at the site of a mild to moderate obstructive lesion, or at the site of a non-obstructive plaque, or in patients without coronary atherosclerosis. These patients typically present with severe rest angina with transient ST elevation occurring during episodes of anginal pain.
- *Progressive mechanical obstruction* Progressive luminal narrowing is most frequently observed when restenosis occurs after a coronary angioplasty. However, it can also occur in patients who have no intracoronary procedures performed on them. It is due to rapid proliferation of cells within the stenotic lesion leading to a critical obstruction of the lumen.
- *Increased myocardial oxygen demand* In patients with stable coronary artery disease, a sharp increase in myocardial oxygen demand due to extrinsic factors may precipitate the acute coronary syndrome, particularly unstable angina. Increased myocardial oxygen demand occurs in—
  - Sudden increase in blood pressure; in increasing aortic stenosis.
  - Tachycardia due to fever, anemia, thyrotoxicosis, supraventricular tachycardia, atrial fibrillation with a fast ventricular rate, other hyperdynamic circulatory states.

  The acute coronary syndrome could also be precipitated or worsened by—
  - Impaired oxygen delivery as in patients with a low output syndrome, anemia, hypoxia from any cause, hyperviscosity states.
  - Metabolic derangements, in particular hypoglycemia.

The clinical determinants of the acute coronary syndromes are related to the severity and duration of myocardial ischemia.

Unstable angina is generally induced by a temporary, non-occluding thrombus within the coronary artery lumen.[7] Thrombus formation is a dynamic process; a thrombus after being formed may in time be fibrinolyzed. Temporary and repeated accretions of fresh thrombi over the site of plaque rupture may critically narrow the lumen to produce rest angina. Partial spontaneous resolution of the thrombus within 10–20 minutes would provide relief and this generally occurs in unstable angina.

In a NSTEMI, the thrombus is larger and generally does not completely occlude the lumen. It may cause significant obstruction for 20–30 minutes before being partially, or at times completely, resolved. The degree of myocardial ischemia is significantly great to cause myocardial necrosis with liberation of cardiac enzymes.

In a STEMI, there is a thrombus that completely occludes a coronary vessel in over 95% of patients. This can lead to fairly extensive necrosis (often associated with a Q-wave), surrounded by an area of injury, which is in turn surrounded by an area of ischemia.

Whether a partially or a completely obstructing thrombus in a coronary artery results in unstable angina, a ST elevation infarct or a non-ST elevation infarct, will to an extent be also influenced by the presence or absence of coronary collaterals, by the degree of coronary vasoconstriction and by associated increase in myocardial oxygen demand.

It is to be noted that the earlier classification of MI into subendocardial and transmural has been given up, as these descriptions are clinically inaccurate when correlated with autopsy findings.

The subsequent sections now deal with the diagnosis and management of unstable angina and MI.

CHAPTER 20

Unstable Angina

INTRODUCTION

Acute total occlusion of a coronary artery results in a ST elevation myocardial infarction (STEMI), whereas severe but not total occlusion results in unstable angina (UA) or non-ST elevation myocardial infarction (NSTEMI). UA or NSTEMI is a condition now also referred to as non-ST elevation acute coronary syndrome (NSTE-ACS). The incidence of NSTE-ACS both in absolute terms and also relative to STEMI is increasing. In India, this is largely due to the high and increasing incidence of diabetes in the population; diabetes being an important risk factor for UA or NSTEMI. In the West and the USA, both diabetes and an increasing number of older people are equally responsible for this rise.[1]

Unstable angina or non-ST elevation myocardial infarction signifies a seriously prejudiced circulation in one or more coronary arteries and carries a risk of serious cardiac arrhythmias, cardiac failure and sudden death. The problem therefore is of immense concern and of great importance to the critical care physician.

Though figures for our country as a whole are not available, in the Western world and in the USA, among patients with the ACS, women present more often with UA, representing 35–45% of patients with this condition compared with 25–30% of patients with NSTEMI and only 20% of patients with STEMI.[2] Approximately, 80% of patients with UA or NSTEMI have a history of coronary artery disease before the acute event.

The diagnosis of UA depends on the presence of one or more of the following—

- New-onset angina, i.e. angina occurring for the first time within a one-month period, and brought on by minimal exertion.
- Increasing severity of a previously stable angina. This may take the form of more protracted anginal pain, or pain with more extensive radiation, or more frequent angina (more than three times a day), or angina brought on by less effort or by other precipitating factors which previously had not produced any discomfort. Angina, which is incompletely relieved or unrelieved by nitroglycerin, also denotes a worsening pattern and constitutes UA. The increase in frequency and severity of angina is superimposed on a pattern of a relatively stable exertion-related angina.
- Rest angina denotes anginal episodes at rest. In the acute or emergent form, many such anginal episodes may occur over 24 hours. At times, angina at rest may occur more frequently at night. In the less emergent (yet dangerous) situations, rest angina may occur at infrequent intervals after lapses of two or more days.

Approximately two-thirds of patients with UA have elevated cardiac enzymes—troponin I or T and creatinine kinase isoenzyme (CPK-MB) in the blood. These patients are diagnosed to have NSTEMI. As measurements of troponin levels in the blood become increasingly sensitive, a greater number of patients with NSTE-ACS will demonstrate some release of troponin; these should be considered as NSTEMI. As a corollary, a diagnosis of NSTEMI can only be made if troponin levels are increased against a background of clinical features of myocardial ischemia.

Braunwald[3] has proposed a clinical classification of UA or NSTEMI taking into consideration three degrees of clinical severity, three clinical circumstances, the response to medical therapy and the presence or absence of electrocardiographic changes. The increasing degree of clinical severity is classed as follows[3]—

- Class I—severe or frequent new onset angina (<2 months).
- Class II—rest angina in the past month, but not during previous 48 hours.
- Class III—anginal attacks at rest within prior 48 hours.

The three clinical circumstances considered by Braunwald are as follows[3]—

1. Patients with secondary angina (Class I); there is a secondary cause that exacerbates angina (e.g. anemia, fever, hypoxemia, tachyarrhythmia, thyrotoxicosis, hypoglycemia).
2. Patients in whom no precipitating cause can be found (Class II).
3. Patients with postinfarction angina (within 2 weeks of a myocardial infarct).

Braunwald[3] also considered symptom severity and clinical circumstances of a given patient in relation to treatment—whether the patient was not on treatment prior to unstable angina, on treatment for previous stable angina, and finally whether unstable angina persisted in spite of maximal treatment. Braunwald's classification has been shown to correlate with clinical outcomes. Patients with severe angina (Class III), poor response to full medical treatment, ST-T changes on the ECG, and those with postinfarction angina have poorer outcomes.[4] A higher clinical grading was predictive of plaques with thrombus at angiography.[4]

The diagnosis of UA rests chiefly on a good clinical history. The basic characteristics of the pain are similar to those observed in stable angina. The pain is substernal and often precordial, and is described as heaviness, constriction, and at times, as just severe pain. It is often interpreted as a feeling of choking in the chest or throat. In UA, the duration of pain may be as long as 15 minutes and may extend to even 30 minutes. The typical sites of radiation include the left shoulder, arm, forearm, hand, right shoulder and upper arm, shoulders and arms, the jaw, the neck, the back and the upper abdomen. On occasion, the pain may not be felt in the chest at all, but may only be experienced at one or more sites of radiation mentioned above.

The diagnosis of UA in a patient with a past history of myocardial infarction (MI), or a typical history of angina on effort, generally presents no difficulty. New onset angina characterized by frequent chest pain at rest may require careful evaluation of the history and a close follow-up, to help distinguish it from nonanginal or noncardiac pain. There are some important negative points that help in the diagnosis of ischemic heart pain—

- Pain localized to the apex is almost always nonanginal.
- Jabbing or pricking pain is also generally nonanginal in etiology.
- Pain which worsens on local pressure or pain which is clearly aggravated by movement is also definitely nonanginal.

Physical findings in UA are more often than not negative. During an attack of pain, one may hear a third heart sound at the apex, a reversed split of the second sound at the base, and a mid to late mitral systolic murmur of papillary muscle dysfunction. Rarely, frequent extrasystoles or even supraventricular or ventricular arrhythmias occur after the onset of pain, and may disappear after the pain subsides.

ECG Transient ST elevation or depression, or T-wave inversion may occur during the pain. However, absence of ECG changes even during periods of severe cardiac pain in no way rules out a diagnosis of UA. Continuous ECG monitoring may at times reveal ST depression characteristic of myocardial ischemia or may detect transient arrhythmias. Not uncommonly ST-T changes are of a nonspecific nature. Transient (<20 minutes) ST elevation, which occurs in approximately 10% of patients with UA or NSTEMI, prognosticates a higher risk of a cardiac event. T-wave changes are sensitive but not specific for myocardial ischemia, unless T-wave inversions are deep and symmetrical.

In patients with a past history of ischemic heart disease (IHD), or when previous investigations clearly denote IHD, the diagnosis of UA can be confidently made on a history alone, even in the absence of ECG changes during episodes of pain. It is only in the group of patients without a history of previous stable angina or previous IHD, that the diagnosis of UA without any ECG changes becomes difficult or inaccurate.

Serum Cardiac Enzyme Levels Among patients presenting with symptoms of UA or NSTEMI a rise in the troponin T or I or the CPK-MB identify those suffering from NSTEMI, which has a worse prognosis. Troponin levels are more sensitive than CPK-MB levels.

The Gusto II Trial[5] showed that elevated levels of troponin T are associated with a higher risk and a higher 30-day mortality. Higher levels of troponin T correlated more strongly with 30-day survival than either ECG changes or changes in CPK-MB levels. Low levels of troponin T were noted to be associated with a low rate of cardiac events. Low troponin levels do not always signify a good prognosis, for catastrophes can still occur.

Specific Unstable Angina Syndromes

- *Unstable angina after angioplasty* Unstable angina after angioplasty is related to restenosis and occurs in over 30% of patients. It may present as angina at rest.
- *Unstable angina after bypass surgery* If this occurs within 6 months after surgery it may signify a single active lesion. Later it often signifies obstruction to venous grafts.
- *Prinzmetal's angina* is a vasospastic variant of UA (see Acute Coronary Syndromes). The pain in this variant typically occurs at night or in the early hours of the morning. It is characterized by transient ST elevation during pain and is relieved by nitroglycerin and by calcium channel blockers.

Risk Stratification

Risk stratification in UA or NSTEMI is important as it helps to determine which patients are at greater risk for impending or near-future cardiac events like sudden cardiac death,

arrhythmias, left ventricular (LV) failure. In essence, it helps to assess possible outcomes in patients presenting with UA or NSTEMI. Risk stratification also helps the critical care physician to decide on the appropriate strategies for management.

High-Risk Subgroup

Clinical Assessment

Advanced age greater than 70 years is associated with a poorer outcome, as is the presence of diabetes, congestive heart failure, or the presence of extracardiac vascular disease such as peripheral vascular or cerebrovascular disease.

Braunwald's clinical classification of UA or NSTEMI has been found to be useful in several studies. High-risk patients include those with ongoing protracted angina, recurrent rest angina, angina unresponsive to medical therapy and postinfarction angina.

Risk Assessment by ECG

The presence of left bundle branch block is believed to be an independent predictor of death in MI. Also the greater the degree of ST depression in the ECG, the greater the risk for cardiac events.[6]

Risk Assessment by Estimation of Cardiac Markers-Troponins and CPK-MB Levels

Patients with NSTEMI identified by a rise in troponins or CPK-MB levels have a worse long-term prognosis compared to those with UA.[7]

Beyond just a positive report, the higher the level of subsequent troponins, the higher the risk of subsequent death in these patients.[8]

Assessment of Other Inflammatory Markers

A significant rise in the CRP indicates an increased risk of death, MI and the urgent need for revascularization. Among patients with negative troponin I, CRP can distinguish between high-risk and low-risk groups. When both CRP and troponins are used, mortality ranges from 0.4% for patients with both markers negative to 4.7% if either CRP or troponin is positive to 9.1%, if both are positive.[9]

7

MANAGEMENT OF UNSTABLE ANGINA AND NON-ST SEGMENT ELEVATION MYOCARDIAL INFARCTION

General Principles

Unstable angina and non-ST segment elevation myocardial infarction spell danger and the patient must be admitted in the intensive care unit (ICU). The ECG should be continuously monitored, an intravenous (IV) line secured and serial enzyme estimates of CPK-MB and troponins should be done.

There are three approaches to management. The first is a conservative approach with medical management. The second is an early invasive strategy involving percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG). The third approach is initial conservative management, which graduates to coronary angiography and invasive intervention in patients who develop worsening myocardial ischemia or develop LV dysfunction or hemodynamic instability.

The most suitable approach to the management of ACS patients who present without ST elevation is dependent on risk stratification. Risk stratification begins on entry into the ICU but continues during hospital stay. It is important to determine as to which patients with UA are likely to progress to MI or suffer death as also which patients with NSTEMI are more likely to worsen, suffer complications or die. Risk stratification with regard to clinical assessment, ECG changes and elevated cardiac enzymes has already been discussed earlier in this chapter. As a general principle, the higher the risk the more the need for an invasive strategy of coronary angiography. Conservative management could be the first or preferred approach in those stratified to be low or medium risk.

Emergency Management

Bed rest is important particularly for patients with protracted angina, recurrent angina or repeated rest angina. The patient is given 300 mg aspirin to be chewed and swallowed as also 300–600 mg clopidogrel to be promptly swallowed. Sorbitrate 5 mg sublingually can be repeated after 5 minutes with close monitoring of the blood pressure and clinical effects.

If pain is unrelieved or even otherwise with a history of protracted cardiac pain, IV nitroglycerin is started. Severe pain may require the initial use of IV morphine (2–4 mg) or IV buprenorphine (0.3 mg). It is crucial to relieve pain; pain induces an increased catecholamine state, which increases anxiety, heart rate, blood pressure and cardiac contractility, thereby increasing myocardial oxygen demand and myocardial ischemia. In the presence of hyperadrenergic states, the judicious use of beta-blockers is of great help.

A constant watch on clinical findings and on the ECG recording is imperative to promptly detect complications, in particular arrhythmias, LV dysfunction and failure, hypotension and early signs of cardiogenic shock.

A quick but careful search for possible factors aggravating or precipitating angina should be made and if possible these should be corrected. Increased myocardial oxygen demand with resulting angina can occur with fever, tachycardia, thyrotoxicosis, tachyarrhythmias, bradyarrhythmias or hypoglycemia. Hypovolemia due to fluid loss in vomiting and diarrhea can also precipitate UA or NSTEMI. In patients with asthma or chronic lung problems, exacerbation of their pulmonary disease can produce hypoxemia, which in turn worsens angina. Recent blood loss as from a gastro-intestinal bleed or anemia from any cause can also precipitate

Box 1: Management of unstable angina

- *General Measures*—
  - Critical care monitoring
  - Serial estimations of troponin T, troponin I, CPK-MB to exclude acute MI
  - Sublingual nitroglycerin to relieve myocardial ischemia
  - Diazepam for relief of anxiety
  - Morphine 2–4 mg IV, if pain severe
- *Nitrates*—
  - Nitroglycerin drip at 10 µg/min, and gradually increased till angina controlled. Systolic BP should not fall less than 100 mm Hg
  - Later oral isosorbide dinitrate 10 mg 6 hourly, or sublingual isosorbide dinitrate or nitroglycerin patch
- *Beta-blockers*—
  - For ongoing severe pain—metoprolol 5 mg IV repeated at 5-minute intervals to a maximum total dose of 15 mg—watch heart rate, BP; then oral metoprolol or propranolol titrated to maintain heart rate between 55–60/min
- *Calcium antagonists*—
  - Use only if ischemia persists in spite of nitrates and β-blockers, Diltiazem 30–60 mg 8 hourly or verapamil 40 mg 8 hourly
- *Anticoagulants, antiplatelet drugs, Glycoprotein (Gp) IIb-IIIa receptor inhibitors*—
  - Either unfractionated heparin (IV 5,000 units bolus, followed by 500–1000 units/hour) for 3–7 days or low molecular weight heparin (enoxaparin 1 mg/kg 12 hourly) for 3–7 days + aspirin 300 mg + clopidogrel 75 mg daily. Eptifibatide (180 µg/kg IV, followed by infusion of 2 µg/kg/min for 96 hours) or tirofiban (loading dose 0.4 mg/kg/min for 30 minutes, followed by 0.1 mg/kg/min for 96 hours, together with unfractionated heparin could be used in refractory or high-risk unstable angina. Risk of bleeding with this therapy
- *Treat factors precipitating or aggravating unstable angina*
- Coronary angiography–indicated if pain is unrelieved or marginally relieved with the above treatment, or if anginal episodes worsen. Early coronary angiography in high-risk patients with UA/NSTEMI

Abbreviations: CPK-MB, creatinine kinase isoenzyme in blood; MI, Myocardial infarction; IV, intravenous; BP, blood pressure.

UA or NSTEMI. A careful assessment of the associated problems outlined above may help in overall management and result in a quick stabilization of the angina (Box 1). Acute mental stress from whatever cause should be promptly recognized and benzodiazepams given to relieve anxiety. Box 2 lists the important aggravating or precipitating factors for UA.

Nitrates

Nitrates act as coronary vasodilators and also act by reducing the preload and therefore the work performed by the heart. They can be given sublingually, orally (5–10 mg isosorbide dinitrate 6 hourly) or intravenously. Intravenous nitroglycerin is preferred in patients with recurrent or protracted or rest angina, as the onset of action is immediate and the drug can be titrated with a fair degree of precision. The dose and method of administration and untoward effects are detailed in the chapter on STEMI. Nitrates should be avoided if there is history of use of sildenefil in the past 24 hours as otherwise there could occur a disastrous and at times fatal hypotension. Tachyphylaxis is often observed with nitroglycerin in that its antianginal effect is reduced despite constant drug infusion. The infusion rate should be increased slightly by about 10% every 24 hours to maintain efficacy. The patient is generally weaned off nitroglycerin 2–3 days after angina ceases or has markedly eased and then started on oral isosorbide dinitrate. A topical 1–2" nitroglycerin patch or paste can be applied to the skin as an alternative.

Box 2: Important aggravating or precipitating factors for unstable angina

- Fever
- Tachycardia
- Thyrotoxicosis
- Tachyarrhythmias
- Bradyrhythms
- Hypoglycemia
- Hypovolemia due to fluid loss in vomiting and diarrhea
- Exacerbation of pulmonary diseases like COPD, asthma
- Recent blood loss (as from a GI bleed) or anemia from any cause
- Acute mental stress

Abbreviations: GI, gastrointestinal; COPD, chronic obstructive pulmonary disease.

Beta-blockers

Beta-blockers in combination with nitrates have been shown to reduce symptoms of myocardial ischemia.[10-12]

They are particularly useful in those who have a tachycardia, provided the latter is not due to LV failure or hypovolemia. Severe UA or NSTEMI are at times associated with a hyperadrenergic state characterized by marked tachycardia, hypertension, pallor, sweating. Beta-blockers effectively counter these hyperadrenergic effects. It is to be noted that a sudden withdrawal of beta-blockers in patients who are on this drug prior to the onset of UA or NSTEMI can cause marked tachycardia and at times hypertension. Restarting beta-blockers in these patients solves the problem. The mode of administration, sideeffects, indications and contraindications have been dealt with in the chapter on STEMI.

Calcium Channel Antagonists

Calcium channel antagonists are currently recommended only in patients who have persistent ischemia in spite of the use of nitrates and beta-blockers or in patients in whom beta-blockade is contraindicated.

Diltiazem or verapamil are calcium channel blockers which slow the heart rate. They are given in a dose of 30–90 mg four times a day, both in UA and in NSTEMI.[13] Amlodipine or felodipine can also be used safely but nifedepine has been shown to increase adverse events when not co-administered with a beta-blocker. Diltiazem is best avoided in patients with left ventricular dysfunction or congestive cardiac failure because of its negative inotropic effect.

Unstable angina or NSTEMI also needs the prompt administration of antiplatelet therapy and anticoagulants. Finally, the intensivist and the cardiologist should take a decision on the need and the timing for interventional management.

Antiplatelet Therapy

Aspirin

The use of aspirin has already been commented upon. The drug acetylates platelet co-oxygenase-1 (COX-1) and thereby blocks the synthesis and release of thromboxane A_2, a platelet activator. Aspirin thereby decreases overall platelet aggregation and prevents arterial thrombi formation. Several studies have shown the beneficial effects of aspirin in UA or NSTEMI. The drug reduces adverse clinical events in the early course of treatment and also prevents recurrence of ischemic episodes in secondary prevention.

Aspirin reduces the risk of death in MI in 50% of patients with UA or NSTEMI. This was observed both on the Veterans Administration (VA) Cooperative Study Group[14] and the Canadian Multicenter Trial.[15]

Ticagrelor

Ticagrelor, the first reversibly binding, direct-acting oral P2Y12 receptor antagonist has been FDA-approved as an oral antiplatelet agent for the prevention of thrombotic events, in patients with acute coronary syndromes (unstable angina, NSTEMI and STEMI). Ticagrelor and its major metabolite reversibly interact with the platelet P2Y12 ADP-receptor to prevent signal transduction and platelet activation.

The recommended dosage is 180 mg—loading dose followed by 90 mg twice daily as the maintenance dose.

ADP Antagonists

Thienopyridines

These agents include clopidogrel, prasugrel and ticlopidine.

Clopidogrel Patients admitted with a diagnosis of UA or NSTEMI should be given clopidogrel in addition to aspirin. The initial dose of clopidogrel is 300–600 mg followed by a maintenance dose of 75 mg. The antiplatelet effect of clopidogrel is observed within 4 hours if 300–600 mg is given. On the other hand, a daily dose of 75 mg clopidogrel would need 4–7 days for antiplatelet effect. The Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) Trial[16] observed that the use of this combination resulted in a decrease in cardiovascular death, MI or stroke not only in patients who undergo PCI but also in patients who receive medical treatment.

Prasugrel It is also a reasonable choice of an antiplatelet agent in place of clopidogrel in patients with ACS. There is however a greater risk of bleeding and it should not be used in patients with history of stroke or transient ischemic attack (TIA) and avoided in patients older than 75 years.

Prasugrel is administered as a 60 mg loading dose followed by 10 mg/day maintenance dose. The duration of clopidogrel therapy depends on whether the patient has received a stent. It is at least 4 weeks (preferably 3 months) if it is a bare metal stent and tentatively at least 12 months if it is a drug eluted stent.[17,18] More data is required to give a definite recommendation on the duration of clopidogrel therapy in patients with drug eluted stents.

Anticoagulant Therapy[18]

Unfractionated heparin given IV has been the mainstay of the treatment of UA or NSTEMI for several years. Therapy with unfractionated heparin plus aspirin has been shown to lead to a 33% reduction in death or MI compared to aspirin alone. Current guidelines advise a weight adjusted dose of 60 units/kg bolus, followed by 12 units/kg per hour with 6 hourly monitoring of activated partial thromboplastin time (APTT) which should be kept at 2–2½ times the control. The dose may need titration to maintain the required APTT time. Adverse effects include bleeding particularly if the APTT is unduly high and heparin induced thrombocytopenia.

Low molecular weight heparin (LMWH) is now often preferred to unfractionated heparin in the treatment of NSTEMI, the dose being the same as that recommended for STEMI. LMWH has the following advantages—

- A more predictable anticoagulant response, so that estimation of partial thromboplastin time (PTT) is not necessary.
- A lower incidence of heparin induced thrombocytopenia.
- Easily administered and therefore suitable for administration over a longer period of time.
- The LMWH enoxaparin reduced the combined endpoints of death, MI or recurrent ischemia at both 14 days and 30 days when compared to unfractionated heparin. It is given by injection subcutaneously in a dose of 1 mg/kg every 12 hours. Patients older than 75 years or who have renal dysfunction need a reduced dose of 0.5–0.75 mg/kg every 12 hours.

Direct Thrombin Inhibitors

Bivalirudin is the only direct thrombin inhibitor indicated for the use of acute coronary syndrome.[18] Its use when combined with heparin even in combination with glycoprotein IIb/IIIa inhibitors does not confer any added advantage. Most units in this country are unfamiliar with its use.

Glycoprotein IIb/IIIa Receptor Antagonists

Glycoprotein IIb/IIIa receptor antagonists block the fibrinogen mediated cross-linkage of platelets. The three agents available in this class are (1) Abciximab, a monoclonal agent approved only in patients undergoing PCI, (2) Eptifibatide and (3) Tirofiban (small molecule inhibitors).[18] Each drug when administered is given as a IV bolus followed by a continuous infusion. Their blocking activity and the associated risk of bleeding subside once the infusion is stopped.

The benefits of glycoprotein IIb/IIIa receptor antagonists in patients with UA or NSTEMI has been reported to be a significant 11% relative reduction in death or MI at 30 days.[19] This benefit is greater in high-risk patients such as those with marked ST segment changes and high troponin levels as also in diabetics. These subgroups have more thrombosis at coronary angiography with a greater risk of microembolization.

For patients with UA or NSTEMI undergoing an initial invasive approach, the current recommendations are to administer either a glycoprotein IIb/IIIa receptor antagonists or clopidogrel in additon to aspirin and heparin. However, if the patient is considered high-risk, both a Glycoprotein IIb/IIIa receptor antagonists plus clopidogrel can be given in addition to heparin.

It is to be noted that the risk of major bleeding is significantly higher for patients treated with glycoprotein IIb/IIIa receptor antagonists, occurring 2.4% compared to 1.4% for placebo. The risk of thrombocytopenia (<50,000/mm^3) is greater in those treated with glycoprotein IIb/IIIa receptor antagonists than with heparin alone.

Interventional Management

When should interventional management be undertaken? Coronary angiography serves three purposes: (1) it helps in risk stratification by demonstrating the extent and severity of coronary artery disease; (2) it is a prelude to possible revascularization either through angioplasty or CABG surgery, and (3) it can confirm or refute the presence of epicardial coronary artery obstruction when the diagnosis of UA or NSTEMI is in doubt.

Indications for Coronary Angiography and Invasive Interventional Strategies in UA or NSTEMI

Several randomized recent trials and meta-analysis have advocated an early invasive strategy in patients who have the following features—

- ST segment changes or positive troponins on admission or if these evolve over the subsequent 24 hours.
- Recurrent angina, protracted angina, poor relief on medical therapy, persistent angina on rest.
- Evidence of left heart or congestive heart failure.
- UA or NSTEMI within 6 months of a prior PCI and in whom a blocked stent may be the cause.
- UA or NSTEMI in a patient with prior CABG.
- Hemodynamic instability.
- Ventricular arrhythmias.

The risk of an invasive strategy increases in the presence of hemodynamic instability but the risk of continuing with conservative medical management is perhaps greater.

Two studies which advocate a strategy of early invasive intervention are given below.

The Intracoronary Stenting with Antithrombotic Regimen Cooling Off (ISAR-Cool) trial showed a benefit of immediate invasive strategy with an average time of only 2 hours from randomization to catheterization, compared to delayed strategy in which the average time to catheterizations was 4 days.[20]

The Timing of Intervention in Patients with Acute Coronary Syndromes (TIMACS) trial[21] again showed a trend for reduction of the primary end-point (death, MI, stroke) in patients submitted to an early invasive strategy. There was an even more significant reduction in the primary end-point in patients with a high GRACE risk score. There was also a significant 28% reduction of the secondary endpoint of death, MI and refractory ischemia in the group. Both these trials lend support to an early interventional strategy particularly in high-risk patients.

Notwithstanding the evidence gathered from studies mentioned above, a wise physician should always place clinical judgment ahead of statistical evidence gleaned from a study of large groups of people. Besides patient factors, the physician should consider the expertise and experience of the interventional cardiologist, the facilities available if urgent need for CABG arises, the cost to the patient, the degree of improvement in the quality of life likely to accrue through the procedure. High-risk patients particularly those who are hypotensive, in pump failure or have recurrent arrhythmias need aortic balloon support before and during coronary angiography and angioplasty. An intra-aortic balloon counter pulsation device can cause lower limb ischemia in 10% of cases. A close watch over pulsations in the lower limb should be maintained.

Coronary angiography in UA not responding to conventional medical therapy helps to identify several subgroups (Box 3).[22]

- Patients with a left main stenosis who require emergency bypass surgery.
- Patients with severe triple or multivessel disease who are advised bypass surgery within 7–10 days on a semi-urgent basis.
- Patients having multivessel disease with LV dysfunction, or diabetes with multivessel disease, who also will require bypass surgery to help prolong their life-span.
- Patients with single or two vessel disease with an identifiable culprit lesion. These patients are suitable for angioplasty. Current angioplasty success rates are over 95%.[23]

Box 3: Subgroups (with management) identified by coronary angiography in patients with unstable angina

- Patients with left main coronary artery disease—urgent bypass surgery indicated
- Patients with severe triple or multivessel disease (including proximal LAD)—bypass surgery advised on semi-urgent basis (7–10 days)
- Patients with multivessel disease and LV dysfunction; patients with multivessel disease and diabetes—bypass surgery required to improve long-term survival
- Patients with single or double vessel disease with identifiable culprit lesion in form of proximal discrete stenosis—angioplasty with stenting is procedure of choice
- Patients with diffuse distal coronary artery disease—medical therapy indicated as surgery gives poor results
- Small minority of patients (5%) with no demonstrable organic coronary artery disease—medical management indicated

Abbreviations: LAD, left anterior descending artery; LV, left ventricular.

Yet, there is an increased rate of acute complications in the form of abrupt closure of the vessel or MI, following angioplasty in patients with UA, or in those with a visible occluding thrombus, when compared to patients with stable angina or in those in whom a thrombus is not visible. The use of coronary stents has, however, reduced the incidence of emergency bypass surgery, and the increasing use of glycoprotein IIb/IIIa inhibitors has reduced the incidence of death and MI.

- Patients with diffuse distal coronary artery disease for whom only medical therapy is advocated, as surgery shows poor results.
- A small minority of patients (in our experience 5%) with no significant organic coronary artery disease, who should continue with medical treatment.

After a successful angioplasty with stenting of a culprit vessel, the patient is monitored in the ICU. Sudden occlusion of the vessel on which angioplasty is done (blockage of the stent) results in cardiac pain, and ECG changes of impending infarction. This constitutes an emergency, which is tackled by either attempting to reopen the vessel by performing a fresh angioplasty, or by doing an emergency coronary artery bypass surgery. A standby surgical team should always be present when an angioplasty is done.

Patients with UA who respond to medical treatment will subsequently require a work-up to determine the nature and extent of their coronary artery disease so that elective treatment can be planned. This is done preferably 7–10 days after symptoms related to UA or NSTEMI have been well controlled, though many units would prefer to do coronary angiography earlier.

CHAPTER 21

Acute Myocardial Infarction

GENERAL CONSIDERATIONS

Acute myocardial infarction (AMI) signifies ischemic necrosis or death of a portion of the myocardium. Atherosclerotic narrowing of the coronary vessels is the basic underlying pathology in most patients, and an occluding thrombus is usually present in a major coronary artery or its branch. Myocardial infarction (MI) still carries an overall mortality between 10–30%. Prompt diagnosis and early transfer to a critical care unit, whenever possible, are essential if mortality is to be reduced. The importance of quick diagnosis and early transfer to a well-equipped intensive care unit (ICU) is related to two factors—

1. Fifty percent of deaths in AMI occur within the first 2 hours, and 80% within the first 24 hours. Early deaths occurring during this period are invariably due to primary ventricular fibrillation which can be promptly treated with good results in an ICU setting.
2. The present day management of AMI involves not only the relief of pain and other supportive treatment, but an active interventional approach directed toward restoring blood flow to the ischemic myocardium. This interventional approach is through the use of thrombolytic agents with a view to dissolving a thrombus occluding a coronary artery, and/or in selected instances the use of angioplasty to physically open and stent an occluded vessel. The earlier, this is done after the onset of MI, the better the results.

In the past, MI was considered to be either a Q-wave (transmural) infarction or a non-Q (nontransmural) infarction. This terminology was replaced by MI with ST-segment elevation (ST-elevation MI (STEMI) or MI without ST-segment elevation (non-STEMI or NSTEMI). In STEMI, clinical features of myocardial ischemia coupled with raised ST-segment in the electrocardiograph (ECG) determined treatment. In NSTEMI, clinical features of myocardial ischemia are not associated with diagnostic elevated ST-segments on the ECG. A rise in serum markers over time is necessary to indicate a NSTEMI. This terminology still prevails. However, MI has been more recently further defined and categorized according to the many different clinical situations in which it can occur.

In 2007, The European Society of Cardiology and the American College of Cardiology along with the World Heart Federation and American Heart Association published the Universal Definition of MI. This definition classifies infarction based on different clinical situations in which MI occurs.[1]

The term MI signifies evidence of myocardial necrosis in the presence of clinical features consistent with myocardial ischemia. Under these conditions, any one of the following criteria meets the diagnosis. The different types of AMI are—

Type 1 Spontaneous MI related to ischemia due to a primary coronary event such as plaque erosion. The type 1 of AMI demonstrates a typical rise and/or fall of cardiac biomarkers (preferably troponin), with at least one value above the 99th percentile of the upper reference limit (URL), together with evidence of myocardial ischemia manifested by at least one of the following—

- Symptoms of ischemia.
- Electrocardiographic changes indicative of new ischemia [new ST-segment and/or T-wave changes or a new left bundle branch block (LBBB)].
- Development of pathologic Q-waves on the ECG.
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality.

Type 2 Myocardial infarction secondary to ischemia due to either increased oxygen demand or decreased supply (e.g. coronary artery spasm, coronary embolism, anemia, arrhythmias, severe hypertension or significant hypotension).

Type 3 Sudden, unexpected cardiac death involving cardiac arrest, often with symptoms suggestive of myocardial ischemia, and accompanied by presumably new ST-elevation, or new LBBB, and/or evidence of fresh thrombus by coronary angiography and/or at autopsy, but death occurring before blood samples could be obtained or at a time before the appearance of cardiac biomarkers in the blood.

Type 4 Myocardial infarction associated with percutaneous coronary interventions (PCI), with or without intracoronary stent. For PCI in patients with normal baseline troponin values, elevations of cardiac biomarkers above the 99th percentile URL are indicative of periprocedural myocardial necrosis. By convention, increases of biomarkers greater than 3 × 99th percentile URL have been designated as defining PCI-related MI. A subtype related to a documented stent thrombosis is recognized.

Type 5 Myocardial infarction associated with coronary artery bypass graft (CABG). For CABG in patients with normal baseline troponin values, elevations of cardiac biomarkers above the 99th percentile URL are indicative of periprocedural myocardial necrosis. By convention, increases of biomarkers greater than 5 × 99th percentile URL plus either new pathologic Q-waves, or new LBBB, or angiographically documented new graft or native coronary artery occlusion, or imaging evidence of new loss of viable myocardium have been designated as defining CABG-related MI. Also, pathological findings of an AMI define the type 5 AMI.

A patient with an AMI may be admitted to the ICU from the community. On the other hand, a patient who is already being treated for a critical ailment may develop AMI as an added complication. Septic shock or hypovolemic shock for example, could cause either a STEMI or a NSTEMI due to the added physiological stress on the heart. This is even more likely to occur in older patients with coronary artery disease which may have been clinically silent prior to the critical illness. Also, such a patient could conceivably have no clinical evidence of myocardial ischemia if he were obtunded, sedated and/or on ventilator support.

It is not the purpose of this chapter to extensively detail the pathophysiology, clinical features and diagnosis of AMI. Only the basic features of diagnosis are touched upon so that mistakes are perhaps less frequent and management is not unnecessarily delayed.

DIAGNOSIS

Notwithstanding the current subclassification of MI, the diagnosis of AMI in a patient admitted to the Emergency Department or ICU is based on a positive history of cardiac pain, ECG changes, and elevated cardiac enzymes. A diagnosis should be made if any two of these three factors are present. In those patients who show no early serial ECG changes, a 4 hourly serial estimation of the cardiac enzyme in particular the troponin T, troponin I, creatine kinase (CK) and the CK-myoglobin (CK-MB) fraction should be monitored. A rise in the troponin levels, even if a little delayed, confirms the diagnosis. If, however, quick interventional therapy is to be instituted to salvage myocardium, a diagnosis has to be made on the history (and clinical findings), and on the ECG changes, as the rise in cardiac enzymes may take time to detect.

Cardiac pain is the most important clinical feature of AMI. In some, the pain is agonizingly severe, while in others it may be so mild as to be totally ignored by the patient and overlooked by the doctor. It is not necessarily the severity of pain, but the site and radiation of pain, as well as its character, which are diagnostic. The character of the pain is as in angina, felt substernally and over the precordium with radiation to the shoulder, arms, neck or jaw. Patients with AMI may present with pain in the right chest or one single site at which ischemic cardiac pain is known to radiate. At times patients with inferior myocardial infarct may complain of severe headache as the main site of pain. Whereas pain in angina lasts less than 15 minutes, patients with AMI generally experience protracted pain over 30 minutes. Pain is often accompanied by associated features, like sweating, pallor, vomiting, breathlessness due to left ventricular failure (LVF), hypotension and disturbances in the rate and rhythm of the heart.

Clinical examination may be essentially normal, or may reveal a diastolic gallop and basal crepitations denoting LVF, or early evidence of shock in the form of pallor, sweating, hypotension, or evidence of arrhythmias. Any one or more of these features may be present.

There are a few points to be kept in mind in relation to the clinical diagnosis of AMI—

- In diabetics, elderly patients, and at times for no apparent cause, there may be little or no pain.
- In some patients, symptoms are perceived as gastrointestinal, with epigastric fullness, pain and vomiting.
- Acute MI may manifest with angina equivalent syndromes without pain. A recent large survey of 434,877 confirmed AMI patients reported that approximately 30% lacked chest pain on presentation, noting only the anginal equivalent complaints.[2] The most common anginal equivalent complaint is dyspnea.
- The geriatric patient may also present atypically with acute weakness (3–8%) and syncope.[3] Among the very elderly, anginal equivalent syndromes typically involve neurological presentations with disturbances in the mental status and stroke.
- Acute MI may occasionally present with the following clinical variants—
  - Acute LVF.
  - Acute shock of unexplained etiology.
  - Cardiac arrhythmias.

- ❖ Embolic complications, which draw attention to an underlying MI.

- ❑ Clinical examination may be perfectly normal with no change in the pulse or blood pressure (BP) even in the presence of an extensive infarction.
- ❑ A number of other noncardiac conditions can cause severe, protracted chest pain. To give just a few examples, chest pain may be due to musculoskeletal problems, esophageal spasm, a lower esophageal tear, acute abdominal problems, pulmonary embolism, pneumothorax, pleurisy, acute pericarditis and dissecting aneurysm of the aorta. *It is particularly important to exclude acute pericarditis and dissecting aneurysm of the aorta, as the use of thrombolytic therapy by mistake in either of these conditions can have disastrous consequences.*

ELECTROCARDIOGRAPHIC CHANGES

The ECG is an extremely important study in the evaluation of a patient with chest pain suspected of AMI. It provides critical information in a patient with STEMI, providing not only the diagnosis, but guiding management. It can also provide valuable information with regard to diagnosis and management in other coronary related events. Nevertheless, the ECG has its shortcomings and an awareness of these is of importance to physicians. To start with it, should be made clear that an AMI cannot be excluded even if the initial ECG is normal. The ECG should be repeated as changes may take hours or even a couple of days to manifest. Other shortcomings include the non-diagnostic interpretation, ECG changes in a NSTEMI (which may be nonspecific in nature) and the difficulty of ECG recognition of an isolated posterior or high lateral wall infarction.

ST-Elevation Myocardial Infarction

The earliest change in the STEMI is the presence of hyperacute T-waves which appear within minutes of stoppage of coronary blood flow through a coronary artery. This rapidly evolves into ST-elevation within 5–30 minutes.

Features of note in the elevated ST-segments in AMI are listed below—

1. ST-segment elevation in AMI tends to have a convex or obliquely flat morphology of the wave form. Patients with noninfarcted ST-elevation as with early repolarization or left ventricular hypertrophy related changes, tend to have concave morphology of the wave form. An analysis of ST-segment wave form confers specificity to the diagnosis of AMI in a person with chest pain.
2. Significant (2 mm rise) ST-segment elevation occurring in at least two anatomically oriented leads is an indication for fibrinolysis or PCI.
3. Left bundle branch block patterns, ventricular paced rhythms, left ventricular hypertrophy may obscure the typical ECG findings of AMI and may produce noninfarcted-ST-elevation, which may lead to mistakes in diagnosis.
4. ST-segment elevation can occur in acute pericarditis and in early repolarization. A wrong diagnosis of AMI can lead to dangerous therapy in a patient with pericarditis and unnecessary therapy in patient with ECG changes of early repolarization.
5. Q-waves generally develop 8–12 hours after a transmural infarct. They signify myocardial necrosis.
6. Right ventricular infarction and true posterior wall infarction can be missed on a 12 lead ECG. An additional lead V_4R evaluates the right ventricle and leads V_7 V_8 the posterior wall.

Non-ST-Elevation Myocardial Infarction

Patients with NSTEMI can present with various ECG abnormalities. These include symmetrically convex downward ST depression, inverted or biphasic T-waves. Unfortunately, the ECG findings in some instances initially appear normal. Regardless of the ECG presentation in NSTEMI patients, a diagnosis of MI in these patients can only be made if the troponins and creatinine phosphokinase (CPK), cardiac enzymes are clearly raised.

The importance of serial changes in the ECG, even if minor cannot be over-emphasized as these changes may constitute the only ECG evidence of MI. Also, ECG changes may occur well after the onset of symptoms; a diagnosis of MI should then be made in the presence of a typical clinical picture and corroborative evidence of myocardial necrosis in the form of raised cardiac enzymes particularly troponin I, T, CK, CK-MB. Posterior, high lateral and right ventricular infarcts are not easily detectable on the ECG and may evolve later.

Electrocardiography may also not always be helpful in the diagnosis of MI in patients with multiple previous infarcts, in LBBB, right ventricular paced patterns, the Wolff-Parkinson-White (WPW) syndrome and in patients on digitalis therapy. *The occurrence of a new or a fresh bundle branch block, particularly a fresh LBBB in a patient with ischemic cardiac pain should be taken as a sign of a fresh infarct.* In a patient with a pre-existing LBBB pattern or ventricular paced pattern, the presence of cardiac pain together with a loss of the normal discordance on the quasi-random signal-T (QRS-T) axis also suggests an underlying MI. Unfortunately, a lack of prompt ECG corroboration in some patients necessitates a delay in diagnosis and this delay may deprive a patient of thrombolytic or other interventional therapy to help salvage ischemic myocardium.

CARDIAC ENZYMES

The rise of cardiac specific enzymes troponin I and T in the blood are now considered the preferred biomarkers for the diagnosis of an acute myocardial infarct. A rise in absolute value of this troponin is observed in 2–3 hours in 80% of patients with MI thereby proving the diagnosis. Almost all patients will show a rise by 6–8 hours. It is however wise to do a 12-hour test as well, if clinical symptoms are highly suggestive and the earlier test for the troponins are not significantly elevated.

At 12 hours, the test is almost 100% sensitive for AMI;[4] a negative test at 12 hours in a patient presenting with chest pain effectively rules out AMI. What is more, a positive troponin test in patients with chest pain even with a nondiagnostic ECG and a negative CPK-MB independently confers the same prognosis as in patients with STEMI.[5] An important advantage of the troponin test over the CPK-MB (besides the greater sensitivity of the former) is that troponins remain elevated for as long as 7–8 days. It is important to do serial tests and document the rise and gradual fall of troponin levels after AMI.

It should be noted that troponin levels can rise in conditions other than MI. It is however the rise or fall of troponin values with one above the 99th percentile of the URL, coupled with clinical evidence of myocardial ischemia that differentiates AMI from other causes responsible for high troponin levels.

Others conditions causing a rise in troponin levels are shock from any cause, myocarditis, cardiomyopathies, congestive heart failure, pulmonary embolism, sepsis, renal failure, polytrauma, rhabdomyolysis. A rise may also be observed after extreme physical exercise. Causes of troponin T and I rise are listed in Box 1.

Box 1: Causes of serum troponin T and I elevations, including both acute coronary syndromes, noncoronary cardiac events, and noncardiac ailments

- Acute coronary syndrome or acute myocardial infarction
- Shock of any form (cardiogenic, obstructive, distributive)
- Myocarditis and myopericarditis
- Cardiomyopathies
- Acute congestive heart failure (pulmonary edema)
- Sepsis
- Pulmonary embolism
- Renal failure
- Sympathomimetic injections
- Polytrauma
- Burns
- Acute CNS event
- Rhabdomyolysis
- Cardiac neoplasm, inflammatory syndromes and infiltrative diseases
- Congenital coronary anomalies
- Extreme physical exertion

Abbreviation: CNS, central nervous system.

MANAGEMENT OF ST-SEGMENT ELEVATED MYOCARDIAL INFARCTION

Following admission to the ICU or the emergency department, a patient suspected of having AMI should be given complete bed rest, 300 mg of soluble aspirin (preferably chewed and swallowed), and 450 mg of clopidogrel. He is given oxygen, sublingual nitroglycerin (unless the systolic BP is <90 mm Hg) and given morphine or its derivatives for relief of pain and anxiety. An intravenous (IV) line is promptly secured (simultaneously sending blood for relevant investigations) and the patient is connected to an ECG monitor. A quick clinical examination is then performed with special reference to the cardiovascular and respiratory systems and a 12-lead ECG recorded. Points in diagnosis touched upon earlier are considered to determine whether the diagnosis of a suspected MI is probable or certain. Acute aortic dissection, acute pericarditis, and acute pleural and pulmonary problems need special consideration in the differential diagnosis. Complications of AMI are then carefully looked for—in particular LVF, arrhythmias and features of early shock; if present these are promptly treated.

If the ECG shows an ST-segment elevation of more than 1 mv in two or more contiguous leads, it signifies thrombotic occlusion of a coronary artery and the patient needs immediate reperfusion therapy. The diagnosis of an ST-segment elevated MI may at times be difficult as for example in the presence of LBBB of if the patient has a permanent pacemaker. A new LBBB pattern in the presence of symptoms of myocardial ischemia should be considered as an AMI and treated accordingly. In fact, patients with STEMI and LBBB derive greater benefit from reperfusion strategies compared to STEMI.[6]

For convenience, this chapter discusses management of STEMI in the following order. First, there is a brief discussion on the immediate supportive measures in AMI. It then discusses reperfusion strategies in STEMI. *It cannot however be sufficiently overstressed that reperfusion strategies should be promptly put into effect, as a matter of urgent priority as soon as a diagnosis of STEMI is made provided there are no contraindications*. Reperfusion strategies consist of the use of fibrinolytic drugs, PCI and surgical reperfusion (CABG).

Next is a brief discussion of the benefits of aspirin, antiplatelet drugs and anticoagulants used as adjuncts to fibrinolytic drugs and the use of PCI. The chapter then briefly mentions a few cardiac drugs that may be used later in the natural history of AMI. This is followed by a brief mention of the hemodynamic assessment of MI. Finally, there is a discussion on treatment of major complications.

Supportive Medical Therapy

Bed Rest

Complete bed rest is essential to start with. Most patients are nursed flat in bed; those with LVF need to be slightly propped up. The patient is encouraged to turn and move in bed from the very first day to minimize the risk of phlebothrombosis of the leg veins and hypostatic pulmonary congestion. In the absence of cardiac failure, arrhythmias, or shock, we encourage the patient to use a bedside commode to move his bowels. Most Indians find the bedpan an uncomfortable contraption; in fact, straining over a bedpan can prove disastrous and we tend to avoid its use as far as possible. If the patient is too ill to get out

of bed, and is unfamiliar with the bedpan, he is encouraged to move his bowels in bed into a large pad of cotton.

Relief of Pain

Severe unrelieved pain can lead to increasing anxiety, shock and may even trigger dangerous arrhythmias. The best drug to relieve both pain and anxiety in AMI is morphine. In patients with severe pain, morphine (if available) is given intravenously—2–4 mg being diluted and given slowly. Morphine is unfortunately not always easily available. The next best drug is buprenorphine, 0.3 mg intravenously. A careful watch is kept on respiration and blood pressure. 2 mg morphine (or 0.3 mg buprenorphine) may need to be repeated every 15–30 minutes till the pain is relieved, or there is evidence of toxicity. Severe vomiting, respiratory depression, or hypotension preclude its further use. In patients with mild or moderately severe pain, 15 mg morphine given subcutaneously suffices for pain relief. This can be repeated as necessary, although it is best not to use more than 60 mg morphine over 24 hours.

Morphine by relieving pain, anxiety and restlessness associated with AMI, results in a decrease in the myocardial oxygen demand. It also has a beneficial action in patients with pulmonary congestion due to LVF. This is because it produces vasodilatation and reduces the preload (particularly in those with excessive sympathetic activity), reduces the heart rate through increased parasympathetic activity and reduced sympathetic tone, and decreases the work of breathing by slowing respiration.

Hypotension following morphine can be countered by nursing the patient flat in bed or in the head-low position. A bolus or volume load of 150–200 mL dextrose saline generally suffices to raise the systolic pressure to above 100 mm Hg. The use of atropine 0.5–1 mg intravenously together with morphine counters the parasympathomimetic effect of the drug, particularly if bradycardia and a lowered systolic BP are present to start with. Vomiting is countered by the use of 25 mg intramuscular promethazine. Respiratory depression is surprisingly uncommon even with repeated doses of morphine in the presence of severe pain, or tachypnea due to pulmonary congestion. It should however be always watched for, especially in the aged and the feeble, and when present can be reversed by naloxone 0.1–0.2 mg intravenously. This dose can be repeated every 15 minutes till the respiration is no longer depressed.

Initially, morphine suffices to relieve anxiety. When pain is no longer present, anxiety should be relieved by benzodiazepine (diazepam 5 mg twice or thrice daily orally).

Establishing an Intravenous Line

An IV line is essential and is secured as soon as the patient is admitted, through an indwelling catheter in a peripheral vein. A 5% dextrose infusion is started at a very low flow rate through the IV line. This is a patency drip to be used for administering drugs. It is important to ensure that large quantities of fluids are not given intravenously (except for a specific purpose), for fear of inducing or aggravating pulmonary edema. If peripheral veins are unobtainable due to shock, a central line (either subclavian or internal jugular) is secured percutaneously. Blood samples for blood count, glucose, creatinine, CK, CK-MB, troponin I and T, serum glutamic-oxaloacetic transaminase (SGOT) and other relevant biochemical tests are collected when the IV line has been secured. It is best to avoid injections prior to sending blood CK levels to the laboratory, as intramuscular injections can by themselves cause a rise in the CK, and this can be misleading in diagnosis.

Oxygen

Oxygen at 2–4 L/minute is generally administered to a patient with a fresh MI for the first 24 hours. In a stable patient, without complications with an O_2 saturation well over 90%, oxygen perhaps confers no added advantage. Oxygen is however imperative in the presence of severe or persistent pain, in patients with an O_2 saturation less than 90%, or in the presence of breathlessness or shock, and in these situations it is given at a higher flow rate of 6 L/minute.

Electrocardiographic Monitoring

This is an extremely important aspect of critical care, as prompt detection of arrhythmias and their response to treatment can only be determined by continuous ECG monitoring. A high rate audiovisual alarm should be set at 110/minute, and a low rate signal at 50/minute. Monitoring of BP, temperature, urine output are other important features of critical care in MI.

Use of Nitrates

Nitrates are useful in the management of AMI provided there is no hypotension (systolic <100 mm Hg or a fall of >40 mm Hg from the baseline). In patients with severe or protracted pain, or when pain waxes and wanes, a slow infusion of nitroglycerin should be started at a rate of 5–10 μg/minute, the infusion rate being gradually increased every 10–15 minutes. There is no fixed optimal dose, but the infusion is titrated so that there is substantial pain relief or a drop in the systolic arterial pressure by 10–20%. In Indian patients, it is best not to exceed a dose of 50 μg/minute. The BP should not be allowed to fall below 100 mm Hg, and should be carefully monitored. Titration to total pain relief may be impossible in AMI. IV nitroglycerin infusions can be continued for 2–4 days if so required. Generally after 2–3 days the infusion is substituted by the application of nitroglycerin paste (1.5–2 inches) every 8 hours or by oral nitrates, e.g. isosorbide dinitrate 10 mg 8 hourly. It is best to avoid long-acting nitrates following AMI as titration of the dose is difficult. Patients who are stable from the start and whose pain has been virtually relieved by morphine, are treated in many units initially

with oral nitrates or local application of nitroglycerin paste, without prior use of IV nitroglycerin infusions. Flaherty and colleagues[7] have shown in a prospective randomized trial that the use of IV nitroglycerin for 48 hours followed by the use of nitroglycerin paste for 72 hours, enhanced postinfarction improvement of myocardial function in a scintigraphic study.

Nitrates are vasodilators. They reduce the venous return, the preload and therefore the workload on the heart. Myocardial oxygen demands are reduced, and this in turn leads to a reduction in myocardial ischemia. Nitrates also have a direct coronary vasodilator action and enhance blood supply to the ischemic myocardium. Both these modes of action contribute therefore to the relief of pain, and to preservation of ischemic myocardium. Patients in whom ST-segment elevation and myocardial ischemia are due to occlusive coronary artery spasm may experience prompt relief with IV nitroglycerin. A reduction in preload also leads to reduced filling pressures in the left ventricle, and may be of great benefit in patients with pulmonary congestion and edema due to left ventricular failure (LVF).

Nitrates are among the first line drugs used for symptomatic relief of myocardial ischemia; and in patients with MI who develop LVF. Despite these benefits, the Gruppo Italiano per lo Studio della Soprawivenza dell' Infarto Miocardico-3 (GISSI-3) and International Studies of Infarct Survival-4 (ISIS-4) trials failed to show a significant reduction in mortality from routine acute and chronic nitrate therapy.[8,9] The main side effect of nitrates is hypotension. Unfortunately, the prior presence of hypotension or a sharp hypotensive response soon after starting nitrates, at times limits the use of these drugs. They should be used with great caution in patients with inferior wall infarction as even a small dose may cause a precipitous fall in BP and heart rate—a reaction which can be promptly treated by IV atropine plus IV fluids. Nitrates, and in particular IV nitroglycerin are best avoided in patients with suspected right ventricular infarction. These patients often develop severe hypotension following their use because of inadequate right ventricular filling produced by vasodilatation. Hypotension induced by nitrates is dangerous; it reduces coronary perfusion, aggravates ischemia, and potentiates myocardial injury.

Headache is common with nitrates but only rarely is it severe enough to warrant discontinuation of the drug. Prolonged use of large doses has been known to cause methemoglobinemia. Elevated methemoglobin levels impair the oxygen-carrying capacity of the blood, and may increase myocardial ischemia.

Beta-blockers

Beta-blockers can be of benefit both in early AMI and as long-term therapy provided there are no contraindications to their use. Many act by causing a reduction in the heart rate, BP, myocardial contractility and hence in myocardial oxygen demand, thereby relieving chest pain and limiting infarct size. They may also help to reduce the incidence of post-infarction angina, ventricular arrhythmias, myocardial rupture and ventricular remodeling, thus reducing the overall mortality in AMI.[10]

Current evidence on the benefit conferred by the use of beta-blockers is a bit conflicting. In the Clopidogrel and Metoprolol in MI Trial-Second Chinese Cardiac 2 (COMMIT-CCS 2) trial of 45,852 patients with STEMI were randomized to receive treatment with metoprolol (3 IV injections of 5 mg each followed by oral 200 mg/day for up to 4 weeks) and placebo. Surprisingly, there was no difference in the primary endpoint of death, reinfarction, or cardiac arrest between the two groups. Based on these findings, the routine use of beta-blockers in the absence of hypertension is not recommended.[11]

On the other hand, in the CArvedilol Post-infaRct survIval COntRoL in Left Ventricular Dysfunction (CAPRICORN), a randomized placebo-controlled trial, there was clear benefit in the carvedilol arm after 1.3 years compared to the placebo both with regards to all-cause mortality and non-fatal MI.[12] This study supports the claim that beta-blocker therapy after acute MI reduces mortality irrespective of reperfusion therapy or angiotensin-converting enzyme (ACE) inhibitor use.

Notwithstanding conflicting evidence (so frequent in critical care medicine), it is perhaps best not to use beta-blockers on a routine basis soon after AMI particularly in massive infarcts which are likely to be associated with or followed by LVF. Beta-blockers however help in the following circumstances—

- In patients whose infarction is complicated by persistent or recurrent ischemic cardiac pain, particularly when associated with tachycardia.
- In patients with marked sinus tachycardia, particularly when associated with anxiety and hypertension.
- In patients with tachyarrhythmias refractory to the usual antiarrhythmic drugs. In fact, *tachyarrhythmias related to hyperadrenergic states in AMI including ventricular tachycardia (VT) at times respond best to the judicious use of beta-blockers*.
- In patients who have been beta-blocked prior to infarction, a sudden withdrawal of the drug may produce severe tachycardia. In such cases, beta-blockers should be continued in smaller doses.

Contraindications Beta-blockers are contraindicated in patients with LVF, hypotension (systolic BP <100 mm Hg), bradycardia (heart rate <60–65/minute) or heart block. They are also contraindicated in a patient with a history of asthma, or of chronic airways obstruction.

Mode of use The beta-blocker most commonly used in AMI is metoprolol given intravenously in three 5 mg bolus doses to a total of 15 mg. The patient is observed for 5 minutes after each bolus dose. No further dose is given if the heart rate falls below 60 beats/minute or systolic BP falls to less than 100 mm Hg or the PR interval is prolonged beyond 0.24 second,

Box 2: Indications for using beta-blockers in acute myocardial infarction

- Within the first 4–6 hours after AMI (early use), provided no contraindications exist
- *Later in the natural history of AMI*
- In patients with marked sinus tachycardia
- In patients with marked sinus tachycardia (not due to left ventricular failure), particularly when associated with anxiety and hypertension
- In patients in whom infarction is complicated by persistent or recurrent ischemic pain, especially if associated with tachycardia and/or hypertension
- In patients with tachyarrhythmias refractory to conventional antiarrhythmic drugs
- In patients who have been beta-blocked prior to AMI

Abbreviation: AMI, acute myocardial infarction.

or basal crackles or a diastolic gallop appear. If the patient remains hemodynamically stable after the last bolus dose for 30 minutes, metoprolol is continued orally, 50 mg 12 hourly. The dose needs to be titrated to ensure that hypotension, bradycardia or LVF do not occur. The drug is also promptly stopped if bronchospasm occurs.

The CAPRICORN study suggests that carvedilol (a beta-blocker) given postinfarct gives a clear benefit with regard to mortality, reinfarction and death Box 2.

Interventional Therapy

Fibrinolysis

Numerous clinical trials provide overwhelming evidence that fibrinolytic agents administered early in the course of AMI reduce infarct size, preserve left ventricular function and substantially reduce mortality in ST elevated MI.[9-11]

The benefit occurs from the ability of fibrinolytic agents to lyse clots within a coronary artery and thereby re-establish perfusion of blood to the affected area of the myocardium. The Fibrinolyitc Therapy Trialists' Collaborative Group (FTT)[13] showed that mortality in Q-wave infarction is reduced by 25–30%, if fibrinolytic therapy is instituted in patients with either ST-segment elevation or new bundle branch block up to 12 hours, and possibly as much as 18–24 hours after the onset of symptoms. The maximum benefits were observed in patients with anterior ST-segment elevation but patients with inferior ST-segment elevations also benefit. Patients with Q-wave infarction, who are at the greatest risk, have the greatest benefit. The sooner treatment is instituted, the better the results.

This is beautifully illustrated below by a study of pooled findings from 22 randomized-controlled trials of thrombolyitc therapy published between 1983 and 1993.[13] This study noted the following—

Time when thrombolysis started	Additional lives saved per 1,000 people treated with thrombolytics compared with 1,000 people treated with standard therapy
In the first hour	65
In the second hour	37
In the third hour	26
Between 3 and 6 hours	26
less than 12 hours	18
Between 12 and less than 24 hours	9

The imperative need to use fibrinolytic agents as early as possible in patients with AMI where fibrinolytic therapy is indicated, and where no contraindications to this therapy exist, is clearly evident.

Indications When a patient with AMI (suspected or proven) is referred to the ICU, the immediate question is to determine whether the patient is a candidate for thrombolytic therapy. The following criteria for the use of thrombolytic agents in AMI must be considered—

- Chest pain for more than 30 minutes, consistent with AMI.
- Electrocardiography changes showing—
  - ST-segment elevation more than 1–2 mm in at least two contiguous frontal leads (leads I, aVL, II, III, aVF) or two precordial leads (the V leads) or in STEMI with or without Q-waves. It is to be noted that a right ventricular infarct may manifest with an elevated ST in V_4R, and a tall R in V_4R. It is often associated with elevated ST in leads II, III, aVF. The ST deviation in all patients should be measured 0.4 second after the J point, using the PQR segment as the isoelectric line.
  - New or presumed new LBBB, because this invariably denotes an acute anterior myocardial infarct.
- Although bleeding complications following fibrinolysis are more frequent in patients more than 75 years, it is generally accepted that age is not an absolute bar to fibrinolysis, provided the benefit that accrues is judged to be greater than the risk.
- The therapy to be effective should be given early in the course of AMI. It is most beneficial if given within 6 hours of the onset of pain (or pain equivalent). It is less beneficial but is still used between 6 hours and 12 hours of pain. It may be used between 12 hours and 24 hours after onset of pain, particularly if pain persists, but with decreasing benefits.
  Fibrinolytic therapy is not indicated in patients with unstable angina, in myocardial infarcts with ST depression or nonspecific ST changes, i.e. in NSTEMI.
- There is, however, a subset of patients eligible for thrombolysis even though they do not present either with ST-elevation or LBBB. These are patients with—
  - True posterior wall infarction that may have a tall R in V_1 and V_4R or present with marked ST-segment

Box 3: Contraindications to fibrinolytic therapy

- *Absolute—*
  - Bleeding diathesis or chronic liver disease with portal hypertension
  - Active recent internal bleeding
  - Cerebrovascular accident in the recent past (3 weeks)
  - Recent trauma, head injury or major surgery
  - Aortic dissection
  - Proliferative hemorrhagic diabetic retinopathy
  - Uncontrolled severe hypertension
  - Known presence of aneurysm or arteriovenous malformations
- *Relative—*
  - Serious organic disease associated with increased risk of bleeding or embolization
  - Poorly controlled hypertension
  - Prolonged cardiopulmonary resuscitation
  - Pregnancy or postpartum or menstruating women

depression in V_1 to V_4 which represents a posterior current of injury. The infarction is generally due to an occlusion of the circumflex artery, or occlusion of the posterior descending branch of the right coronary artery.

- Anterior MI, which in the very early phase may show hyperacute giant T-waves without ST-segment elevation.

Contraindications The major danger in the use of fibrinolytic therapy is bleeding. Contraindications to its use are outlined in Box 3.

These include a bleeding diathesis, an active peptic ulcer, active recent internal bleeding, history of a cerebrovascular accident in the recent past (3–4 weeks), recent major surgery, recent intracranial or spinal surgery, recent trauma, recent head injury, severe uncontrolled hypertension (diastolic >110 mm Hg), known presence of an aneurysm or an arteriovenous malformation, aortic dissection and proliferative diabetic retinopathy. Relative contraindications include a recent arteriotomy or puncture of a major vessel, poorly controlled hypertension, recent organ biopsy (2–3 weeks), recent obstetric delivery and recent protracted cardiopulmonary resuscitation.

Risks of Fibrinolytic Therapy

Bleeding Bleeding generally occurs from puncture wounds (arteries and veins). However, the general fibrinolysis caused by thrombolytic agents can occasionally cause catastrophic bleeding leading to death. The most dreaded of all complications is an intracranial bleed.

Reperfusion arrhythmias Reperfusion arrhythmias are occasionally observed in patients during or immediately after fibrinolytic therapy. These take the form of accelerated idioventricular rhythm and frequent ventricular ectopics. Rarely ventricular fibrillation may occur abruptly. Marked sinus bradycardia and hypotension may be observed following reperfusion in inferior wall infarction. There is considerable interest in the physiopathology of reperfusion arrhythmias. Metabolites accumulate in the ischemic and injured myocardium following occlusion of a coronary vessel. A wash-out of these metabolites following reperfusion results in electrical and chemical gradients across cell membranes, resulting in arrhythmias.[14]

Assessing the Efficacy of Fibrinolytic Therapy

Fibrinolytic therapy can be gauged to have succeeded, if there is relief of pain, a reduction in ST-elevation by about 50%, and by an improved hemodynamic state. The occurrence of an accelerated idioventricular rhythm after fibrinolysis generally denotes successful reperfusion. Persistent pain, an unimproved hemodynamic state, with no change in the elevated ST-segments, and even perhaps an extension of the infarct size, point to a failure of fibrinolytic therapy.

Fibrinolytic Drugs

Streptokinase (SK) was the first lytic agent used in MI; it has now been largely replaced by tissue plasminogen activator (tPA), which is more fibrin selective and has a higher early coronary patency rate (70–80%).[15] Reteplase (rPA) is a deletion mutant of tPA but its use has no added advantage compared to tPA.[16] Tenecteplase-tPA (TNK-tPA) is a genetically engineered tPA with a longer half-life; it is resistant to plasminogen activator inhibitor 1, and has increased fibrin specificity. TNK-tPA is given as a single bolus which results in coronary flow rates identical to those seen with accelerated tPA, with equivalent 30-day mortality and bleeding complications.[17] An ideal fibrinolytic agent has not yet been developed. Such an ideal drug should have greater fibrin specificity, should remain in the circulation for a longer time and should be even more resistant to protease inhibitors than agents in current use. The newer agents have by and large equal efficacy but are more easily administered and therefore have gained greater popularity. It must be noted that although tPA and its newer derivatives are superior lytic agents compared to SK, the latter continues to be used in our country and in other poor developing countries of the world because of its low cost.

Dosage Streptokinase is administered in a continuous IV infusion of 1.5 million units over 1 hour. The administration of SK occasionally causes anaphylactic reactions which range from itching and urticaria to bronchospasm and severe hypotension. If severe, the drug is stopped and the anaphylactic reaction countered by IV hydrocortisone.

Tissue plasminogen activator Administration of tPA follows an accelerated regime consisting of a 15 mg bolus, 0.75 mg/kg (up to 50 mg IV) over 30 minutes and then 0.5 mg/kg (up to 35 mg) over the next 60 minutes.

Table 1: Weight adjusted dosing of tenecteplase

Patient weight (kg)	*Tenecteplase (mg)*	*Volume of tenecteplase to be administered (mL)*
<60	30	6
60–69	35	7
70–79	40	8
80–89	45	9
≥90	50	10

Reteplase is given as two 10 U boluses 30 minutes apart.

Tenecteplase is dosed-based on weight and is given as a single-bolus injection over 5 seconds (Table 1). This drug is not compatible with dextrose, and therefore, should not be given in the same IV line. Lines containing dextrose should be flushed before and after administration.

Fibrinolytic therapy is followed by the use of heparin. The use of heparin, other anticoagulants as adjunctive therapy is considered later—following the discussion on Primary Coronary Angioplasty.

Re-use of fibrinolytic therapy If fibrinolytic therapy fails to afford relief, a rescue angioplasty is generally indicated. If, however, facilities for a rescue angioplasty are lacking, as is so in a number of critical care units, thrombolysis may be attempted again. The following points need to be stressed—

- If SK is used for initial fibrinolysis, it should not be used again as it can cause severe anaphylaxis.
- Re-use fibrinolytic therapy should therefore always be with tPA. If prior fibrinolytic therapy was given 12 hours back for tPA, or 24 hours back for SK, 25–50% of the usual dose of tPA is administered. If more time has elapsed after initial therapy, the full dose of tPA can be given.

PRIMARY PERCUTANEOUS CORONARY INTERVENTION

Primary percutaneous coronary intervention if performed early and with sufficient expertise has been shown to be superior to the use of fibrinolytic drugs. The major advantages of PCI over fibrinolytic therapy are the achievement of a higher rate of normal blood flow [thrombolysis in MI (TIMI) grade 3],[18] a reduced risk of intracranial hemorrhage and the ability to stratify risk with regard to the nature, distribution and extent of coronary artery disease. There are a few points in favor of PCI vis-à-vis fibrinolytic therapy. These are—

- Percutaneous coronary intervention ensures a reperfusion rate of 90–95% compared to the reperfusion rate of 70–80% with the best available fibrinolytic therapy.
- The reocclusion rate in patients undergoing fibrinolytic therapy is higher than those undergoing percutaneous transluminal coronary angioplasty (PTCA).
- Percutaneous transluminal coronary angioplasty is feasible in all patients with AMI including those who are not eligible for fibrinolytic therapy.

Points against PCI also need mention—

- The logistic difficulty of performing a PTCA preferably within 4 hours, or at most within 12 hours of the onset of AMI—a time period when its efficacy is proven; also to be effective, PCI should be within 90 minutes of reaching the hospital; door to balloon time should be within 90 minutes (medical contact to balloon).
- The unavailability of the necessary equipment, expertise, experience and logistic support in many centers in developing countries.

Several randomized trials have suggested the superiority of PCI over fibrinolytic therapy in several subsets of AMI patients at higher risk.[19] The largest of these trials is the GUSTO-IIb Angioplasty Substudy, which randomized 1,138 patients and showed at the end of 30 days a small to moderate clinical benefit in the combined primary endpoint of death, nonfatal reinfarction, and nonfatal stroke in the patients treated with PTCA compared to patients treated with tPA.[20]

Recent meta-analysis comparing direct PTCA with fibrinolytic therapy suggests lower mortality and lower rates of reinfarction in patients treated with PTCA.

However, more important than the method of revascularization is the time taken to revascularize. PCI is the preferred method for revascularization in STEMI only if the door to balloon (or medical contact to balloon) time for PCI is less than 90 minutes.[21] Similarly, if fibrinolytic therapy is offered to a patient with STEMI the door-to-needle (or medical contact to needle) time ideally should be 30 minutes.[22] Timely reperfusion is the key to success—reducing or limiting infarct size, preserving LV function and increasing survival.[23,24]

Special indications for PCI are—

- In patients in whom fibrinolytic therapy is contraindicated.
- Failure of fibrinolytic therapy.
- In patients with severe ischemic cardiac pain, with a marked rise in the cardiac enzymes or in those with a possible stuttering infarction and yet with no typical ECG features of MI.
- In a patient in whom acute pericarditis or a dissecting aneurysm of the aorta cannot be ruled out. A coronary angiography followed by an angioplasty if there is occlusion of a major artery can be done.
- In patients who are hemodynamically unstable or in cardiogenic shock.
- In patients who have had coronary artery bypass surgery in the past and in patients who have had a prior myocardial infarct.
- In elderly patients well over 75 years in whom the risk of bleeding from fibrinolytic therapy is significant.

Percutaneous coronary angioplasty in AMI is always followed by stenting the involved artery.

The Primary Angioplasty in MI (PAMI) stent trial (a large randomized trial) was carried out to determine if routine stenting in MI could reduce angiographic restenosis and

improve clinical outcomes when compared to balloon angioplasty alone. There was no difference in mortality in the two groups at 6-months but there was improvement in target driven revascularization and improvement in angina in stented patients compared to balloon angioplasty alone.[25] Stenting however remains a universal policy in patients with AMI treated by PCI. In most instances a drug eluting stent is preferred to a bare metal stent although there are no definitive clinical trials to support this preference.

SURGICAL REPERFUSION (CORONARY ARTERY BYPASS SURGERY)

Coronary artery bypass surgery has indeed a very small place in the management of AMI. It is indicated under the following conditions—

- When coronary dissection with occlusion develops during cardiac catheterization, coronary angiography or during PTCA.
- Surgical reperfusion is to be considered in a small subgroup of patients who are undergoing or have completed fibrinolytic therapy, but who continue to have ischemic pain and are hemodynamically unstable. Rescue angioplasty is to be preferred but if this fails or is not feasible, or if the angiography shows left main disease or multivessel disease, emergency surgical revascularization is of benefit. Good centers report a low mortality and morbidity.[26,27]
- Surgical reperfusion after an infarct has just fully evolved is invariably unsafe, unwise and contraindicated. However, in some patients, infarction appears to occur in a stuttering manner over a period of days producing increasing hemodynamic instability and shock. Revascularization in these patients, although fraught with danger, may at times be successful and followed by recovery.

Adjunctive Therapy

The purpose of fibrinolytic therapy or PCI is: (1) to restore blood flow to the thrombosed infarct related artery; (2) to limit microvascular damage and reperfusion injury. The latter is accomplished with the use of adjunctive therapy which is now described in the section below.

Adjunctive Therapy to Primary Percutaneous Coronary Intervention or to Fibrinolytic Therapy

Aspirin Aspirin is an effective cheap antiplatelet drug with relative low toxicity. The drug has been shown to reduce mortality in AMI to the same degree as fibrinolytic therapy. When used together with fibrinolytic therapy, its effect is additive. The drug should always be administered in all acute coronary syndromes—STEMI, NSTEMI, unstable angina as soon as possible. Contraindications to its use are active peptic ulcer disease, history of intolerance to the drug.

Thienopyridine These antiplatelet drugs inhibit both the activation and aggregation of platelets. Clopidogrel is the drug most frequently used. Prasugrel is a more recent thienopyridine and is now easily available in India. Clopidogrel is a pro-drug which is converted to its active metabolite in the liver via the cytochrome p450. This metabolite prevents activation of the GP IIb/IIIa receptor complex and reduces platelet aggregation. A loading dose of 300–600 mg inhibits platelets within 2 hours, whereas a dose of 75 mg achieves inhibition of platelets in 24–48 hours. Peak effect is at 6 hours after a loading dose of 300–600 mg and 5–7 days with a loading dose of 50–100 mg.[28]

The large Clopidogrel as Adjunctive Reperfusion Therapy-TIMI 28 (CLARITY TIMI-28) study[29] randomized 3,491 STEMI patients to clopidogrel (300 mg loading dose + 75 mg daily) and placebo. The study showed: (1) the efficacy of clopidogrel to maintain infarct artery patency; (2) prior reuse of clopidogrel in patients who underwent PCI resulted in a significant reduction in cardiovascular death, MI or stroke at 30 days without causing excessive bleeding.[30] Clopidogrel is therefore administered in a dose of 300–600 prior to PCI even if there is the possibility that the patient may require coronary artery bypass surgery in the near future.

Prasugrel, a more recent thienopyridine is also a pro-drug which acts only after its conversion to its active metabolite. It is a more powerful drug compared to clopidogrel in that it inhibits platelet aggregation to a greater degree. A dose of 60 mg inhibits platelet aggregation in 30 minutes, the peak effect being observed in 4 hours.[31] The side effect of both clopidogrel and prasugrel is bleeding, the rate of major bleeding episodes being higher with use of prasugrel. Prasugrel should not be used in patients with a history of transient ischemic attacks and/or stroke, in patients more than 75 years and in patients with a body weight less than 60 kg.

Currently both aspirin and clopidogrel (or prasugrel) are given to all patients prior to PCI as mentioned above. On the basis of data provided by the COMMIT-CCS-2 study, all patients would benefit from the addition of clopidogrel to aspirin regardless of whether they do or do not undergo reperfusion therapy. The duration of clopidogrel use following AMI has not been defined.

Ticagrelor Ticagrelor is the new antiplatelet drug used in the treatment of both, NSTEMI and STEMI. The recommended dosage is 180 mg—loading dose followed by 90 mg twice daily as maintenance dose (also see Chapter Unstable Angina).

Glycoprotein IIb/IIIa receptor antagonists Glycoprotein IIb/IIIa receptor antagonists inhibit the final common pathway of platelet aggregation by blocking cross linking of aggregated platelets. Prior to the use of clopidogrel and aspirin as antiplatelet therapy the efficacy of abciximab (a glycoprotein IIb/IIIa receptor antagonist) in patients with STEMI who underwent primary PCI was established. Recent trials have questioned whether abciximab when added to aspirin and clopidogrel offers any additional benefit in patients with STEMI.[32]

Current guidelines suggest that when a STEMI patient is treated with clopidogrel and aspirin plus an anticoagulant such as unfractionated or low molecular weight heparin, the glycoprotein IIb/IIIa inhibitor at the time of PCI may benefit but cannot be recommended for routine use.[22]

Anticoagulants Following fibrinolytic therapy, it is important to administer heparin to diminish reocclusion after successful reperfusion. Sixty units/kg up to a maximum of 4,000 units are given as a bolus followed by an infusion rate of 12 U/kg up to a maximum of 1,000 U/hour, the infusion being titrated to keep partial thromboplastin time (PTT) at two to two and half times the control. Heparin should be continued for 48 hours.

For patients undergoing PCI who have already received aspirin and clopidogrel, both unfractionated heparin and bivalirudin can be used as anticoagulants. Bivalirudin is a thrombin inhibitor and is administered in a bolus injection 0.75 mg/kg followed by an infusion at 1.75 mg/kg per hour for the duration of PCI. *Bivalirudin* is the anticoagulant of choice in patients with a history of heparin induced thrombocytopenia. It is as effective as heparin and its use is less often complicated by bleeding episodes.

Enoxaparin is a low molecular weight heparin with proven efficacy in patients with STEMI who have received fibrinolytic therapy or are undergoing PCI.[33] It is given by injection subcutaneously in a dose of 1 mg/kg every 12 hours. Patients more than 75 years or who have renal dysfunction need a reduced dose of 0.5–0.75 mg/kg every 12 hours.

There are many who prefer the use of low molecular weight heparin (LMWH) to unfractionated heparin following fibrinolytic therapy and as an anticoagulant before, during and after PCI.

Fondaparinux is a Factor XA inhibitor which can be used in place of low molecular weight heparin (LMWH). It is given subcutaneously in a dose 2.5 mg once daily. It has proven efficacy when used in patients with STEMI. However, the use of fondaparinux in STEMI patients undergoing PCI has been associated with an increased incidence of catheter related thrombosis.[34] If fondaparinux is used in the above situation, fractionated heparin should also preferably be administered.

Medical supportive therapy during the early phase of AMI has already been discussed. It now remains to briefly mention the role of other drugs in AMI.

Calcium antagonists Both verapamil and diltiazem are best avoided immediately after a STEMI. They may be tried in post-MI angina or in slowing the ventricular rate in atrial fibrillation when beta-blockers are ineffective or contraindicated. Calcium channel blockers have a negative inotropic effect on the heart.

Angiotensin-converting enzyme inhibitors These are avoided during the immediate phase of STEMI but may be of benefit after a few days. ACE inhibitors are of particular use in patients with clinical evidence of heart failure, in those with an ejection fraction less than 40%, and in those with a history of previous MI. If captopril is used, it is given in a dose of 6.25 mg orally twice daily, titrating the dose slowly to 25 mg twice daily, provided there is no significant hypotension, nor a rise in the serum creatinine. Lisinopril, enalapril or ramipril could also be used in appropriate titrated doses. One should aim to reduce the systolic BP by approximately 10% in normotensive individuals and by 30% in hypertensive individuals. ACE inhibitors should not be used when the systolic pressure is less than or equal to 100 mm Hg.

Box 4: Indications for hemodynamic monitoring in acute myocardial infarction (AMI)

- Cardiogenic shock
- Refractory pulmonary edema due to left ventricular failure
- Suspicion of right ventricular infarction or pulmonary embolism
- Ventricular septal rupture or papillary muscle rupture causing mitral regurgitation
- When using combination of inotropes and vasodilators
- Suspicion of cardiac tamponade

The heart outcomes prevention evaluation (HOPE) trial[35] randomized 9,297 patients with documented vascular disease or those at high risk for atherosclerosis to treatment with ramipril (target dose 10 mg/day), or placebo. There was a significant 22% reduction in the combined endpoint of cardiovascular death, MI, and stroke observed in those treated with ramipril. Also, an improved survival was additive to the benefits of aspirin and beta-blockers.[35]

Angiotensin-converting enzyme inhibitors reduce the afterload and thereby the work of the heart. There is probably also a limitation of LV dysfunction and LV remodeling that often follows in AMI. An observed reduction in ischemic events is probably related to reduced workload on the heart.

Intravenous magnesium It has been suggested that IV magnesium is an inexpensive and relatively safe means of reducing serious arrhythmias and deaths from AMI.[36] Eight mmoL of magnesium sulfate is given intravenously over 5 minutes, followed by 65 mmoL over 24 hours. It probably acts by preserving myocardial tissue as well as by suppressing arrhythmias.

Lipid-lowering agents Statins decrease the rate of ischemic events in patients with coronary artery disease.[37] A high-dose statin administration (as a loading dose) has been advocated prior to PCI for STEMI. The STATIN STEMI trial appears to endorse the use of this therapy.[38] Currently, this therapy is not considered essential prior to PCI. However, all patients with the acute coronary syndrome should be discharged on a statin prior to discharge.

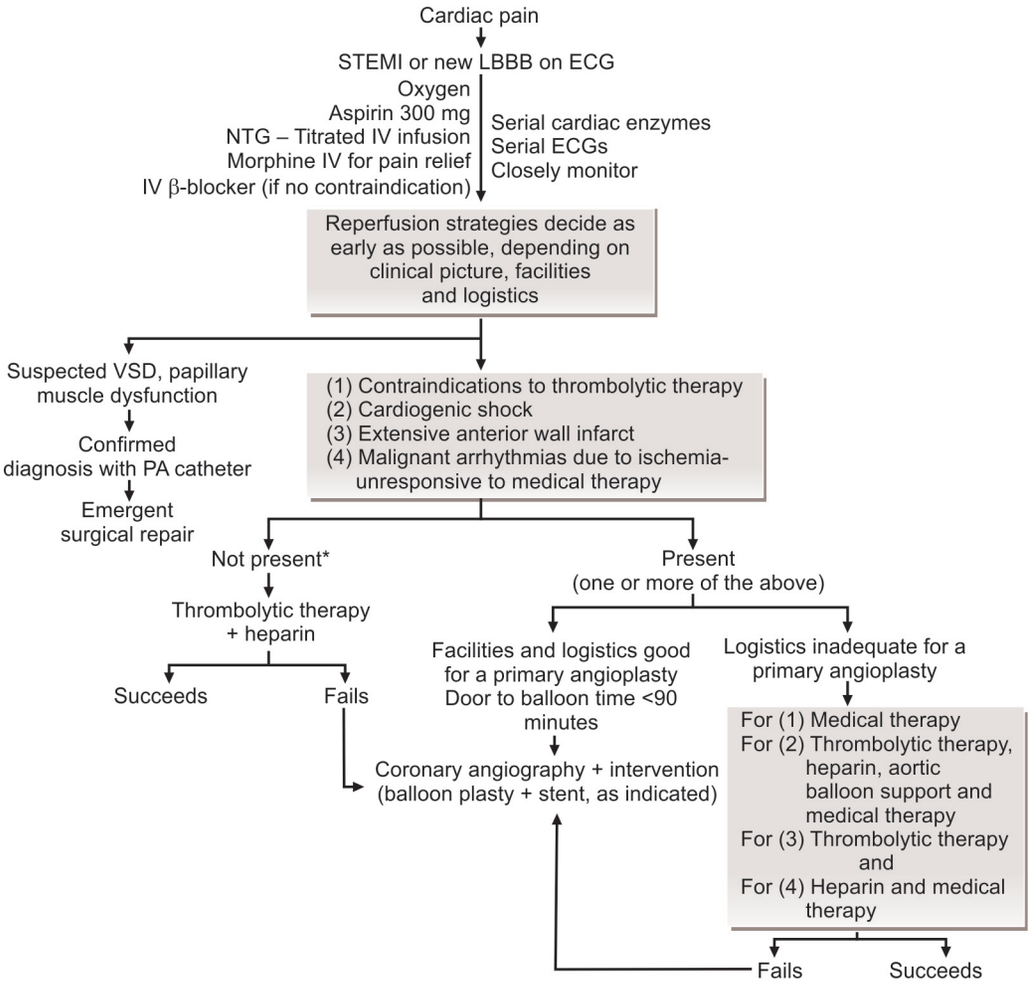
An algorithm for the management of STEMI is given in Flowchart 1.

HEMODYNAMIC ASSESSMENT OF ACUTE MYOCARDIAL INFARCTION

With experience, most patients can be assessed satisfactorily with regard to their hemodynamic status by clinical methods and by noninvasive monitoring (Box 4). We reserve invasive monitoring with a Swan-Ganz catheter for the following situations—

- Cardiogenic shock.
- Refractory pulmonary edema due to LVF.

Flowchart 1: Algorithm for the management of ST-elevation myocardial infarction (STEMI)



Cardiac pain
STEMI or new LBBB on ECG
Oxygen
Aspirin 300 mg
NTG – Titrated IV infusion
Morphine IV for pain relief
IV β-blocker (if no contraindication)
Serial cardiac enzymes
Serial ECGs
Closely monitor
Reperfusion strategies decide as early as possible, depending on clinical picture, facilities and logistics
Suspected VSD, papillary muscle dysfunction
Confirmed diagnosis with PA catheter
Emergent surgical repair
(1) Contraindications to thrombolytic therapy
(2) Cardiogenic shock
(3) Extensive anterior wall infarct
(4) Malignant arrhythmias due to ischemia-unresponsive to medical therapy
Not present*
Thrombolytic therapy + heparin
Succeeds
Fails
Present (one or more of the above)
Facilities and logistics good for a primary angioplasty Door to balloon time <90 minutes
Logistics inadequate for a primary angioplasty
For (1) Medical therapy
For (2) Thrombolytic therapy, heparin, aortic balloon support and medical therapy
For (3) Thrombolytic therapy and
For (4) Heparin and medical therapy
Coronary angiography + intervention (balloon plasty + stent, as indicated)
Fails
Succeeds

*Some well-equipped units would prefer primary angioplasty to thrombolytic therapy (if door to balloon time <90 minutes).

Abbreviations: STEMI, ST-elevation myocardial infarction; LBBB, left bundle branch block; ECG, electrocardiography; NTG, nitroglycerin; IV, intravenous; VSD, ventricular septal defect; PA, pulmonary artery.

- Suspicion of right ventricular infarction or pulmonary embolism.
- Ventricular septal rupture, or papillary muscle rupture causing mitral regurgitation.
- Suspicion of cardiac tamponade.

TREATMENT OF MAJOR COMPLICATIONS

1. *Cardiogenic shock* Shock following AMI has been discussed separately (described in Chapter Cardiogenic Shock). The present trend is to restore some stability to the hemodynamic state so that the patient can have a coronary angiography done, and if possible a rescue angioplasty performed. These procedures should be carried out with the help of an aortic balloon assist device.
2. *Left ventricular failure* This has been discussed separately.
3. *Congestive cardiac failure* The principles of management have been dealt with in a separate chapter.
4. *Arrhythmias* Arrhythmias need to be promptly detected and controlled. Ventricular arrhythmias are particularly common during the first 24 hours. Some units prefer to start prophylactic IV lidocaine in all patients with fresh infarcts. Others prefer to treat arrhythmias as and when they arise.
5. *Postinfarction angina* Postinfarction angina requires prompt return to the ICU and the administration of IV nitroglycerin and restarting of IV heparin. An aggressive approach is important because of the risk of reinfarction and sudden death. This is particularly true in patients with a NSTEMI where the absence of marked ECG changes to start with may lull the physician into complacency. The use of diltiazem 30–60 mg 8 hourly may reduce the immediate short-term risk of reinfarction and death in these patients.[39]
6. *Persistent postinfarction angina* always needs to be investigated by a coronary angiography. Further management

(whether an angioplasty or surgical reperfusion through coronary artery bypass surgery) depends on the angiographic findings.

7. *Right ventricular infarction* Right ventricular infarction should always be thought of in patients with inferior wall infarction who develop hypotension with poor perfusion, whose central venous pressure (CVP) is raised, and in whom the lung fields are relatively clear. An ECG shows an elevated R and an elevated ST-segment in V_4R; this change may disappear within 24 hours. Bradyarrhythmias may occur, necessitating the use of a temporary pacemaker. Echocardiography reveals right ventricular dilatation, wall motion abnormalities and often left ventricular dysfunction. Invasive hemodynamic studies through a S-G catheter reveal a raised right atrial pressure, a raised right ventricular end—diastolic pressure, and a normal to low pulmonary artery diastolic or pulmonary capillary wedge pressure. The cardiac output is reduced. These patients should be carefully volume loaded in spite of an increased CVP, to increase the left ventricular filling pressures and cardiac output. They invariably need inotropic support with dobutamine and dopamine as well.
8. *Pericarditis* Pericarditis generally occurs after 48 hours causing pericardial pain, and fever. The pain is worse on lying supine, breathing deeply, and swallowing. It is relieved by sitting up; a friction rub is generally audible. It is often mistaken for an extension of the infarct or for postinfarction angina. In mild cases, it is relieved by nonsteroidal anti-inflammatory agents. When severe, it is relieved by dexamethasone 4 mg intravenously 8 hourly, tapered off within a week. Rarely, pericardial effusion is large enough to cause a cardiac tamponade; this necessitates a pericardial paracentesis. Heparin should be withheld in the presence of pericardial effusion.
9. *Rupture of the interventricular septum* Septal rupture is characterized by the sudden appearance of a pansystolic murmur, generally best heard in the fourth left intercostal space, close to the left sternal border or midway between the left sternal border and the apex. Biventricular failure always follows. The diagnosis can be confirmed by two-dimensional (2D) Doppler echocardiography. An S-G catheter will help to demonstrate a step-up of oxygen saturation from the right atrium to the right ventricle (due to a left to right shunt at the ventricular level). Immediate management is concerned with restoring hemodynamic stability. Afterload and preload are reduced by a slow infusion of IV nitroprusside, and inotropic support is provided by dopamine or dobutamine to maintain the systolic BP 90–100 mm Hg. An intra-aortic balloon pump is used to help to stabilize the circulation. Ventilatory support is often required. *It is important to opt for quick surgical repair, and it is wrong to wait for days or weeks before undertaking surgery*. Invariably, delay results in a progressive worsening of the hemodynamic state, and the evolution of multiple organ failure. Once the latter complication ensues, surgery, even if attempted, is almost always unsuccessful.
10. *Rupture of a papillary muscle* Papillary muscle rupture produces a pansystolic murmur at the apex due to severe mitral incompetence. It needs to be distinguished from a ruptured interventricular septum. There is no step-up in the oxygen saturation from the right atrium to the right ventricle in this condition, and large regurgitant V-waves are observed in the pulmonary wedge tracing. A papillary muscle rupture leads to LVF with pulmonary edema together with failure of forward flow and impaired tissue perfusion. Management is on the same lines as for intraventricular septal rupture. A combination of afterload and preload reduction by using sodium nitroprusside, together with inotropic support with dopamine, is necessary. Preload may need to be further reduced by furosemide. An aortic balloon pump is to be used to help restore a semblance of hemodynamic stability. Urgent surgical repair should be considered in these patients.
11. *Myocardial rupture* Rupture of the free wall of the ventricle typically occurs 3–5 days after an infarction. It usually presents with rapid hypotension and pericardial tamponade progressing quickly to electromechanical dissociation and death. Patients are almost never salvageable. If there is a comparatively slow leak of blood into the pericardium, time for possible rescue measures may be available. The diagnosis of tamponade should be made on clinical grounds. Echocardiography, if available, can be extremely useful. Treatment consists of emergency pericardiocentesis, infusion of fluids, inotropic and vasopressor support, ventilatory support and rapid transfer to the theater for surgical repair. We have never had the good fortune of salvaging a patient with rupture of the ventricular wall following an MI.
12. *Embolic complications* Embolic complications can arise from mural thrombi that may form within the ventricle over the infarcted area. Clinical features depend on the site of embolization. Neurological deficits due to emboli in the cerebrovascular circulation may at times be the presenting feature of an underlying MI. Anticoagulation is recommended in such patients. Rarely a saddle block due to an embolus straddling the aortic bifurcation, produces a loss of blood supply to both lower limbs. Removal of the obstructing clot through a Fogarty's catheter introduced through the femoral artery should be promptly done; this is followed by anticoagulation (Box 5).
13. Pulmonary embolism. Pulmonary emboli can arise from thrombi within the right atrium or right ventricle or from thrombi within the deep veins. This complication worsens pregnosis (see Chapter Pulmonary Embolism).

MYOCARDIAL STUNNING OR HIBERNATION

These entities have attracted considerable attention. In myocardial stunning, systolic dysfunction persists for a time after an ischemic episode even though reperfusion has been

established. It can occur after thrombolysis in AMI and after cardiopulmonary bypass. A hibernating myocardium is poorly contractile but still viable area of myocardium due to poor coronary blood flow. The myocardial dysfunction improves when coronary blood flow to the area is re-established.

DURATION OF INTENSIVE CARE

An uncomplicated acute myocardial infarct can be transferred out of the ICU after 2 days. An AMI with complications should stay till such time as intensive care is necessary. The need for hemodynamic monitoring, use of inotropes or of drugs to reduce afterload or preload and close nursing supervision necessitate a longer stay in the ICU.

CHAPTER 22

Acute Left Ventricular Failure with Pulmonary Edema

INTRODUCTION

Acute left ventricular (LV) failure with pulmonary edema is always associated with a marked increase in the LV end-diastolic pressure and the pulmonary capillary wedge pressure (PCWP). The increased pressure in the pulmonary capillaries and veins leads to a transudation of fluid into the interstitial tissues of the lung (interstitial edema), and later into the alveoli, producing alveolar flooding. Acute LV failure may vary in severity. When mild, it is characterized by paroxysmal attacks of breathlessness, which abate spontaneously; these attacks are related to sharp but transient rise in the LV end-diastolic and the capillary wedge pressures. When severe, it is associated with frank pulmonary edema, the patient literally drowning in his own secretions. Fulminant pulmonary edema is associated with an increase in the LV filling pressure (LV end-diastolic pressure) close to or more than 30 mm Hg.[1,2]

Acute LV failure with pulmonary edema constitutes an important cause for emergency admission to an intensive care unit (ICU). Also, patients admitted to an ICU for other critical illnesses may suddenly develop acute pulmonary edema due to LV dysfunction. The latter may be pre-existing but may have gone undetected, and could well be unmasked by the stress of a critical illness (e.g. fever, tachycardias, seizures), or by therapy used to treat a critical illness, e.g. fluid infusions, which cannot be easily handled by a diseased or poorly functioning left ventricle. LV dysfunction and failure can also be induced in a previously healthy heart by an acute illness, e.g. overwhelming sepsis, or a fulminant viral infection for which the patient has been admitted to the ICU.

HEMODYNAMIC PROFILES IN LEFT VENTRICULAR FAILURE

Failure of the pumping action of the left ventricle leads to two basic disturbances in the hemodynamics of the circulation—

1. An increase in backward pressure from the failing left ventricle, which results in pulmonary edema.
2. A failure of forward flow, which leads in time to a decreasing cardiac output, decreasing arterial blood pressure, and above all to a fall in tissue perfusion.

Both the above features may be present in varying degrees in the same individual. Also each one of these disturbances may occur independently of the other (see Chapter Cardiogenic Shock). The following hemodynamic patterns may be observed—

1. An increased LV end-diastolic pressure and PCWP with resulting pulmonary edema; an adequate forward flow with a cardiac index not less than 2.5 L/min/m^2 and adequate tissue perfusion. To start with, the cardiac output in acute LV failure may be normal in spite of pulmonary edema, because the ventricle still responds to the increase in preload, as per Starling's law—a basic compensatory mechanism in cardiac failure. The arterial pressure is unchanged and for various reasons may even show a temporary rise.

   The mechanics of this hemodynamic change is illustrated in Figure 1 which shows the right and LV function curves in a patient with acute pulmonary edema due to poor LV function. Two features worthy of note in this figure are: (i) a normal right ventricular function curve; (ii) a LV function

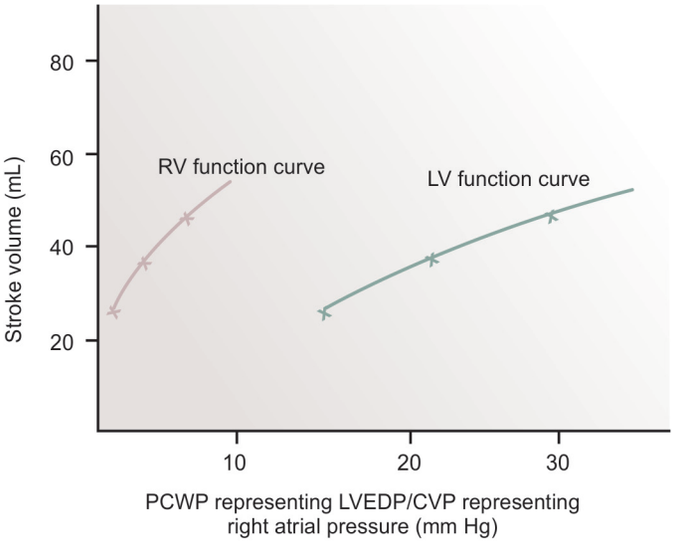

Fig. 1: Right and left ventricular (LV) function curves in a patient with acute LV failure causing fulminant pulmonary edema. Note that the LV function curve is shifted to the right, and has a lesser slope compared to the right ventricular (RV) function curve. Fulminant pulmonary edema occurs when pulmonary capillary wedge pressure (PCWP) exceeds 30 mm Hg, at which time the right atrial pressure is about 7 mm Hg. Note that a rise in right atrial pressure from 2 mm Hg to 7 mm Hg is associated with a rise in the LV filling pressure from 15 mm Hg to 32 mm Hg

curve which is shifted to the right, and whose slope is moderately reduced.

2. Increased PCWP causing pulmonary edema; a failure of forward flow with a drop in the cardiac index to less than or equal to 2.2 L/min/m^2, and a fall in tissue perfusion. As failure of forward flow increases, the arterial blood pressure drops in spite of compensatory mechanisms. The mechanics of this hemodynamic change is the same as in (1) except that the slope of the LV function curve is markedly reduced, pointing to a more severe dysfunction than in the first case (see Chapter Cardiogenic Shock).
3. No pulmonary edema as the PCWP is not raised; however, there is marked failure of forward flow with a low cardiac index (often <1.8 L/min/m^2), a low arterial blood pressure and poor tissue perfusion often causing a lactic acid acidosis. The picture is akin to that of cardiogenic shock without pulmonary edema. This hemodynamic profile has been dealt with in the Chapter Cardiogenic Shock.
4. Increased right-sided heart pressures together with the increased left-sided heart pressures noted above. Thus, in addition to an increased LV end-diastolic pressure and PCWP, there is also an increased pulmonary artery pressure, increased right ventricular end-diastolic and right atrial pressure and a rise in the central venous pressure. This is due to a progressive increase in pressure backward from the failing left ventricle, ultimately resulting in right heart failure. The clinical picture is not only that of pulmonary edema, but also includes raised jugular venous pressure, enlarged tender liver and pitting edema of the feet. This picture of congestive cardiac failure (left- and right-sided heart failure) can evolve rapidly as after a massive anterior myocardial infarct or evolves subacutely if a patient with LV failure is inadequately treated or brought late to the ICU.

SYSTOLIC AND DIASTOLIC HEART FAILURE

There are significant differences between the pathophysiology of systolic heart failure (SHF) and diastolic heart failure (DHF) even though the clinical features in both are very similar. SHF is due to diminished contractility of the myocardium. In chronic SHF, there is progressive eccentric remodeling of the left ventricle leading to progressive dilatation and a resultant decrease in left ventricular ejection fraction (LVEF). In DHF, there is concentric remodeling with a normal LV end-diastolic volume.

The hallmark of DHF is diastolic dysfunction. DHF has been defined as impaired LV filling capacity due to abnormalities in active relaxation and to increased stiffness (i.e. lowered compliance) of the myocardium. Hemodynamically these changes become evident as an upward and leftward shifted end-diastolic pressure volume relationship. In DHF, the contractility of the myocardium (in contrast to SHF) is normal so that ejection fraction is within normal limits.

Among the general heart failure population, close to half have DHF. DHF increases with age; it is present in 46% of patients more than 45 years of age and increases to near 60% in patients older than 85 years.

The important risk factors for diastolic dysfunction and DHF are hypertension, increasing age, obesity, female sex, diabetes, aortic stenosis, chronic kidney disease and coronary artery disease. Restrictive cardiomyopathy, positive pressure mechanical ventilation and pericardial effusion can also through different mechanisms impair diastolic LV filling.[3-5]

It is important to remember that in many patients systolic and diastolic dysfunction co-exist. This is typically seen in patients with coronary artery disease. Systolic dysfunction and systolic failure in these patients can be caused by new or old myocardial infarction (loss of contractile mass) and by active or acute myocardial ischemia. Diastolic dysfunction and failure can result from replacement of muscle by fibrous tissue following infarction and by the acute reduction in myocardial distensibility during ischemia.

Measurement of the PCWP does not distinguish between systolic and DHF because the wedge pressure is increased in both. However, the LV end-diastolic volume for a given end-diastolic pressure is significantly greater in systolic dysfunction when compared to diastolic dysfunction.

The diagnosis of DHF is made by the presence of clinical symptoms and signs of the LV failure in combination with preserved LV systolic function (LVEF >50%). Evidence of diastolic dysfunction is obtained by echocardiography, Doppler examination, and if the need arises by invasive hemodynamic study. The B-type natriuretic peptide (BNP)

is elevated in both systolic and DHF but values are typically lower in DHF compared to SHF.

Echocardiographic Criteria for Diagnosis of Diastolic Dysfunction

Echocardiography is a reliable noninvasive investigation to determine the presence and degree of diastolic dysfunction. Color M-mode and Doppler tissue imaging have been recently introduced for the diagnosis of diastolic dysfunction.

Mitral flow velocity determined by using pulsed wave Doppler consists of four variables: (1) peak early diastolic flow (E), (2) peak late diastolic flow (A), (3) early deceleration time (DT) and (4) A wave duration (A dur). The normal E/A ratio is 0.75–1.5 and the normal deceleration is less than 220 milliseconds.

With progressive increase in diastolic dysfunction, there is an increase in the E/A ratio to greater than 1.5 (the E wave being large and the A wave small), and a significant decrease in the DT (<150 milliseconds). If this pattern remains fixed with the Valsalva maneuver, the diastolic dysfunction is judged to be advanced or grade IV.

Precipitating factors for LV failure and pulmonary edema in patients with diastolic dysfunction include pressure overload, volume overload, rhythm disturbances causing a fast ventricular rate and myocardial ischemia. The above precipitating factors need to be controlled in management of failure.

DIAGNOSIS[1]

The diagnosis of pulmonary edema due to acute LV failure is generally easy. The patient is breathless and often orthopneic.[6] Pulmonary edema is clinically manifest by crackles, which may be restricted to only the lung bases. In severe edema, loud crackles or bubbling moist sounds are heard all over both lungs; in fulminant edema, pinkish frothy edema fluid may well out of the mouth and nose, the patient literally drowning in his own secretions. Occasionally, there are more polyphonic wheezes than crackles. In rare instances, wheezing with prolonged expiration is indistinguishable from that heard in severe bronchial asthma. If the chest is not too noisy, a diastolic gallop may be generally heard; a diastolic third heart sound signifies a LV end-diastolic pressure greater than or equal to 18 mm Hg. There is often, though not always, clinical evidence of underlying left heart disease. Hypertension, acute myocardial ischemia, myocardial infarction, aortic valve disease, mitral incompetence, acute myocarditis, supraventricular and ventricular arrhythmias, complete heart block and cardiomyopathy are important causes of acute LV failure. Acute pulmonary edema can also occur when there is a sudden, sharp rise in left atrial pressure in patients with mitral stenosis. Positive pressure ventilation, particularly when associated with high positive end-expiratory pressure (PEEP) may cause LV diastolic dysfunction and failure. High output failures are characterized by arteriovenous shunting or increased demand for oxygen by tissues. They are observed

Fig. 2: Chest X-ray reveals ill-defined fluffy opacities in both lung fields as a result of pulmonary edema

chiefly in arteriovenous fistulas, severe anemia, thyrotoxicosis and beriberi. In our experience, they more often act as aggravating or precipitating factors of heart failure in patients with underlying cardiac disease. Diagnosis of the underlying etiopathology during an attack of acute pulmonary edema may be difficult, as in severe cases heart sounds and murmurs are inaudible due to the loud bubbling moist sounds, which are heard even at some distance from the patient.

A *chest X-ray* shows clear evidence of pulmonary edema (Fig. 2). Interstitial edema is observed in mild cases; alveolar edema leads to homogeneous alveolar shadows generally spreading from the hilum to the periphery. Occasionally, one lung is considerably more involved than the other. It is important to note that there can be a short time lag between the sudden rise in LV end-diastolic pressure (and with it in the PCWP), and the clinical and radiological appearances of pulmonary edema.[7]

An *electrocardiogram (ECG)* may show evidence of ischemic heart disease or of LV hypertrophy.

An *arterial blood gas analysis* in well-marked pulmonary edema shows a low PaO_2 (as low as 30–40 mm Hg), with hypocapnia. In the moribund patient or when the use of morphine has suppressed the respiratory drive, the $PaCO_2$ rises, and some degree of respiratory acidosis results. In patients with a failing forward flow and impaired tissue perfusion, there is a super-added metabolic (lactic acid) acidosis. A combination of metabolic and respiratory acidosis is of sinister prognosis.

Echocardiography A transthoracic echocardiogram provides information related to ventricular size and systolic function, wall motion, valvular structure and function, presence of intracardiac clots or masses, intracardiac flow, pericardium and ascending and transverse aorta. A normal or near normal LVEF should never preclude the diagnosis of acute pulmonary edema, as diastolic dysfunction may occur with normal or near normal ventricular systolic function in 40% of patients with heart failure.[3-5]

DIFFERENTIAL DIAGNOSIS

When acute LV failure is associated with wheezing and prolonged expiration, it closely resembles a late-onset bronchial asthma. The diagnosis becomes doubly difficult when a patient with a past history of long-standing bronchial asthma develops LV disease. In fact, these are just the patients who when they develop acute LV failure, will manifest with wheezing rather than auscultatory crackles. We have been convinced over the years that individuals with increased bronchial reactivity wheeze rather than 'crackle' during LV failure.

Rarely, it is difficult to distinguish between pulmonary edema resulting from LV failure and noncardiogenic pulmonary edema. A careful clinical history, the evolution of the disease and relevant investigations generally clarify the diagnosis. A PCWP greater than 18 mm Hg as measured by a Swan-Ganz catheter points to LV failure. It must be remembered that a patient with LV dysfunction may well suffer from an unrelated illness that can cause noncardiogenic pulmonary edema; in such individuals more than one cause may be responsible for the pulmonary edema.

MANAGEMENT (BOX 1)[8]

The patient with acute pulmonary edema due to LV failure is nursed propped up in bed. If possible, he should be made to sit up with his legs dangling over the side of the bed. If pulmonary edema is associated with marked failure of forward flow and features of shock, he may need to be nursed flat in bed with the head slightly raised.

Morphine Sulfate[9]

This is an invaluable drug for use as the first immediate emergency measure. Morphine sulfate (15 mg) can be given subcutaneously in moderately severe LV failure. Alternatively, 2–4 mg of the drug is administered intravenously and the dose repeated after 0.5–1 hour if necessary, so that the desired effect of morphine is obtained. Morphine helps in several ways: (1) it allays anxiety, restlessness, and slows the respiratory rate, thereby reducing the work of breathing, and also the overall oxygen demand by the peripheral tissues (through sedation and quietening of the patient); (2) it dilates both arterioles and venules thereby increasing venous capacitance and reducing the preload. A reduced preload causes a drop in the PCWP and in the filling pressure of the left ventricle. This results in a reduction of pulmonary edema.

Morphine is at times impossible to obtain in hospitals and ICUs in India. A useful substitute (but not an equally effective one) is buprenorphine given slowly intravenously in a 0.2–0.4 mg dose. This may need to be repeated till the desired effect is achieved.

Pethidine 75–100 mg intramuscularly can also be used, but lacks the overall efficacy of morphine. The only situation where pethidine is preferable is in patients in acute LV failure who present with severe wheeze and prolonged expiration.

Box 1: Management of acute pulmonary edema due to left ventricular failure

- Morphine 2–4 mg intravenously (IV), or buprenorphine 0.2–0.4 mg IV, repeated after 0.5–1 hour if necessary. If morphine is not available, pethidine 75–100 mg intramuscularly (IM) can be used. Patients with fulminant pulmonary edema and alveolar hypoventilation should first be put on mechanical ventilator support and then administered morphine
- Oxygen at 6–8 L/min through nasal prongs
- Measures to reduce preload—
  - Furosemide 40–100 mg IV
  - Aminophylline 250 mg diluted with dextrose and given IV over 10–15 minutes
  - Application of rotating tourniquets or blood pressure (BP) cuffs to extremities may be used during transport to hospital
- Digitalis—improves cardiac contractility and pump function 0.25 mg given IV slowly and repeated 4–6 hourly till digitalizing dose of 0.75–1 mg given in 24 hours
- Vasodilators—
  - IV nitroglycerine in a slow titrated drip starting at 15 µg/min—reduces preload
  - IV sodium nitroprusside in a slow titrated drip starting at 5 µg/min—reduces both preload and afterload
- Inotropic agents (dopamine/dobutamine) used—
  - When pulmonary edema associated with hypotension and/or reduced tissue perfusion
  - In patients with pulmonary edema refractory to the above-mentioned treatment
- Ventilator support—
  - In fulminant pulmonary edema
  - When respiratory drive fails and patient breathes poorly
  - Respiratory muscle fatigue

Note: Nitroprusside is best avoided except when LV failure is associated with severe hypertension.

In a few of these patients, morphine instead of relieving the wheeze actually worsens it. The major side effects of morphine include hypotension, vomiting, and increased parasympathomimetic activity evinced by bradycardia and bronchospasm. Some patients with acute LV failure may show a strong hypertensive response during the period of failure, even though they are not basically hypertensive. Morphine acts beautifully in such patients and lowers the blood pressure effectively. Vomiting can be controlled by the use of promethazine 25 mg intramuscularly. Most patients with acute LV failure and pulmonary edema have tachycardia, so that a lowering of the heart rate by morphine is a decided advantage. If parasympathomimetic effects are observed, the administration of atropine 0.5 mg intravenously easily reverses these effects.

There is just one strong contraindication to the use of intravenous morphine in patients with acute LV failure. It should not be used as an immediate measure in a patient with fulminant pulmonary edema who is literally frothing with

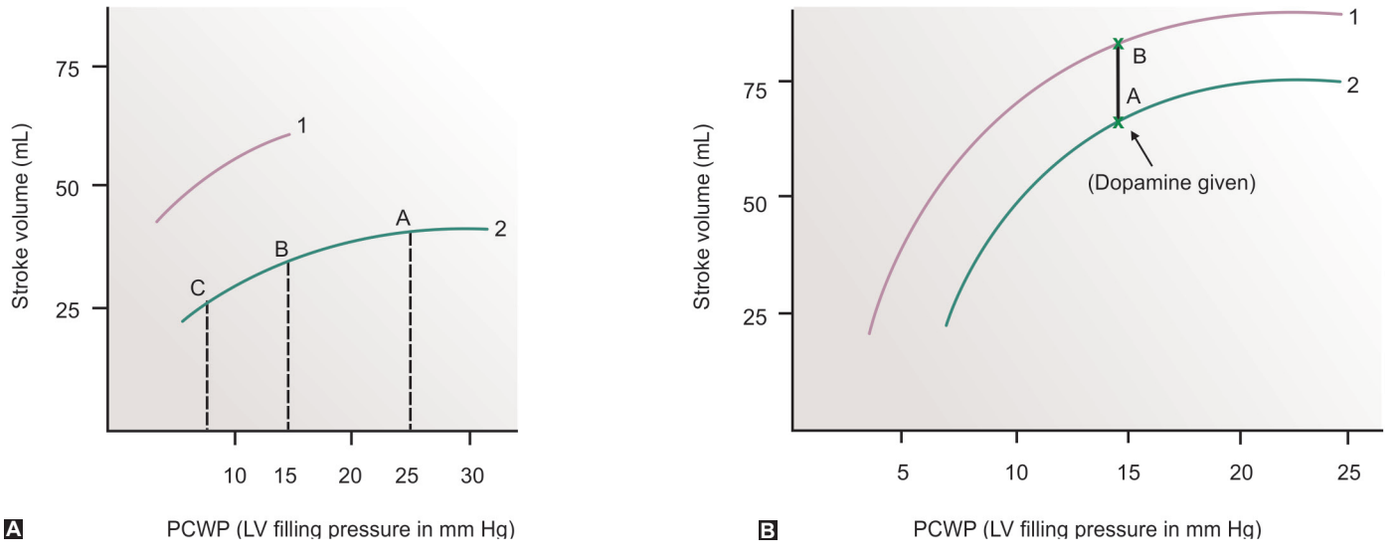

Fig. 3A and B: (A) 1-Normal left ventricular (LV) function curve; 2-LV function curve in patient with LV dysfunction. Administration of furosemide (Point A) reduces preload, causes a fall in pulmonary capillary wedge pressure (PCWP) (Point B), and relieves pulmonary edema, but does not influence stroke volume or cardiac output. Over-use of furosemide will further reduce pulmonary capillary wedge pressure (PCWP) (to Point C) and though pulmonary edema is further relieved, there is now a fall in the already low cardiac output. (B) LV function curves (1) before administration of dopamine; (2) after dopamine administration. In contrast to (A) the use of dopamine improves the cardiac contractility to almost normal levels (point A to point B)

edema fluid. Such patients have ineffective breathing and in fact, their blood gases always show a raised $PaCO_2$ pointing to alveolar hypoventilation. A few of these patients are also so severely hypoxic, that they are obtunded. The use of morphine as the first measure in these patients invariably produces a respiratory arrest. As will be discussed below, these patients should be promptly intubated and ventilated; morphine should be given only subsequent to this emergency procedure.

Oxygen

This is promptly started to combat hypoxia, either through a nasal catheter or nasal prongs at 6–8 L/minute, or through a well-fitting oronasal mask at 5–6 L/minute. In patients with well-marked pulmonary edema, oxygen can be given under continuous positive pressure using a well-fitting oronasal mask. This may provide satisfactory oxygenation, and may at times prevent the need for emergency intubation and ventilatory support.

Measures to Reduce Preload

Use of Diuretics—Furosemide[10-12]

Intravenous furosemide is useful in the management of acute pulmonary edema. Between 40 mg and 100 mg or even more of the drug is given intravenously, depending on the severity of pulmonary edema. Furosemide reduces preload in two ways—

1. It produces almost within minutes a sharp increase in venous capacitance through a venodilating effect, which results in a significant lowering of the preload (as measured by the pulmonary artery end-diastolic and PCWPs). Pulmonary congestion thereby decreases even before the onset of the diuretic action of the drug. There is at times a fall of 5–8 mm Hg in the LV filling pressures after intravenous furosemide.
2. It has an excellent diuretic action. Diuresis starts within 15 minutes and is maximal for 4–6 hours. Some patients are exquisitely sensitive to even small doses (40 mg) of furosemide, and respond with profuse diuresis. Therefore, unless the pulmonary edema is gross, it is wiser to give only 40 mg furosemide initially and then repeat a larger dose if diuresis is inadequate in the first 2 hours. At times, patients require massive doses of furosemide (1 g over 24 hours) to promote an effective diuresis. When more than 100–120 mg of intravenous furosemide are required to produce an effective diuretic effect, it is best to administer the drug by a continuous IV infusion at a rate of 10–40 mg/hour.

The diuresis induced by furosemide reduces the water content of the lungs and thus reduces pulmonary edema. It is important to note that diuretics do not significantly increase cardiac output. In fact, over-diuresis with an over-reduction in the preload is a disadvantage, as this may initially cause a fall in the cardiac output. It is currently believed that a fall in the cardiac output may be further contributed to by an increase in systemic vascular resistance. The latter effect is due to a furosemide-induced stimulation of release of renin and raised circulating angiotensin levels.[13] Figure 3A illustrates the effect of furosemide on the LV function curve in left heart failure. In contrast, the administration of dopamine to these patients improves the cardiac contractility to almost normal levels (Fig. 3B).

The danger of overuse of furosemide is twofold—it renders the patient hypovolemic and can reduce the cardiac output, the sum total of these effects being an impairment of tissue perfusion. The above problems may prove dangerous if

the kidneys continue to be whipped by increasing doses of furosemide, in an attempt to increase a falling urine output in a hypovolemic patient. Features of hypovolemic shock (which may include oliguria and even renal shutdown), may thus be wrongly attributed to cardiogenic shock produced by poor pump function.

Use of Vasodilators

Vasodilators are important in the management of cardiogenic pulmonary edema. Nitrates chiefly act by reducing the preload, whilst sodium nitroprusside when used in selected cases acts by reducing both the preload and the afterload.

Nitrates[14,15] A slow drip of intravenous nitroglycerine is always used in patients with well-marked cardiogenic pulmonary edema, starting with 15 µg/minute and progressively increasing the concentration till the desired relief is obtained. The blood pressure is carefully monitored, and as described under the management of cardiogenic shock, should not be allowed to fall below 100 mm Hg systolic. In previously hypertensive patients, the systolic blood pressure should not be allowed to fall below 130–140 mm Hg. The other side-effects of intravenous nitroglycerine have been discussed at length under cardiogenic shock. It is not always necessary to use a Swan-Ganz catheter for monitoring the PCWP when using intravenous nitroglycerine; noninvasive monitoring with careful clinical assessment generally suffices. However, invasive hemodynamic monitoring is resorted to, when pulmonary edema is associated with poor forward flow and impaired tissue perfusion.

In less severe cases of cardiogenic pulmonary edema, the use of isosorbide dinitrate 10 mg 4 hourly suffices. One can use the drug either sublingually or orally with a careful watch on the arterial blood pressure.

The liberal use of a trinitrate ointment (2–2.5" patch) applied on the skin is also helpful in reducing preload. This method can be used after the patient has been weaned off the intravenous nitroglycerine infusion, which may take from 1 day to 4 days. The trinitrate ointment can be applied on the skin concurrently with oral isosorbide therapy. The ointment can be promptly rubbed off if the arterial blood pressure starts to drop.

Sodium nitroprusside[16] It may be used as a slowly titrated intravenous drip (starting at 5 µg/minute). It reduces both arteriolar and venous resistance thereby reducing both afterload and preload. Reduction of preload relieves pulmonary congestion and edema; reduction of afterload improves the pumping action of the heart.

- Sodium nitroprusside is particularly useful in patients who have pulmonary edema due to LV failure and who also have well-marked hypertension. If used, there should be facilities to monitor the pulmonary artery pressure though a Swan-Ganz catheter and the systemic arterial pressure through an intra-arterial catheter. The use of intravenous nitroprusside in the absence of these monitoring facilities can be tricky and dangerous, particularly in the hands of the inexperienced. The drug should not be used in patients with acute LV failure and pulmonary edema, who are also in cardiogenic shock.

The side effects of nitroprusside, particularly a precipitous fall in blood pressure, should be carefully monitored.

Aminophylline

Aminophylline (0.5 g in a slow intravenous infusion) is administered only in the presence of severe bronchospasm. Aminophylline however, also has a venodilating effect, thereby reducing venous return and preload.

Use of Digitalis[17-19]

Digitalis improves cardiac contractility and therefore improves pump function in LV failure. For prompt effect, digoxin is given in a dose of 0.25 mg very slowly, intravenously. This is repeated every 4–6 hourly till a total digitalizing dose of 0.75–1 mg is given over 24 hours. If the patient has already been taking adequate doses of oral digitalis prior to the onset of acute LV failure with pulmonary edema, it is best to avoid intravenous use of the drug. However, if it is given, no more than 0.125 mg is administered. Determination of serum digoxin levels helps in titrating the dose of digitalis. In a patient who has already been receiving digitalis, the presence of paroxysmal atrial tachycardia with a 2:1 block, A-V junctional tachycardia or recurrent ventricular bigeminy are all suggestive of digitalis toxicity.

Inotropic Agents[20]

An intravenous infusion of dopamine or dobutamine is used under the following conditions in patients with cardiogenic pulmonary edema (Fig. 3B). Their dosage and manner of use have been described on the Chapter Cardiogenic Shock.

- When acute pulmonary edema is associated with hypotension and/or evidence of impaired tissue perfusion.
- When pulmonary edema does not relent quickly in spite of the measures outlined above.

Dobutamine is preferred unless the systolic blood pressure is l below 90 mm Hg, in which case dopamine is used.

Recognition of Factors Frequently Precipitating LV Failure and Pulmonary Edema in the ICU (Box 2)

Important precipitating factors causing cardiogenic pulmonary edema in patients being treated for some other critical illness in the ICU include—

- Increased salt intake.
- *Overloading patients with fluids through intravenous infusions* Pulmonary edema may be triggered in patients with underlying poor LV function by the rapid infusion of fluids, even if the fluid intake is by no means excessive. This is particularly common when intravenous infusions of whole blood, plasma or colloid are given rapidly to patients with poor LV function.

Box 2: Important factors precipitating left ventricular failure (LV) and pulmonary edema in critically ill patients in the intensive care unit (ICU)

- Increased salt intake
- Overloading patients with fluids through intravenous infusions. In patients with LV dysfunction, rapid infusion of fluids (particularly whole blood, plasma, colloids, even if not excessive) may trigger pulmonary edema
- Occurrence of tachyrhythms, e.g. supraventricular tachycardia, atrial fibrillation with fast ventricular rate or ventricular tachycardia. In critically ill patients, even sinus tachycardia due to fever, seizures can increase the workload of the heart and precipitate pulmonary edema
- Occurrence of marked bradyrhythm can increase the filling pressures and precipitate pulmonary edema

- *The occurrence of tachyrhythms* Sinus tachycardia produced by fever, marked restlessness, involuntary movements or seizures, increases the workload on the heart in critically ill patients, and triggers cardiogenic pulmonary edema, thereby unmasking LV failure in these patients. Supraventricular tachycardias, atrial fibrillation with a fast ventricular rate or ventricular tachycardias can have an even more disastrous effect in critically ill patients.
- A marked bradyrhythm can also result in increased filling pressures and cardiogenic pulmonary edema. Pacing may be required to increase the heart rate and reverse the pulmonary edema, particularly if intravenous atropine proves ineffective.
- Severe anemia, thyrotoxicosis and vitamin B_1 deficiency may act as precipitating or contributory factors in acute heart failure.

Acute LV Failure Presenting with Severe Bronchospasm (True Cardiac Asthma)

Patients with a background of asthma or hyperreactive bronchi often present with severe bronchospasm when they develop acute LV failure due to underlying LV disease. In addition to the treatment outlined above, administration of methyl prednisolone 20–40 mg 8 hourly intravenously and nebulization with salbutamol are helpful. Aminophylline 0.5 g administered in an intravenous infusion over 24 hours is also of use.

Use of Ventilator Support in Cardiogenic Pulmonary Edema

This is indicated in the following conditions—

- *Fulminant pulmonary edema* in which secretions bubble within the trachea and the larger bronchi. The patient is grossly hypoxic, often cyanosed, with a PaO_2 less than 45 mm Hg, and often as low as 30 mm Hg. These patients almost always hypoventilate because of ineffective respiration, and this is evinced by a $PaCO_2$ greater than 50 mm Hg. Prompt endotracheal intubation and the use of volume cycled ventilation with inspired oxygen (FiO_2) at 100% is life-saving. Oxygenation improves, ventilation is satisfactory and the positive pressure forces the edema fluid back against the alveolar walls, and at least prevents further transudation of fluid. A PEEP of +5 to +10 cm of water is of help. The therapy described above is often life-saving in a patient with fulminant pulmonary edema who has a palpable pulse and a satisfactory arterial blood pressure (>90 mm Hg). It buys valuable time and gives other therapeutic measures, particularly the use of morphine, digoxin, furosemide, intravenous nitroglycerine infusion and intravenous dopamine support, a chance to take effect. If, however, ventilator support is delayed to a point in time when the pulse is barely perceptible and the arterial blood pressure unrecordable, the prognosis is poor. *In less fulminant cases, noninvasive ventilator support through an orofacial mask is equally effective.*
- *When the respiratory drive fails*, and the patient is observed to breath poorly. This occurs terminally in severe pulmonary edema, or is the result of respiratory muscle weakness in critically ill patients. It also occurs when the respiratory drive has been excessively depressed by the use of morphine or pethidine. A poor respiratory drive is noted clinically and confirmed by blood gas analysis, which shows increasing hypoxia and a rise in $PaCO_2$. The average patient with cardiogenic pulmonary edema is hypocapnic; hence increasing hypercapnia with a $PaCO_2$ of greater than 60–70 mm Hg can portend disaster.

Mechanical Support

In patients with pulmonary edema and severe shock unresponsive to conventional methods, mechanical support with an intra-aortic balloon pump or rarely with a ventricular assist device may help to temporarily tide over a crisis.

Invasive Monitoring in Cardiogenic Pulmonary Edema

Clinical judgment with routine noninvasive tests (which should include chest X-ray and arterial blood gas analysis) generally suffice to guide management. A Swan-Ganz catheter with monitoring of pulmonary artery and PCWPs (and indirectly of LV filling pressures), and measurement of cardiac output are indicated under the following circumstances—

- When the diagnosis of cardiogenic versus noncardiogenic pulmonary edema is uncertain on clinical grounds.
- When the knowledge of a patient's volume status is of vital importance, but cannot be determined from the history and clinical examination.
- In severe cases of pulmonary edema which do not respond to conventional therapy.
- On rare occasions when intravenous sodium nitroprusside is used to reduce both afterload and preload.
- When acute pulmonary edema is associated with a sharp fall in arterial blood pressure, reduced tissue perfusion or with obvious shock.

- When in a patient presenting as acute heart failure, it is important to exclude cardiac tamponade or an acute left to right shunt.

Improvement in cardiogenic pulmonary edema is gauged clinically and by chest X-rays. In patients with a Swan-Ganz catheter, one can titrate therapy to maintain the PCWP close to 15–18 mm Hg, ensuring that a fall in preload does not cause a sharp fall in the cardiac index. It is important to remember that there is a significant time lag between reduction of preload with a fall in the PCWP to safe levels and the radiological clearing of edema fluid. It is therefore important not to overdiurese these patients merely because of persistent alveolar shadows in the lung fields, as this could lead to unwanted hypovolemia.

CHAPTER 23

Tachyarrhythmias in the Intensive Care Unit

Tachyrhythms occur very frequently in patients under intensive care. They are not restricted to patients with underlying heart disease; in fact, they occur against a wide spectrum of background diseases—in shock from any cause, acute infections, acute respiratory problems, during ventilator support, following hypoxia, and fluid and electrolyte disturbances. The sudden appearance of a tachyrhythm in a critically ill patient or in a patient on his way to recovery from a critical illness invariably makes even an experienced critical care physician's heart skip a beat! What is it due to? Should one react to it and if so how? Some tachyrhythms come and go all in a flash and produce no problems; others portend disaster. The answer to the two questions listed above, in spite of experience and wisdom gathered over the years, can sometimes be unfortunately given only by hindsight rather than by foresight.

Tachyrhythms can result from enhanced automaticity, triggered activity as in ectopic impulses or from a process called *re-entry*. In the *re-entry phenomenon*, a triggered impulse encounters a block when being propagated forwards through a conducting pathway. The impulse, however, is permitted to pass in the return or retrograde direction. Retrograde transmission can allow such a triggered impulse to result in a continuous self-sustained tachycardia. The re-entry phenomenon is an important underlying mechanism in many paroxysmal tachycardias.

This chapter has not dealt in detail with the electrophysiology and detailed mechanisms underlying tachyrhythms. It briefly deals with the quick recognition of the nature of different tachyrhythms, and describes the urgent management strategies in an identified tachyrhythm occurring in an intensive care unit setting. This is followed by a brief section on digitalis-induced arrhythmias. The next chapter details relevant aspects of important and commonly used drugs in the management of tachyarrhythmias.

QUICK RECOGNITION OF TACHYRHYTHMS

A quick study of the rhythm strip is of great help in identifying the nature of the tachyarrhythmia. The features that should be quickly noted are the rate, the regularity or irregularity of the RR intervals, and the width of the QRS complex—whether less than 0.12 seconds, equal to or greater than 0.12 seconds.

Narrow complex (QRS <0.12 s) regular tachycardias[1] are sinus tachycardia, atrial flutter with a fixed block, paroxysmal atrial tachycardia, junctional (nodal) tachycardia or atrioventricular (AV) nodal re-entrant tachycardia. A look at the P-waves in a rhythm strip can help in further identification. Uniform P-waves suggest a sinus tachycardia, saw-tooth P-waves an atrial flutter, inverted P-waves a junctional (nodal) tachycardia, absent P-wave activity a paroxysmal atrial tachycardia, multiple varying P-waves a multifocal atrial tachycardia. It is preferable to monitor V_1 so that the rhythm strip will depict a V_1 tracing where the P-wave configuration, particularly in atrial flutter, is quickly discernible. A 12-lead tracing to study P-waves and their configuration is however often necessary.

Marked irregularity of a narrow complex tachycardia is observed in atrial fibrillation, multifocal atrial tachycardia, atrial flutter with varying block and when there are many supraventricular ectopic beats in patients with sinus rhythm.

The rate as computed from a rhythm strip is of comparatively less value. It, of course, distinguishes a tachyrhythm (>100 beats per minute) from a bradyrhythm (<60 beats per minute). Sinus tachycardia is uncommon with rates greater than 200 beats per minute. Again, the higher the rate in a

tachyrhythm, the greater is the chance of a compromised circulatory system.

Wide complex (QRS >0.12 s) tachycardias[2] can be ventricular tachycardia (VT), supraventricular tachycardia (SVT) with delayed or aberrant conduction, or torsade de pointes which is a particularly dangerous form of VT. To distinguish between VT and SVT with delayed or aberrant conduction can be extremely difficult. Relevant distinguishing features are discussed later. As a matter of principle, a wide QRS tachyarrhythmia should be considered to be a VT unless clearly proved otherwise.

A short description of narrow QRS complex tachycardias and management strategies to counter them is now given. This is followed by a similar description of wide QRS tachyrhythms.

NARROW COMPLEX TACHYCARDIAS (SUPRAVENTRICULAR TACHYCARDIAS)

General Considerations

Patients in the ICU with narrow complex or SVTs often have underlying cardiac disease involving the conduction pathways. However, supraventricular arrhythmias can also occur in the absence of organic heart disease. They can thus be caused by hypokalemia, hypomagnesemia, hypoxia, increased adrenergic activity or tone, or by drugs. Most paroxysmal supraventricular tachyrhythms are caused by re-entry mechanisms. Re-entrant tachycardia is initiated by a supra-ventricular ectopic beat and is promptly terminated by a direct current (DC) shock or by overdrive pacing. Occasionally, SVTs are caused by a sudden enhancement of an autonomous focus in the atria or the junctional AV nodal tissue, which discharges or fires at a rate generally between 150–220 beats per minute. Enhanced autonomic activity of an ectopic focus is often due to metabolic derangements or to drugs, and SVTs due to this etiology often respond to a correction of the underlying metabolic derangement. Though all SVTs are sudden in onset and offset, SVT due to enhanced autonomic activity are not as sudden as those due to re-entry mechanisms.

ATRIAL FLUTTER AND FIBRILLATION

Atrial flutter is characterized by typical flutter waves (described later) at a rate of 300–350 beats per minute. A block at the AV node, generally a 2:1 block allows the ventricles to beat regularly at 150 beats per minute. A varying AV block produces an irregular ventricular rhythm.

Atrial fibrillation[3] is the most common supraventricular arrhythmia. The atria fibrillate and the ventricular rhythm is irregularly irregular because of a constantly changing AV block. Atrial fibrillation is usually associated with cardiac disease—chiefly hypertension, ischemic heart disease, mitral valve disease and congestive heart failure. In about one-third of patients, it occurs without clinical evidence of cardiac disease—lone atrial fibrillation.

As mentioned briefly earlier, identification of the atrial activity (P-waves) and its form is of crucial importance. It helps, as will be discussed later, to distinguish between SVT with delayed conduction and VT, and also helps to arrive at the nature of a SVT with narrow QRS complexes. A full 12-lead electrocardiogram (ECG) aided by carotid sinus massage (a vagal maneuver that slows the heart, and thereby brings out the P-wave) may be necessary. If no emergency exists, the use of an esophageal lead will invariably identify atrial activity.

Clinical Presentation[3]

The main presentation of most supraventricular tachyarrhythmias is the sudden onset of regular palpitations with an abrupt onset. This is particularly so with AV nodal re-entry tachycardia and AV re-entry tachycardia. Tachycardia, which involves the re-entry phenomenon through the AV node, can often be terminated by the Valsalva maneuver. Other symptoms include dizziness, weakness, diaphoresis, chest discomfort and polyuria due to the release of atrial natriuretic peptide.

Syncope may occur in 10–15% of patients, particularly if the ventricular rate is over 200 beats per minute. It is observed more commonly if the patient remains standing, occurs generally at the onset of the arrhythmia or occurs following a long pause after the termination of the arrhythmia. In older patients with a background heart disease, such as mitral valve stenosis, aortic stenosis, ischemic heart disease, poor left ventricular function, hypertrophic obstructive cardiomyopathy, or in patients with cerebrovascular disease, even a moderately fast ventricular rate can cause hemodynamic collapse with profound hypotension and syncope.

A point of importance is that patients presenting with AV re-entry tachycardia may also present with atrial fibrillation. If an accessory pathway has a short antegrade conduction, it may conduct to the ventricles at a very high rate and cause ventricular fibrillation (VF) and death. Sudden death from supraventricular tachyarrhythmia in otherwise young healthy individuals though rare may well be related to this phenomenon.

Irregular palpitations are observed in atrial fibrillation, atrial flutter with changing block, multifocal atrial tachycardia and multiple atrial premature beats. In patients with poor ventricular function, uncontrolled atrial fibrillation, can cause rapidly progressive congestive heart failure, hypotension and hemodynamic collapse. Atrial fibrillation with very slow AV conduction or complete heart block (Frederick's syndrome) can also cause hemodynamic collapse.

SINUS TACHYCARDIA

This is the commonest tachycardia seen in the ICU. Though the rate is generally below 200 beats per minute, in young patients with acute infections (and in severe tetanus in particular), the rate may exceed 200 beats per minute. The P-wave has a normal configuration. Sinus node re-entry tachycardias and atrial tachycardia due to autonomic activity from an

ectopic focus close to the SA node may be indistinguishable from sinus tachycardia. Tachycardias decrease diastolic filling time; in a normal heart, the heart rate must exceed 180 beats per minute before the cardiac output falls.[3] In poorly compliant ventricles, diastolic filling and cardiac output are reduced with comparatively smaller increases in the heart rate. The management of sinus tachycardia is to first identify and then treat its cause. An unexplained rise in an otherwise stable pulse rate in a critically ill individual is a matter of common concern. Important causes of sinus tachycardia are severe anxiety, unrelieved pain, hypovolemia, hypoxemia, sepsis, infection, early shock from any cause, blood loss, pneumothorax, pulmonary embolism, the use of adrenergic drugs, myocardial ischemia or infarction and thyrotoxicosis. Once the cause is treated, the sinus tachycardia disappears. Sinus tachycardia in patients with myocardial ischemia or infarction may warrant the use of beta blockers to slow the heart rate and thereby reduce the oxygen demands of the myocardium. Beta blockers should however not be used in patients with ischemic heart disease who also have poor pump function see Chapters Unstable Angina and Acute Myocardial Infarction).

ATRIOVENTRICULAR NODAL RE-ENTRY TACHYCARDIA[4]

An AV nodal re-entry tachycardia involves dual anatomical and functional pathways in the AV node. One pathway has a long refractory period and faster conduction; the other has a short refractory period and slower conduction. Normally, the impulse arising from the SA node passes through the fast pathway to depolarize the ventricles. If an atrial ectopic beat occurs early when the fast pathway is refractory, the impulse is blocked so that it is now propagated to the ventricle through the slower pathway. It then travels back via the fast pathway which by then has recovered its excitability, thereby initiating a slow-fast AV nodal re-entry tachycardia.

Electrocardiogram

The rhythm is regular at a rate of 140–250 beats per minute. The atria are activated retrogradely producing inverted P-waves in leads II, III, and aVF. However, since the atria and ventricles are depolarized simultaneously, the P-waves are buried in the QRS complexes and cannot be discerned on the ECG. In a small proportion of patients with this tachycardia, the retrograde activation of the atria is observed in the form of small positive terminal deflections in aVR or V_1, and by a small negative 's' in the inferior leads (II, III and aVF).

ATRIOVENTRICULAR RE-ENTRY TACHYCARDIA

Atrioventricular re-entry tachycardia is dependent on the presence of one or more accessory pathways connecting the atria to the ventricle. Accessory pathways capable of antegrade conduction are termed manifest. A sinus impulse conducted antegradely through an accessory pathway produces a delta wave, as it does not encounter AV delay. The PR interval is short; the QRS is wide. This occurs because the atrial impulse entering via the accessory pathway excites initially a nonspecialized part of the ventricular myocardium; depolarization proceeds slowly at first giving rise to the delta wave, before it is overtaken by depolarization occurring through the normal conducting pathways. An accessory pathway capable of conducting solely in a retrograde fashion is regarded as concealed, as it does not produce a delta wave nor a short PR interval during sinus rhythm.

Usually, the re-entry circuit in atrioventricular re-entry tachycardia consists of the impulse traveling from the atria to the ventricle through the AV node and then traveling retrogradely through the accessory pathway to reach the atrium. A circle of activation is thereby perpetuated. Rarely the atrial impulse could travel antegradely through the accessory pathway to the ventricles and return to the atria by passing retrogradely via the AV node. Atrial fibrillation is generally encountered in patients with an antegrade conducting accessory pathway.

EMERGENCY MANAGEMENT

It may be difficult in an emergency to distinguish between AV nodal re-entry tachycardia and AV re-entry tachycardia. This is not of consequence because treatment is the same for both. If the patient is hemodynamically stable, these tachycardias often respond to vagal measures, such as the Valsalva maneuver, carotid sinus massage, inducing vomiting by tickling the pharynx, or by facial immersion in cold water (diving reflex). It is important never to massage both carotid sinuses at the same time as this can result in catastrophic cardiac arrest.

Drugs that block the AV node, such as adenosine, verapamil, diltiazem and beta blockers, can terminate both AV nodal re-entry and AV re-entry tachycardias. Adenosine is the drug of choice as it terminates these re-entry tachycardias in more than 90% of cases and is effective within 30 seconds of its intravenous injection. An added advantage (when compared to verapamil or diltiazem) is the absence of a negative inotropic effect so that the drug is safe in patients who are hypotensive or have poor left ventricular function.

It is important to note that adenosine generally does not abolish atrial flutter, nor does it revert automatic atrial tachycardia. It can however produce high-grade AV block during which the atrial tachycardia persists, though the ventricular rate is slower. Adenosine has no effect on VTs.

Adenosine is administered intravenously as a very rapid 3–6 mg bolus. The bolus dose should be promptly followed by a 20 mL saline flush so as to hasten its effect. If the drug is ineffective, another 6 mg or even 12 mg is administered intravenously after 2–5 minutes, followed by 20 mL saline flush. The dose of adenosine should be reduced by 50%, if it is given through a central venous catheter instead of a peripheral vein.[5] This is because ventricular asystole is known to occur

when a standard dose of adenosine is given through a central venous catheter.

Adverse effects of adenosine include facial flushing, chest tightness, dyspnea and a bradyrhythm because of AV block. These adverse effects are short-lived as the drug is metabolized very quickly, its half-life being just 10 seconds.

Rarely, adenosine may shorten the atrial refractory period and promote atrial flutter or fibrillation or accelerate conduction over the accessory AV pathway producing a rapid ventricular response.[6] Adenosine has an important drug interaction with the bronchodilator, theophylline. Theophylline blocks adenosine receptors, thereby preventing the proper action of adenosine so that the drug may be ineffective in these circumstances. Finally, a significant side effect in asthmatic patients is bronchoconstriction. The drug should therefore not be used in patients with asthma.

Verapamil and Diltiazem

Verapamil is administered as a 5 mg IV bolus over 2 minutes; the tachycardia is expected to revert in 5–10 minutes after the injection. If necessary, a second IV bolus of 5–10 mg may be given 30 minutes after the initial dose. Its disadvantage is that it has a negative inotropic effect; also, it is not as quick and as effective in its action as adenosine. There are four contraindications to the use of verapamil—

1. It should not be used in patients with heart failure or poor left ventricular function.
2. It should not be used for broad complex tachycardias.
3. It is contraindicated if oral or IV beta blockers have already been given.
4. It should not be used in patients with atrial fibrillation associated pre-excitation syndrome, as it could result in accelerated induction over the accessory pathway, resulting in a very rapid ventricular response or even in VF.

Diltiazem

Diltiazem could be used in place of verapamil. Its negative inotropic effect is less marked, but it has a lower effective rate for termination of tachycardias compared to verapamil. The drug has the same contraindications as verapamil. The drug is administered in a dose of 0.25 mg/kg over 2 minutes. If there is no response, an additional 0.35 mg/kg is given after 15–30 minutes followed by a 5–15 mg/hour infusion for rate control.

Beta Blockers

Esmolol is the quickest acting beta blocker and allows rapid dose titration to desired effect. The dose is 500 µg/kg IV over 1 minute. It is then infused at a rate of 50 µg/kg per minute. The rate is increased by 25 µg every 5 minutes, if necessary, to a maximum of 200 µg/kg per minute. The side effects are hypotension, bradycardia and even heart block. There could be deterioration of ventricular function in patients with organic heart disease.

Metoprolol is a more readily available beta blocker. It is given in an intravenous dose of 5 mg over 2 minutes. Repeat doses of 5 mg may be given if necessary every 10–15 minutes till a maximum dose of 15 mg.

It is important to note that excessive bradycardia caused by the AV node blocking agents should be countered by the use of 0.6 mg IV atropine. This can be repeated if necessary.

The above mentioned drugs are highly effective in terminating AV nodal re-entry and AV re-entry tachycardia. If for some reason, drugs are either contraindicated or ineffective, one could try amiodarone as a 300 mg IV infusion over 30 minutes (in a 60 kg individual) followed by a 24-hour IV infusion (700–800 mg).

Digoxin (at one time in use) is now no longer used. It is poorly effective and may facilitate conduction over an accessory pathway and promote atrial fibrillation.

Atrial Pacing

In patients with implantable devices, overdrive-pacing facilities can be used to terminate the arrhythmia. However, there is also a risk of inducing atrial fibrillation with a rapid ventricular response in a patient with an antegradely conducting accessory pathway.

Long-term Management

Atrioventricular nodal re-entry tachycardia and AV re-entry tachycardia should be referred to a cardiologist for electrophysiologic evaluation and non-pharmacological alternatives, including ablation of an accessory pathway, which is widely available.

ATRIAL FLUTTER

This is a common tachyrhythm in the ICU particularly in patients with severe chronic airways obstruction and ischemic heart disease. It is also an important problem following major surgery, particularly coronary artery bypass surgery.

Mechanism

The classification of atrial flutter is dependent on the underlying electrophysiological mechanism and ECG presentation. The reader is referred to a textbook on cardiology for the different atrial flutter circuits and their electrophysiological mechanisms.

Typical, or isthmus-dependent atrial flutter involves a macroreentrant right atrial circuit, the wave front descending along the right atrial wall, between the tricuspid annulus and the inferior vena cava, and then ascending up the interatrial septum, giving rise to the most frequent pattern, named *counterclockwise flutter*. When re-entry can also occur in the opposite direction, it is termed clockwise or reverse flutter.

Electrocardiographic Presentations

The flutter waves beat at 250–350 beats per minute leading to a AV block of 2:1 or occasionally 4:1. A changing or varying block leads to an irregular ventricular rhythm. A 2:1 AV block generally causes a regular ventricular rhythm at 150 beats

per minute. Any regular fixed ventricular rate of 150 beats per minute should arouse prompt suspicion of an underlying atrial flutter, even if the flutter waves are not clearly discernible. In the most frequently observed counter clockwise atrial flutter, the typical saw-tooth flutter F-waves are negative in lead II, II, aVF and V_5, V_6 and positive in leads V_1 and V_2. Clockwise atrial flutter has positive F-waves in lead II, III, aVF and negative waves in V_1 and V_2.

Atrial flutter associated with a very fast ventricular rate as in a 1:1 conduction can produce serious hemodynamic instability and even collapse, particularly in patients with underlying organic heart disease.

ATRIAL FIBRILLATION[3]

Atrial fibrillation is characterized by rapid fibrillatory F-waves that vary in size and configuration. The response depends on the rate and irregularity of atrial activity, the refractory properties of the AV node and the prevailing sympathetic and parasympathetic tone. Many atrial impulses are blocked at the AV node, but the ventricular responses are irregularly irregular unless there is a complete AV block.

Adverse Effects of Atrial Fibrillation

The loss of effective atrial contraction in atrial fibrillation together with the decrease in diastolic filling time of the ventricles due to a fast and irregularly irregular ventricular rate impairs cardiac filling. The normal atrial kick (contraction) is responsible for 25% of the end-diastolic ventricular volume (preload). When this is lost as in atrial fibrillation, cardiac performance is hampered, particularly in patients with a noncompliant left ventricle as also in patients with ventricular systolic dysfunction. Left atrial pressures rise, followed by a rise of pressure in the pulmonary circuit causing pulmonary edema. Right-sided pressures also rise causing engorged neck veins, enlarged tender liver and pitting edema of the feet.

The other important adverse consequence of atrial fibrillation (and also of atrial flutter though perhaps to a lesser extent) is the danger of the formation of mural thrombi in the atria. This could lead to either systemic embolization (if the mural clot is in the left atrium) or pulmonary embolism (if the mural thrombus is in the right atrium).

Clinical Classification

Clinical classification of atrial fibrillation is as under—

1. First detected, paroxysmal (up to 7 days).
2. Persistent (more than 7 days).
3. Long standing persistent (>1 year).
4. Permanent.

It is important to bear this classification in mind as it helps decide between rhythm restoration and rate control. First onset atrial fibrillation (<48 hours onset) is best treated by restoration to sinus control. However, episodes of atrial fibrillation may be asymptomatic so that the first episode detected by the physician need not necessarily be the actual first. Perhaps, it would be safer to opt for rate control and anticoagulation when doubt exists on this score.

Persistent or permanent atrial fibrillation should be treated by rate control and anticoagulation.

MANAGEMENT[3]

The management is the same for atrial flutter and fibrillation.

Objectives

1. Cardioversion to sinus rhythm either through a DC cardioversion or through pharmacological (through the use of drugs) cardioversion provided indications for either one or the other are met.
2. Rate control. The ventricular rate is reduced through the use of appropriate drugs to less than 100 beats per minute preferably close to 80 beats per minute. In atrial fibrillation, this invariably abolishes the apex-pulse deficit.
3. Anticoagulation to prevent thromboembolism.
4. In critically ill patients, causes outside the heart may precipitate atrial fibrillation. These include hypoxia, pH, fluid and electrolyte abnormalities, pulmonary embolism and thyrotoxicosis. Unsuspected cardiac causes include mitral valve disease, a recent silent myocardial infarct or myocardial ischemia and pericardial disease. A quick but careful evaluation should unearth and help treat these underlying precipitating or causative factors.

Emergency Management

Patients with atrial flutter or atrial fibrillation with fast ventricular rate, who are in hemodynamic collapse or on the verge of hemodynamic collapse, need emergency electrical cardioversion.

Direct Current Cardioversion

Atrial flutter can generally be converted with a synchronized DC shock energy as low as 50 J. Many prefer to use 100 J as it is invariably successful in cardioversion.

In recent onset atrial fibrillation, sinus rhythm can be restored by a DC shock 100 J, though here again many could prefer to start with an initial energy level of 200 J or greater. Patients with chronic obstructive lung disease or obese individuals may require a higher setting at 300–350 J.

Direct current cardioversion is a painful procedure, so that premedication with midazolam or fentanyl is indicated. Each shock should be synchronized with the R-wave of the QRS complex to prevent electrical stimulation in the vulnerable phase of ventricular repolarization, which usually coincide with peak of the T-wave.

Rate Control

Rate control is important and relevant for all atrial tachyarrhythmias, particularly if restoration of sinus rhythms is not desirable or is deferred.

Intravenous diltiazem, verapamil, beta blockers can control the ventricular response in atrial fibrillation with a fair degree of rapidity. The efficacy of rate control is however less marked in atrial flutter than in atrial fibrillation. There is a 20–30% decrease in the ventricular rate, 20–30 minutes to maximal effect, and 12–25% adverse reactions with each of the above drugs.

The use of beta blockers, like metoprolol or esmolol, for rate control is preferable and particularly useful in patients with recent myocardial infarction, in postoperative atrial fibrillation and when thyrotoxicosis is suspected to be the cause of the tachyarrhythmias.

Intravenous amiodarone[7] is also used for rate control; it also converts atrial fibrillation to sinus rhythm in some patients. It is often used as the drug of choice in critically ill patients with organic heart disease and in the postoperative period following cardiac or cardiothoracic surgery. Its advantage over the calcium antagonists and the beta blocker is that it has less of a negative inotropic effect on the heart.

Digoxin given intravenously used to be the treatment of choice for rate control in earlier years. It is no longer so because of the delayed onset of its therapeutic effect which reaches its peak as long as 4–6 hours after its administration. However, digoxin has a positive inotropic action, it may be safer to use in patients with poor ventricular function who have a moderately fast heart rate. Also, digoxin may convert atrial flutter to atrial fibrillation, in which control of the ventricular rate is easier to achieve.

Digoxin for rate control is given IV in a dose of 0.25 mg and repeated 6 hourly till a maximum dose of 0.75–1 mg is administrated.

Digoxin may not be effective in the control of a fast ventricular rate in the presence of high fever, acute infection and thyrotoxicosis. Digoxin is also ineffective and may produce a paradoxical increase in the ventricular rate when atrial fibrillation complicates the Wolff-Parkinson-White syndrome. Failure of digitalis to act or an increase in the ventricular rate after its use should therefore always suggest an underlying Wolff-Parkinson-White syndrome.

Pharmacological Conversion

If atrial fibrillation or flutter is hemodynamically stable and of recent onset, pharmacological conversion is often effective and should be attempted.

The only drug for pharmacological conversion easily available in India is amiodarone.[7] Amiodarone is preferably given through central line in a dose of 5 mg/kg over 30–60 minutes followed by infusion of 15–20 mg/kg for a total of 24 hours generally not exceeding a total of 1–1.2 g. The drug is given orally in a dose of 200 mg thrice daily from the next day, the IV infusion being stopped by the third or fourth day. A maintenance dose of 200 mg once or twice daily may be required to prevent a recurrence.

Pharmacological conversion of atrial fibrillation can perhaps be better accomplished (compared to amiodarone) with the IC class of antiarrhythmic drug—flecainide and propafenone[8] administered orally as a single dose of 300 mg and 600 mg respectively. The efficacy of these drugs for conversion to sinus rhythms is 60–80%. Both oral and IV routes of administration are equally effective; IV administration results in a quicker conversion to sinus rhythms. Both these IC drugs significantly slow the atrial rate to 300–350 beats per minute; this can result in a 1:1 AV conduction. Hence, calcium channel blockers (verapamil and diltiazem) or beta blockers which exert a blocking effect on AV nodal conduction should be used concomitantly with these IC drugs.

Class IC drug are ineffective for the conversion of atrial flutter to sinus. They may prolong the cycle length by slowing conduction, but they do not break the flutter circuit.

The class III agent ibutilide[9] is the drug of choice for terminating atrial flutter. It is administered in dose of 1–2 g intravenously over 10 minutes and has a success rate of 60%. Its adverse effects are a prolonged QT with a risk of torsades de pointes.[10] Higher doses of ibutilide—two successive IV infusions of 1 g are usually required to terminate atrial fibrillation. Ibutilide can achieve conversion to sinus rhythms in patients who persist with atrial fibrillation or flutter for as long as 30 days. The success rate of conversion in these circumstances drops to 20–30%.

Neither the class IC nor the class III agent ibutilide are easily available in our country. Table 1 lists the drugs, their dosages and their adverse effects.

Atrial Pacing

Over drive pacing can terminate atrial flutter in the majority of cases. It is particularly feasible after cardiac surgery when patients have already epicardial pacing wires in place or in patients with dual chamber pacemakers and defibrillators. Overdrive pacing may however at times induce atrial fibrillation. This is usually short-lived and is generally followed by sinus rhythm.

Anticoagulation

Anticoagulation is mandatory if atrial flutter or fibrillation persists for more than 24–48 hours or if the duration is unknown. The danger of thromboembolic complications is equal in both flutter and fibrillation. In patients who are hemodynamically stable with either atrial flutter or fibrillation of more than 48 hours duration, rate control and 3 weeks anticoagulation with warfarin (INR 2–2.5) are necessary before intervention by DC conversion or pharmacological conversion is attempted.[11]

If for any reason cardioversion cannot be deferred, transesophageal echocardiography[12] should be done for the presence of thrombi in the atria or ventricles; short-term anticoagulation with low molecular weight heparin is reported to be both safe and effective.

Post-cardioversion anticoagulation should be given if atrial fibrillation has been present for 48 hours or more or if thromboembolic risk factors are present (Table 2 and Flowchart 1).[11,13]

Table 1: Antiarrhythmic drugs for pharmacologic conversion of atrial tachyarrhythmias (flutter, fibrillation)

Drug	*Route of administration*	*Dose*	*Potential adverse effects*
Flecainide	Oral or intravenous	Loading oral dose 200–300 mg or slow injection 1.5–2 mg/kg over 10–20 min; if no response, infusion 1.5 mg/kg for 1 h, then 0.1–0.25 mg/kg over 24 h	Rapidly conducted atrial flutter, possible deterioration of ventricular function in the presence of organic heart disease, monomorphic ventricular tachycardia
Propafenone	Oral or intravenous	Loading oral dose 450–600 mg or 1.5–2 mg/kg IV over 10–20 min, followed by infusion 5–10 mg/kg if needed	
Ibutilide	Intravenous	1 mg over 10 min; if no response, additional 1 mg	QT prolongation, torsades de pointes, hypotension
Amiodarone	Intravenous (preferably central line)	5–7 mg/kg over 30–60 min, followed by infusion 20 mg/kg for 24 h (total 1,200–1,800 mg)	Hypotension, bradycardia, QT prolongation, torsades de pointes (?), gastrointestinal upset, constipation, phlebitis
Procainamide	Intravenous	100 mg IV every 5 minutes until the cardiac dysrhythmia is controlled or the total dose reaches about 15 mg/kg	QRS widening, torsades de pointes, rapid atrial flutter

Table 2: Risk stratification and indications for anticoagulation in atrial fibrillation and flutter

Risk of stroke	*Definition*	*Therapy*
Low (1%/yr)	Age <65 yr; ejection fraction ≥0.50; no stroke or transient ischemic attack, hypertension, heart failure, or valvular heart disease	Aspirin 325 mg
Low to moderate (1.5%/yr)	Age 65–75 yr; no risk factors	Aspirin 325 mg
Moderate to high (2.5%/yr)	Age 65–75 yr and either diabetes or coronary heart disease	Warfarin (INR 2.0–3.0)
High (6%/yr)	Age <75 yr and hypertension, heart failure, or ejection fraction <0.50	Warfarin (INR 2.0–3.0)
	Age >75 yr, particularly women, even in the absence of risk factors	
Very high (10%/yr)	Age >75 yr and hypertension, heart failure, or ejection fraction <0.50	Warfarin (INR 2.0–3.0)
	Any age with a history of stroke or transient ischemic attack or valvular heart disease	

Abbreviation: INR, International Normalization Ratio.

ACCELERATED ATRIOVENTRICULAR (NODAL) RHYTHM

Nodal or Junctional tachycardia is caused by abnormal automaticity in the AV node. The QRS complex due to ventricular depolarization is narrow with the ventricular rate ranging between 80 and 250 beats per minute. There is AV dissociation because the atria continue to be activated by the sinus node while the ventricles are activated by the ectopic junctional site. The commonest cause of this abnormal rhythm is digitalis toxicity. Normal rhythm is restored if digitalis is withdrawn. If the rate of impulse formation within the AV node is not too fast, atropine administered intravenously increases the discharge rate from the sinus node and allows it to take charge of the normal impulse formation and conduction of the cardiac impulse. AV junctional tachycardia is also a feature of the sick sinus syndrome, which may well need to be countered by the insertion of a dual chamber pacemaker.

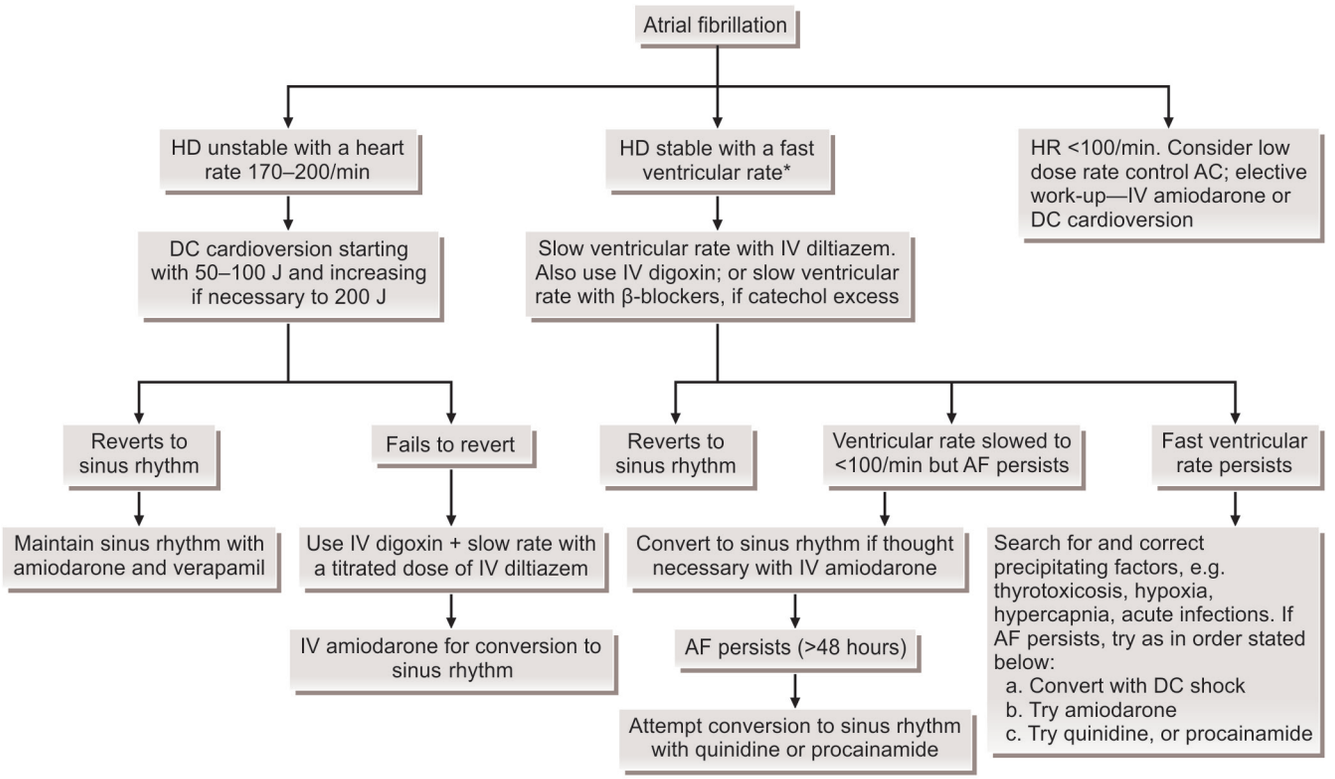
ATRIAL TACHYCARDIA

Paroxysmal atrial tachycardia is generally due to enhanced automatic activity within the atrial ectopic focus discharging regularly at 120–250 beats per minute. Generally, the rate is below 200 beat per minute. Paroxysmal atrial tachycardia can also be due to triggered activity or intra-atrial re-entry.

Electrocardiographic Pattern

The P-waves precede the narrow QRS complex and the PR interval is longer than observed in normal sinus rhythm, the P-wave morphology being different from that observed in sinus rhythm. The P-wave morphology depends on the site of origin of the atrial ectopic focus. When the ectopic focus is within the left atrium, the P-waves are negative in lead I, avL, V_5, V_6.

Flowchart 1: Algorithm for the management of atrial fibrillation



Atrial fibrillation
HD unstable with a heart rate 170–200/min
HD stable with a fast ventricular rate*
HR <100/min. Consider low dose rate control AC; elective work-up—IV amiodarone or DC cardioversion
DC cardioversion starting with 50–100 J and increasing if necessary to 200 J
Slow ventricular rate with IV diltiazem. Also use IV digoxin; or slow ventricular rate with β-blockers, if catechol excess
Reverts to sinus rhythm
Fails to revert
Reverts to sinus rhythm
Ventricular rate slowed to <100/min but AF persists
Fast ventricular rate persists
Maintain sinus rhythm with amiodarone and verapamil
Use IV digoxin + slow rate with a titrated dose of IV diltiazem
Convert to sinus rhythm if thought necessary with IV amiodarone
Search for and correct precipitating factors, e.g. thyrotoxicosis, hypoxia, hypercapnia, acute infections. If AF persists, try as in order stated below:
a. Convert with DC shock
b. Try amiodarone
c. Try quinidine, or procainamide
IV amiodarone for conversion to sinus rhythm
AF persists (>48 hours)
Attempt conversion to sinus rhythm with quinidine or procainamide

*Many units use IV amiodarone in a bolus dose of 300 mg followed by an infusion of 750 mg as the first choice in preference to IV diltiazem and digoxin.

Acute Management

Patients in whom atrial tachycardia is associated with a high ventricular rate (>200 beats per minute) may show hemodynamic stress or even failure particularly if they are old or have underlying heart disease. DC cardioversion converts atrial tachycardia to sinus rhythm, if the tachycardia is based on triggered activity or on re-entry mechanism. However, it may not terminate automatic tachycardias. Atrial overdrive pacing may slow the rate, but generally does not suppress the automatic ectopic focus.

Verapamil and beta blockers can either terminate the tachycardia or can produce good rate control. Quinidine 0.4 g every 2 hours for 3–4 doses is also effective in conversion to sinus control, but unfortunately, this drug is no longer available.

Flecainide, sotalol and amiodarone are also effective in converting to sinus rhythm.

ATRIAL TACHYCARDIA WITH ATRIOVENTRICULAR BLOCK

Atrial tachycardia with an atrioventricular block is classically due to digitalis toxicity. It may however also occur in patients with organic heart disease.

If atrial tachycardia with a 2:1 block is due to digitalis toxicity, the drug is stopped. Potassium should be administered in a slow 5% dextrose infusion.

MULTIFOCAL ATRIAL TACHYCARDIA

This is an irregularly irregular rhythm caused by a rapid irregular atrial activity with P-waves of varying morphology and varying PR intervals. It is typically observed in chronic obstructive pulmonary disease particularly when there has been an overuse of theophylline and β_2 agonists.[14,15]

Management

1. Theophylline is discontinued. This in itself can restore sinus rhythm in some patients.[15]
2. Intravenous magnesium sulfate may prove effective. The protocol suggested is 2 g magnesium sulfate in 50 mL saline over 15 minutes followed by 6 g of magnesium sulfate in 500 mL saline over 6 hours.[16] In one study, use of the above protocol led to conversion of multifocal atrial tachycardia to sinus rhythm in close to 90% of patients. The mechanism of action is unknown.
3. Correct hypomagnesemia and hypokalemia if they exist. Hypomagnesemia must be corrected before hypokalemia.

4. Intravenous verapamil in a dose of 100 μg/kg IV either slows the tachycardia, exerting rate control or converts to sinus rhythm in 50% of cases.[17] Metoprolol in a dose of 5 mg IV repeated if necessary at 5 minute interval to a maximum of 15 mg is also effective in converting multifocal atrial tachycardia to sinus rhythm. Metoprolol is however best avoided in patients with COPD where unfortunately this rhythm disturbance is most frequently observed.

WIDE COMPLEX (QRS >0.12 S) TACHYARRHYTHMIAS

These chiefly include VT and torsade de pointes, which in fact is an unusual or peculiar form of polymorphic VT. SVTs with delayed or aberrant conduction can also produce wide QRS complexes (>0.12 s), which are difficult to distinguish from VTs. As a matter of principle, it should be remembered that VT probably causes more than 95% of wide complex tachycardias in patients who have underlying cardiac disease. Therefore, in an ICU setting a wide QRS complex should be taken as VT unless proved otherwise.

There are a number of ECG features which help to distinguish VT from SVT with delayed or aberrant conduction, and these are tabled in Table 3.

The features of note are as follows—
In a long-rhythm strip, the presence of fusion beats, capture beats, and/or AV dissociation in a wide QRS tachycardia, point to a VT.

In a 12-lead ECG, VT is more likely if: (1) in the presence of a right bundle branch block pattern, the pattern in V_1 is monophasic. If it is biphasic, then R is taller than r'; small r and large S-waves or a QS pattern is present in V_6; (2) in the presence of a left bundle branch block pattern, the axis is to the right, the QRS is wider than 0.16 seconds, and V_6 shows a small q and a low amplitude R-wave, or a QS pattern; (3) QRS complexes are similar in V_1–V_6, either all positive or all negative.

Table 3: Differentiating features between ventricular tachycardia and supraventricular tachycardia (SVT) with delayed or aberrant conduction

SVT with delayed or aberrant conduction	*Ventricular tachycardia*
Slowing or termination by increase in vagal tone	Fusion beats present Capture beats present
Premature P-waves present at onset	Atrioventricular dissociation present QRS duration >140 ms
PR interval <100 ms	Left axis deviation often present
QRS duration usually <120 ms	QRS complexes: specific QRS patterns often seen in precordial leads (see text)
P and QRS rate and rhythm often linked to suggest that ventricular activation depends on atrial discharge QRS complexes: rSR' frequently seen in V_1	

VENTRICULAR TACHYCARDIA

Incidence in the Critical Care Setting

A multicenter study[18] involving over 1,341 patients in 26 ICUs over a month revealed that 12% had episodes of sustained arrhythmias—8% with supraventricular arrhythmias, 2% with ventricular arrhythmias and 2% with conduction abnormalities. The in-hospital mortality was 29% in patients with arrhythmias and 17% in those without arrhythmias. A detailed analysis revealed that only ventricular arrhythmias were associated with increased mortality. Supraventricular arrhythmias and conduction abnormalities were instead markers of severity of illness and did not independently contribute to the risk of death.

Diagnosis

Ventricular tachycardia is a dangerous tachyarrhythmia characterized by a series of three or more ventricular ectopic impulses (wide QRS complexes) at a rate of 100 or more beats per minute. *Accelerated ventricular rhythm* is defined as a ventricular rhythm occurring at 50–100 beats per minute. Identifying the rhythm is important. Accelerated ventricular rhythm usually indicates ischemic heart disease and antiarrhythmic treatment for this rhythm disturbance is not necessary. VT can be brief, subsiding within 30 seconds (non-sustained VT), or it can last for longer periods (>30 s) of time (sustained VT). The most frequent and the most likely cause of VT is myocardial ischemia or a recent myocardial infarction. Other organic heart diseases complicated by VT include aortic valve disease, cardiomyopathies and VT following coronary artery bypass surgery, particularly after aneurysmectomy or aneurysmorrhaphy of a ventricular aneurysm.

Ventricular Fibrillation

Ventricular fibrillation is characterized by irregular wave forms of varying duration, contour, amplitude without identifiable QRS and T-waves. VF (and pulseless VT) are akin to cardiac arrest and cause unconsciousness within seconds. Generalized seizures, and agonal breathing follow; death occurs unless promptly diagnosed and treated.

In an ICU setting, VT can also occur in the absence of serious organic heart disease. It is important to look for potentially reversible factors, which may initiate or perpetuate serious ventricular arrhythmias. Important reversible conditions causing sustained VT have been listed in Box 1.

These factors include hypoxia, hypercapnia, hypoglycemia, hypokalemia, hypomagnesemia, hypocalcemia, excessive use of inotropes (catecholamines) or excessive endogenous catecholamine production, hyperthyroidism, drug toxicity

Box 1: Potentially reversible causes of ventricular tachycardia

- Ischemic heart disease
- Hypoxia/hypercapnia
- Acidosis
- Electrolyte abnormalities—Hypokalemia, hypocalcemia, hypomagnesemia
- Hyperthyroidism
- Excess of circulating catecholamines—Endogenous/exogenous
- Drug toxicity—particularly digitalis
- Presence of intracardiac catheters

(commonly produced by antiarrhythmic drugs), digitalis toxicity and the presence of intracardiac catheters.

The initial workup should therefore include measurements of serum electrolytes, calcium, magnesium, arterial pH, blood gas analysis and cardiac enzymes. If the patient has an indwelling catheter, e.g. a Swan-Ganz catheter or a central venous line, it is important to check with an X-ray that it does not lie within the right ventricle.

Management of Ventricular Tachycardia

Premature ventricular contractions (PVCs) and episodes of non-sustained VT have no immediate hemodynamic significance. Management consists of a proper assessment, identification and removal of factors that may contribute to these episodes. The risk of evolving into sustained VT increases if PVCs are very frequent, occur in pairs or triplets, or exhibit the R on T phenomenon, particularly when this is observed in the ICU, against a background of ongoing myocardial ischemia, myocardial infarct or in patients with poor left ventricular function. Under these circumstances, and more so if frequent PVCs and ill-sustained episodes of VT appear to precipitate angina or hemodynamic instabilities, IV 150–300 mg of amiodarone given over 20 minutes, followed by an infusion of 750 mg amiodarone over 24 hours may well be justified. Oral amiodarone 200 mg TDS is started so as to overlap the IV infusion. Patients with on-going ischemia or a recent infarct are often hyperadrenergic. Besides attending to reperfusion, beta blockers given orally may also control frequent PVCs or frequent episodes of non-sustained VT. In general, however, non-sustained VT occurring in asymptomatic patients without underlying heart disease require no specific therapy.

Management of Sustained Ventricular Tachycardia

Patients in severe hemodynamic failure and collapse characterized by marked hypotension, or acute heart failure, or patients who have pulseless VT, polymorphic VT, and VF should promptly receive unsynchronized electric shocks and advanced cardiac life support.

Direct current unsynchronized cardioversion should be given with an initial shock of 100 J followed by repetitive shocks of 200, 300 and 360 J if necessary. These critically ill patients would almost certainly die if not for prompt cardioversion and advanced cardiac life support (see Chapter Cardiopulmonary Resuscitation and Cerebral Preservation in Adults).

- Any patient with a wide QRS complex tachycardia, who shows evidence of hemodynamic instability, should also be converted by DC cardioversion. One does not want a hemodynamic collapse in these patients before using cardioversion, which is considered the most effective form of therapy, to revert VT to sinus rhythm. IV midazolam or fentanyl need to be used as premedications.
- In patients with monomorphic VT who are hemodynamically stable, the intensivist needs to—
  - Identify as far as possible arrhythmogenic factors that could trigger VT and sustain VT in a particular patient. The factors commonly present in critically ill patients are—
    - Acid base and electrolyte abnormality.
    - Hypoxia, hypercapnia, hemodynamic abnormalities.
    - Use of pro-arrhythmogenic drugs.
    - A prolonged QT interval.
    - Hyperadrenergic states. Use of inotropic drugs, like dopamine or dobutamine, which in some patients might induce VT even when not used in excess.
    - An underlying myocardial infarct or active myocardial ischemia.
    - Mechanical stimulation of the myocardium as by a central line within the right ventricle or a pulmonary artery catheter abutting against the wall of the right ventricle.

    Treatment of arrhythmogenic factors outlined above in itself can terminate an arrhythmogenic episode or at least prevent its recurrence. In particular, stress should be given to correction of electrolyte imbalance, treatment of myocardial ischemia, discontinuation of drugs that prolong the QT interval and reducing or omitting drugs, which increase adrenergic stimulation or have an inotropic action. Repositioning a central venous pressure line or a misplaced pulmonary artery catheter may well abort an attack or prevent its recurrence.
  - Decide on the method to revert the VT to sinus rhythm.

    Both DC synchronized cardioversion and the IV administration of antiarrhythmic drugs are equal first-line options. Antiarrhythmic drugs are generally preferred as anesthesia is not necessary and their antiarrhythmic effects persist after the reversion of VT to sinus rhythm.

    The antiarrhythmic drug of choice is amiodarone[19] given in a dose of 5 mg/kg IV over 20 minutes followed by an IV infusion of 750 mg to 1 g over the next 24 hours. An IV infusion of 500–750 mg given over the next 2 to 3 days may be necessary. Oral amiodarone

in a dose of 200 mg thrice daily is given as a preventive once the rhythm has reverted.

Amiodarone should also be administered to patients with sustained monomorphic VT who are refractory to conversion after electric shocks .

Lidocaine was the drug of choice for VT before the advent of amiodarone, which has by and large replaced lidocaine. However, even today in patients in whom stable monomorphic VT is associated specifically with unstable angina or myocardial infarction, lidocaine is considered by some authorities to be a reasonable initial choice.[20] Lidocaine is administered in a bolus of 75 mg; a bolus of 50 mg may be repeated if necessary after 5 minutes. This is followed by an IV infusion of the drug at 1–2 mg/hour for continued control. The drug is metabolized by the liver and is avoided in patients with liver cell dysfunction. Lidocaine toxicity chiefly involves the central nervous system—drowsiness, agitation, confusion, muscle twitching and generalized seizures may occur. These are chiefly observed in elderly people or when larger doses are being used. The drug can also cause bradycardia, hypotension and sinus arrest. Liver cell dysfunction may also occur.

The American College of Cardiology/American Heart Association/European Society of Cardiology (ACC/AHA/ESC) 2006 guidelines[21] for the management of ventricular arrhythmias recognize various drugs besides amiodarone and lidocaine. These drugs include procainamide, flecainide and propafenone. None of these drugs are easily available in our country and probably have no advantage over amiodarone and lidocaine. In Europe, IV procainamide is often used as the initial choice for patients with stable sustained monophasic VT. Procainamide when used is given at a rate of 20 mg/minute until the arrhythmia reverts or a total not exceeding 1,000 mg is administered. Hypotension and a prolonged QT are dangerous side effects. The prolonged QT can result in a drug induced VT. Hypotension may necessitate stoppage of the drug. The drug is contraindicated in patients with a prolonged QT interval. We have stopped using this drug for several years; also, the drug is not easily available in the country.

Whenever one uses amiodarone or lidocaine or any other antiarrhythmic drug, it is now felt that the addition of a second antiarrhythmogenic drug should be discouraged as the proarrhythmic effects of two drugs are compounded. Thus, if the use of the single agent in optimal doses fails to revert VT, it is best to proceed to DC synchronized electrical cardioversion rather than use a second drug. Monophasic wave form electric shocks at an initial energy level of 100 J are generally effective. Comparable energy levels may be effective when using biphasic wave form electric shocks.

- *Transvenous over-drive spacing* is also used for terminating monophasic VT if there is refractoriness to cardioversion or VT recurs despite the use of antiarrhythmic drugs.
- *Ventricular arrhythmias with cessation of effective blood flow.*

  As mentioned at the start, the patient should be immediately cardioverted using an unsynchronized DC shock—200 J from a defibrillator providing bi-wave form and 360 J if the defibrillator provides a monophasic wave form. Following shock delivery, the patient should receive prompt advanced cardiac life support according to the most recent guidelines for cardiopulmonary resuscitation and emergency cardiovascular care.[22] A 1-shock strategy followed by prompt chest compression is now recommended to minimize interruption in chest compression. The shock is repeated every 3–5 minutes if VT or VF persists (see Chapters Cardiopulmonary Resuscitation in Infants and Children, and Cardiopulmonary Resuscitation and Cerebral Preservation in Adults).

The following points are worthy of note—

- Survival after pulseless VT or VF is inversely related to the time elapsed between onset of arrhythmia and the delivery of electric shocks.[23] The survival rate is high when duration of untreated VF is less than 4 minutes.
- With more protracted untreated VF, evidence suggests that a period of closed chest resuscitation before attempting defibrillation could improve outcome.[24,25]
- For patients with shock, refractory or pulseless VT, use of amiodarone may well improve chances of restoration of cardiac activity.[26]

Electric storm is a highly lethal form of VT occurring chiefly during the course of myocardial infarction. Amiodarone, lidocaine, procainamide fail to secure a stable sinus rhythm. The VT also continues to recur again and again even after several DC shocks. The underlying mechanism seems to be related to excessive unbalanced sympathetic activity. It has been recently shown that sympathetic blockade, using IV beta blockers or stellate ganglion blockade is successful in restoring a stable sinus rhythm, thereby dramatically improving the outcome.[27]

TORSADE DE POINTES[28]

Torsade de pointes is a polymorphic VT characterized by wide QRS complexes that change in amplitude and appear to be twisting round the isoelectric line of the ECG—some complexes being above the isoelectric line and others below. This arrhythmia is associated with a prolonged QT, which may be congenital or acquired. The acquired form is caused by electrolyte disturbances and drugs. Drugs chiefly involved are psychotropic drugs, antiarrhythmic drugs, macrolides and quinolones. Electrolyte disorders that can cause torsade de pointes are hypokalemia, hypomagnesemia and hypocalcemia.

Polymorphic VT can also be associated with a normal QT—it is then not termed torsade de pointes but just called polymorphic VT.

Management

Management is guided by the QT interval.

$$QT_c = QT/\sqrt{RR}$$

Where, QT_c = corrected QT interval for rate
QT is the measured QT interval and √RR is the square root of the RR interval.

A prolonged QT_c is defined as a QT_c greater than 0.44 seconds.

Polymorphic VT with a normal QT interval responds to the standard antiarrhythmogenic agents like amiodarone and lidocaine.

Management in patients with a prolonged QT depends on whether the prolongation is congenital or acquired. If the QT prolongation is acquired the treatment is as follows—

- Administration of IV magnesium sulfate starting with 2 g IV over 1 minute, the dose being repeated 10 minutes later if needed.
- Correction of electrolyte abnormalities. It is to be noted that hypokalemia and hypocalcemia may be due to an underlying magnesium deficiency even if serum magnesium levels are normal. Magnesium replacement is therefore of critical importance in patients with hypokalemia and hypocalcemia.
- Discontinuation of drugs that prolong the QT interval.
- Overdrive pacing and the use of beta blockers after pacing.

If the QT prolongation is congenital, beta blockers and implantation of an internal cardioverter defibrillator device should be considered.

CHAPTER 24

Bradyrhythms and Heart Block in the ICU

INTRODUCTION

Bradyrhythms in the intensive care unit (ICU) may be harmless or may portend disaster. They are due to slowing of impulse formation, or a delay in impulse conduction through one or more areas of specialized conducting tissue that propagate the cardiac impulse. A bradyrhythm may be totally asymptomatic. Yet in patients with intrinsic heart disease or in ICU patients admitted for other serious problems, a marked fall in heart rate reduces the cardiac output. This is invariably so if the heart rate falls below 45 beats per minute. A fall in cardiac output is certain to cause a further deterioration in an already seriously ill patient. The rate should be corrected before such a deterioration is clinically observed. Symptomatic bradyrhythms, whatever the etiology, need immediate treatment.[1]

A bradyrhythm is defined as a cardiac rhythm slower than 60 beats per minute.

Bradyrhythms are divided into two major categories—

1. Disturbance in sinus impulse formation and conduction [sinus bradycardia, sinoatrial (SA) block, a Wenckebach block in the SA node, sinus arrest, the sick sinus syndrome].
2. Atrioventricular (AV) block. The term is applied to a delay in conduction in the AV node or in the infranodal conduction tissue. Delayed conduction in infranodal tissue is of far greater prognostic import compared to conduction delay within the AV node itself.

SINUS BRADYCARDIA

In the ICU, this condition is observed chiefly in the sick sinus syndrome or in ischemic heart disease, particularly after an acute inferior myocardial infarction. It can also occur in patients with no organic heart disease—chiefly due to increased intracranial tension, hypothyroidism, to hyperactive vagal reflexes and to drugs. An important example of increased vagal tone is in patients with tetanus. These patients, when undergoing a tracheal suction, may show marked bradycardia that may culminate in cardiac arrest. The above-mentioned problem is also occasionally observed in other critical illnesses. Numerous drugs can also produce sinus bradycardia (chiefly digitalis and beta-blockers).

The following problems can arise as a result of marked sinus bradycardia—

- *A low output state* This may occur suddenly or over a period of time. A slow rate can also produce faintness or syncope.
- *A potentiation of ventricular ectopics* The unfortunate use of antiarrhythmic drugs in an attempt to suppress these ectopics, further slows the heart. Greater ectopic activity is then often observed, and this may lead to ventricular tachycardia or fibrillation. On the other hand, increasing the ventricular rate may abolish ventricular ectopics.

SINOATRIAL BLOCK

A second degree SA block[2] is evident on the monitor or on a rhythm strip, as a long pause between two sinus impulses. A Wenckebach type of SA block is characterized by a progressive shortening of the PP intervals until a long pause occurs because of the blocked beat. A third degree SA block leads to atrial and ventricular standstill, and if this is sufficiently long, a nodal or ventricular escape rhythm is noticed. SA block occurs after excessive vagal stimulation, in inferior myocardial

infarction, acute myocarditis or as a side effect or a toxic effect of drugs like digitalis, propranolol and other antiarrhythmic drugs. It also occurs as part of a sick sinus syndrome, which may manifest as a bradyrhythm due to SA block or even an AV block. Bradytachyrhythms are also often observed with a sick sinus syndrome.

One of the most important causes of SA block (and later an AV block as well) in critically ill ICU patients is hyperkalemia. Hyperkalemia should always be thought of in a patient with a bradyrhythm. The P-waves are absent and the QRS complexes are slow and wide, followed by tall T-waves. A bundle branch block pattern (without preceding P-waves) is sometimes observed. The possibility of hyperkalemia is particularly important in patients with renal insufficiency, or in those on chronic dialysis, particularly if the patient is on ACE inhibitors.

MANAGEMENT

The following points should be noted—

- All drugs that slow the heart rate should be omitted.
- If the bradyrhythm in a critically ill patient falls well below 50 beats per minute, the rate should be increased by drugs. It does not matter whether the bradyrhythm is due to organic heart disease or occurs in other critical illnesses.
- If the bradyrhythm produces a low output state or if an SA block produces faintness or syncope, or is complicated by ventricular ectopics, the basic heart rate should be increased with atropine or isoprenaline, or if needs be, by transvenous cardiac pacing.

Atropine is administered slowly intravenously in a dose of 0.3–1 mg.

In an emergency, isoprenaline is given in an infusion of 1 mg in 500 mL dextrose. The infusion rate is initially kept at 1–4 µg per minute and is carefully increased till the desired effect on the heart rate is achieved. The patient should be carefully monitored for ectopics that may be induced by isoprenaline.

When a symptomatic bradyrhythm persists, or when it fails to respond to drugs, or when the use of drugs produces toxic effects (isoprenaline induced ventricular ectopics or tachycardia), transvenous pacing should be done. Many units would opt for transvenous pacing in symptomatic bradyrhythms or bradyrhythms which cause a low output state without taking recourse to drugs.

When severe persistent bradycardia occurs in acute inferior myocardial infarction and does not respond to atropine, a temporary transvenous pacing is the method of choice to increase the heart rate. Isoprenaline should be avoided in these circumstances, except as a temporary emergency measure; this drug increases myocardial oxygen consumption and thereby can cause an extension in the area of infarction.

If hyperkalemia is strongly suspected as the cause of a SA block, a blood sample is quickly sent for serum K^+ estimation. Between 10–20 mL of 10% calcium gluconate is given intravenously without waiting for the result. This is followed by a dextrose-insulin infusion as detailed in the Section Fluid and Electrolyte Disturbances in the Critically Ill.

ATRIOVENTRICULAR BLOCK

All forms of AV block[3] can be either nodal or infranodal. Infranodal blocks can be intra-Hisian or infra-Hisian and are far more dangerous than nodal blocks.

A first degree AV block is characterized by a prolonged PR interval. It needs no treatment,[4] except careful assessment whether drugs known to produce a first degree AV block can be reduced or omitted. Digitalis is the commonest cause of prolonged AV conduction. Other antiarrhythmic drugs can also do the same.

Second degree AV block of the Wenckebach type (the block in most cases is nodal and not infranodal) is characterized by progressive prolongation of the PR interval with a progressive shortening of the RR interval, till a P-wave is blocked at the AV node and does not produce a ventricular QRS complex. A Wenckebach type of AV block does not constitute a problem, except when it is a forerunner of a high grade block.[5] This is typically observed in some patients with acute inferior myocardial infarction.

A Mobitz type II AV block is of ominous significance as the site of the block is infranodal. It is associated with a sudden block of the P-wave occurring sporadically in an otherwise normal rhythm, or is characterized by a regular 2:1 or 3:1 block at the AV node. It often precedes a high grade or complete AV block and is at times a forerunner to sudden death.

The most important causes of second degree AV block are myocardial infarction, acute myocarditis and drugs—particularly digitalis, quinidine and procainamide.

Atropine may be used for a Wenckebach block. A Mobitz type II block needs prompt transvenous pacing to forestall a possible catastrophe.[4]

Complete or third degree AV block[2] is characterized by a very slow ventricular rate of close to 30 beats per minute, with a total dissociation between the atria and the ventricles. All impulses reaching the AV node are blocked, and the ventricles beat from a focus within the AV node, or from a focus below the AV node. AV dissociation with a ventricular rate greater than 40 beats per minute cannot be called a complete AV block, though a high-grade AV block obviously exists in these patients. Complete or third degree AV block in an ICU setting is observed in acute myocardial infarction, or in drug toxicity, chiefly digitalis toxicity. Most antiarrhythmic drugs used to treat tachyrhythms can also produce a complete AV block as a toxic effect.

Patients with Leriche's disease or Lev's disease, which is characterized by fibrosis of the infranodal conducting tissue, may also find admission to the ICU due to syncopal spells, or to Stokes-Adams attacks occurring against a background of complete AV block. Rarely, acute myocarditis or calcific aortic stenosis may also be associated with a complete AV block.

Hyperkalemia induces both SA block and AV block; the former invariably precedes the latter. Hyperkalemia (serum K^+

>6.5–7 mEq/L) also prolongs the intraventicular conduction, causing slow wide complexes.

Complete AV block with a slow ventricular rate needs emergency transvenous pacing in the ICU.[4]

Complete or high-grade AV block in relation to acute myocardial infarction Acute inferior myocardial infarction often results in a Wenckebach block followed by a high grade, and rarely by a complete AV block. Transvenous pacing should be done for high-grade AV blocks. The block almost always resolves within 7–12 days,[6] with a return to sinus rhythm, when the pacing catheter is withdrawn.

Complete AV block in the presence of acute anterior myocardial infarction is of grave prognostic significance, and carries a high mortality (70–80%).[7] This is because in all such instances there is extensive damage of the anterior wall, the septum and the lateral wall, with ischemic destruction of conducting tissue below the AV node. This may include the bundle of His, the branches of the bundle of His, and the Purkinje conducting fibers as well. As the block is infranodal, ventricular escape rhythms are much slower and more unstable than in patients with heart block due to acute inferior myocardial infarction where the high grade or complete AV block is nodal. The block in acute anterior myocardial infarction is often associated with pump failure, not only because of the marked bradyrhythm, but also because of the extensive myocardial damage. Complete AV block in these patients might occur suddenly, or might be preceded by various combinations of blocks in the branches of the bundle of His. These blocks include: (1) a right bundle branch block with a block in the anterosuperior division of the left bundle branch; (2) a right bundle branch block with a block in the posteroinferior division of the left bundle branch; (3) a left or right bundle branch block pattern; (4) a bilateral bundle branch block, characterized either by a left or right bundle branch block pattern on the electrocardiogram (ECG), with a significantly prolonged PR interval; (5) a trifascicular block which causes an ECG pattern of a bifascicular block with a prolonged PR interval.

Complete AV block needs prompt transvenous pacing. There is a considerable difference of opinion as to which other combinations of blocks involving the bundle of His, need to be paced in acute anterior myocardial infarction. We generally prophylactically pace patients with a bilateral bundle branch block or a trifascicular block. We do not pace those with a right bundle block together with a block in the anterosuperior division of the left bundle branch. We generally pace patients with a right bundle branch block together with a block in the posteroinferior division of the left bundle branch. We do not generally pace a patient who develops an isolated right or left bundle branch block. There are, however, a number of units who would prophylactically pace all or most of these combinations of heart blocks in the His bundle conducting system that have been listed above.

CHAPTER 25

Antiarrhythmic Drugs Used in the ICU

GENERAL CONSIDERATIONS

It is important to be familiar with antiarrhythmic drugs used in the acute or emergency management of arrhythmias in the intensive care unit (ICU). Antiarrhythmic drugs are double-edged weapons—they can effectively reverse an arrhythmia and salvage a potentially dangerous situation. At the same time, they can themselves produce side effects which could be cardiac or noncardiac. Remarkably enough, cardiac side effects include heart failure and induction of arrhythmias. In other words, antiarrhythmic agents could well produce the very problem that they are supposed to eradicate or suppress. Drug induced or drug aggravated cardiac arrhythmias (bioarrhythmias) are a major clinical problem. In one study, proarrhythmic events occurred in 6.9% of 506 consecutive patients and in 3.4% of 1,268 drug trials for ventricular tachycardia (VT) and ventricular fibrillation (VF).[1] Factors predisposing to such proarrhythmias include the presence of left ventricular (LV) dysfunction, treatment with digitalis and diuretics, and a longer pretreatment QT interval.[2] Antiarrhythmic drugs are therefore of help, but need to be used with caution. As a matter of principle, it is wise not to use multiple antiarrhythmic drugs simultaneously. If more than one antiarrhythmic drug is being used, possible pharmacokinetic interactions between various drugs should be noted (Table 1). It is also important to constantly bear in mind whether an arrhythmia one is treating may not have been actually caused or potentiated by the very drugs used to treat it. Finally, arrhythmias can be precipitated by factors such as hypoxia, hypercapnia, electrolyte and acid-base disturbances. Correction of these factors can restore sinus rhythm and is far more important than the use of antiarrhythmic drugs. In the past, antiarrhythmic drugs were the mainstay in the treatment of arrhythmias. Surgical procedures have now been developed for the treatment of the Wolff-Parkinson-White (WPW) syndrome, supraventricular, ventricular tachyarrhythmias and more recently even for atrial fibrillation. The ability to use catheter devices to deliver radiofrequency energy to circumscribed lesions that can destroy focal areas of arrhythmogenesis (idiopathic VT) or to limbs of macroreentrant (AV nodal reentral tachycardia, AV reciprocatory tachycardia, atrial flutter) or to microreentrant tachycardia (ischemic VT) has revolutionized the management of arrhythmias. Radiofrequency catheter ablation is now the treatment of choice for many of these arrhythmias provided the necessary experience and expertise is available.

For patients who have experienced potentially lethal ventricular arrhythmias, implantable cardioverter defibrillators (ICD) were introduced in the 1980s. In the Antiarrhythmics versus Implantable Defibrillators (AVID)[3] and Cardiac Arrest Study Hamburg (CASH)[4] trials, it was shown that, when compared with amiodarone, survivors of cardiac arrest who had ICDs had a lower incidence of cardiovascular and total mortality.

Table 1: Pharmacokinetic interactions of a few antiarrhythmic drugs

Drugs	*Clearance*
Quinidine	Increased by phenytoin, phenobarbital, rifampicin Decreased by cimetidine, amiodarone
Lidocaine	Decreased by cimetidine, propranolol
Digoxin	Decreased by quinidine, verapamil, amiodarone; Volume of distribution decreased by quinidine
Disopyramide	Increased by phenytoin, phenobarbital, rifampicin
Procainamide	Decreased by cimetidine, amiodarone

Antiarrhythmic drugs today are therefore used only to reduce the frequency of shocks delivered by ICDs in survivors of cardiac arrest or in patients at risk for cardiac arrest. Nevertheless, antiarrhythmic drugs are important for two reasons—(1) Comparatively, few centers in developing countries have units with the experience and expertise to employ methods detailed above; (2) in a critical care setting, antiarrhythmic drugs still play an extremely important role and the intensivist must be familiar with their use.

CLASSIFICATION OF ANTIARRHYTHMIC AGENTS[5]

The most frequently used classification of antiarrhythmic agents is the Vaughan-Williams classification. This classification is as follows—

Class I agents are sodium channel blockers.
Class II agents are beta blockers.
Class III agents are potassium channel blockers.
Class IV agents are calcium channel blockers.

The class I agents are classified into class Ia (sodium and potassium channel blockage; kinetics of onset and offset of sodium channel blockers are intermediate in rapidity). This class includes quinidine, procainamide and dispopyramide. These drugs slow the rate of rise of phase 0, lengthen the refractory period and the width of the monophasic action potential. The class Ib agents are pure sodium channel blockers. They do not slow the rate of rise of phase 0 of the monophasic action potential (MAP) and shorten the MAP duration; the onset and offset of sodium channel blockade are rapid. This class includes lidocaine, mexiletine and tocainide. The class Ic agents are strong sodium channel blockers with slow onset and offset kinetics. This class comprises of flecainide and propafenone.

The class III agents are drugs that block the potassium channels as their chief antiarrhythmic effect. The class includes sotalol, dofetilide, ibutilide, amiodarone and bretylium. Class IV are calcium channel blockers and include diltiazam and verapamil.

Vaughan-Williams classification is simple and easy to use but has one major drawback. This drawback is that the major effect of an agent or drug from one group overlaps with the effect produced by agents from other groups. To give an example, quinidine which is classified as Vaughan-Williams Group I antiarrhythmic agent (sodium channel blockade), also blocks the potassium channel (class III) and may lead to torsade de pointes, a dangerous side effect. To give another example, amiodarone which is classified as a class III antiarrhythmic agent has sodium channel blocking (class I), beta blocking (class II) and potassium channel blocking (class III) properties.

This chapter does not propose to give an account of all old and new antiarrhythmic drugs. It deals with important commonly used antiarrhythmic agents in the ICU. It is important to be perfectly familiar with a few important drugs and use them skillfully rather than grapple with a host of drugs. Table 2 lists the commonly used antiarrhythmic drugs with their dosages and major side effects.

Table 2: Indications, doses, and main adverse effects of some antiarrhythmic drugs commonly used in the ICU

Drug	*Indications*	*Adverse effects*	*Loading dose*	*Maintenance dose*	*Special remarks*
Lidocaine	Emergency treatment of VT of any etiology, especially in AMI and after open heart surgery	CNS-dizziness, seizures, confusion, coma, sinus node depression, aggravates LV dysfunction, myocardial depression and hypotension	1–2 mg/kg IV bolus, repeat 1/2 dose in 30 minutes	1–2 mg/min infusion	–
Mexiletine	Treatment of VT when lidocaine ineffective	Dizziness, nystagmus, confusion, vomiting; CVS–bradycardia, hypotension, worsening of arrhythmia	100–150 mg, IV bolus	2–4 mg/min infusion for first 3 hrs, then 0.5 mg/min; later 200 mg, 8 hourly, orally	–
Quinidine	SVT, VT, ventricular ectopics	Nausea, vomiting, diarrhea; CNS–tinnitus, hearing loss, visual disturbances hemolytic anemia, thrombocytopenia; CVS—various blocks, torsade de pointes, myocardial depression	400 mg 2 hourly for 4–5 doses orally	200 mg 6 hourly orally	Elevated serum digoxin levels
Procainamide	Treatment of VT when lidocaine ineffective; treatment of atrial flutter/fibrillation after AV conduction is blocked/slowed	Hypotension, various heart blocks, VT and myocardial depression	25–50 mg IV over 1 minute, repeated every 5 minutes to max of 1,000 mg	2–6 mg/min infusion	Contraindicated in torsade de pointes where QT prolonged

Contd...

Contd...

Drug	*Indications*	*Adverse effects*	*Loading dose*	*Maintenance dose*	*Special remarks*
Amiodarone	VT or SVT refractory to conventional drugs	Hypotension, worsens ventricular arrhythmias, can induce torsade de pointes, aggravates LVF, rise in liver enzymes	5 mg/kg IV over 20 minutes	10 mg/kg/day for 3–4 days	Dose reduced by 25–40% if digoxin being used
Esmolol	Emergency control of ventricular rate in atrial flutter, atrial fibrillation and SVT	Hypotension, heart block, bronchospasm, acute LVF	500 µg/kg/minutes over 1–2 minutes	50–200 µg/kg/minute infusion	Side effects very transient
Verapamil	PAT, AV nodal entry or reciprocating tachycardias; to slow ventricular rate in atrial flutter/fibrillation	Hypotension, LVF, bradycardia, AV block	7.5–10 mg IV over 2–3 minutes	0.125 mg/minute	Contraindicated in heart block, VT, hypotension. Dose of digitalis should be reduced when verapamil is used
Adenosine	Drug of choice for SVT, AV nodal re-entry, reciprocating tachycardia	Transient AV nodal block, flushing, dyspnea	6–12 mg bolus IV		Smaller dose to be used in patients on dipyridamole
Digoxin	Atrial flutter/ fibrillation, SVT	Nausea, vomiting, visual disturbances, induces arrhythmias, particularly in presence of hypokalemia, hypomagnesaemia and renal dysfunction	0.25 mg IV over 5 minutes, repeated 4 hourly till digitalizing dose of 1–1.25 mg reached in 24 hrs	0.25 mg/day	Dose should be reduced when using with quinidine and verapamil. Care to be taken when used with amiodarone

Abbreviations: AMI, acute myocardial infarction; AV, atrioventricular; CNS, central nervous system; CVS, cardiovascular system; ICU, intensive care unit; IV, intravenous; LV, left ventricle; LVF, left ventricular failure; PAT, paroxysmal atrial tachycardia; SVT, supraventricular tachycardia; VT, ventricular tachycardia.

Lidocaine[6]

Lidocaine is an extremely useful class IB antiarrhythmic agent. It depresses depolarization and shortens repolarization in ventricular muscle fibers. It also depresses both normal and abnormal forms of automaticity. It is only effective when given intravenously.

The drug is metabolized in the liver. It has a mean half-life of 1–2 hours in normal subjects, more than 4 hours in patients with uncomplicated myocardial infarction, more than 10 hours in patients with myocardial infarction and associated cardiac failure, and even longer in patients with cardiogenic shock. Severe hepatic dysfunction or reduced hepatic blood flow as in patients with cardiac failure or shock can markedly reduce the metabolism of the drug in the liver. In patients with liver disease, or in those with cardiac failure with low-output states, the dose of the drug should be reduced by one-third to half.

Clinical Indications

Its main indication is the acute or emergency treatment of ventricular arrhythmias of diverse etiology, but particularly those occurring in acute myocardial infarction and after open heart surgery. It is the drug of choice for suppression of ventricular ectopics, sustained VT and symptomatic VT. It should be administered to patients with pulseless VT or VF that is refractory to electrical counter shocks and epinephrine. After VT or VF is terminated, it is advisable to use the drug in a slow intravenous infusion to prevent recurrences of dangerous ventricular arrhythmias. This is particularly imperative in patients with active myocardial ischemia, hypokalemia and myocardial dysfunction. Since most wide QRS complex tachyrhythms are presumed to be ventricular rather than supraventricular, lidocaine is the drug of choice in all wide-complex tachycardias of unknown origin.[6] Lidocaine is of no effect in supraventricular arrhythmias, and in fact, may even accelerate the ventricular response in patients with atrial fibrillation and the WPW syndrome.

It should be noted that since the advent of amiodarone there are a number of critical care units who prefer amiodarone to lidocaine in the treatment of multiple ventricular ectopics, VT and ventricular fibrillation.

Dosage

For multiple ventricular ectopics, sustained VT, symptomatic VT, as also for pulseless VT or refractory ventricular fibrillation, an initial bolus of 1–1.5 mg/kg body weight is given intravenously at a rate of 30–50 mg/minute. A maintenance drip with an infusion rate of 1–2 mg/minute generally suffices to prevent recurrence. A blood lidocaine level of 1.5–6 mg/mL is an effective suppressive range.

If the initial bolus is ineffective, two or more boluses of 1 mg/kg can be given at 5 minute intervals. Patients who require higher doses of the drug and higher plasma levels of lidocaine to revert to sinus rhythm, need a larger maintenance

dose of 2–4 mg/minute. A maintenance drip is generally continued for 24–48 hours. Doses should be reduced by 50% in patients with shock, heart failure or liver dysfunction and in patients older than 70 years.

Cardiac arrest victims may need only a single bolus of lidocaine. The drug can also be administered in patients with cardiac arrest through the endotracheal tube, using 2.5 times the intravenous dose. Once circulation has been restored after successful resuscitation from cardiac arrest, an intravenous infusion of 2 mg/minute of lidocaine should be given.

Adverse Effects

Side effects chiefly involve the central nervous system. These are dose-related effects, and are more frequently seen in the aged. Neurological toxicity includes dizziness, paresthesia, confusion, delirium, drowsiness and even coma. Seizures may also occur. Sinus node depression may occur. The drug is remarkably free of hemodynamic effects, but in large doses and particularly in old patients with poor LV function, the drug may further depress the myocardium, worsen failure and induce hypotension. Lidocaine can increase defibrillation thresholds and has been rarely reported to cause malignant hyperthermia.[7,8]

Quinidine[9-11]

This is a class I antiarrhythmic agent. It depresses depolarization and prolongs repolarization in the atria and the ventricles. It can facilitate atrioventricular (AV) conduction and prolongs the QT interval. Twenty percent of the drug is excreted by the kidneys, the remainder being metabolized by the liver. Plasma quinidine levels peak at about 90 minutes after oral administration of quinidine sulfate. Elimination half-life is 5–8 hours after oral administration. The drug dosage should be reduced in patients with hepatic or renal disease and in those with poor hepatic blood flow (e.g. in cardiac failure and shock).

Indications

Quinidine is a useful antiarrhythmic agent for suppressing supraventricular and ventricular ectopic activity and also for suppressing and reverting both atrial and ventricular sustained tachyrhythms. It does this chiefly by increasing the refractory period of the atria and ventricles and by suppressing atrial and ventricular ectopic activity. Prior to using quinidine for the conversion of atrial flutter or fibrillation to sinus rhythm, the ventricular rate should be first slowed by digitalis or verapamil or a beta blocker. This is because if quinidine is used first, it can slow the atrial flutter rate from 300 beats per minutes to 200 beats per minute. This effect coupled with enhanced AV conduction (a vagolytic effect of the drug) may convert a 2:1 AV response to a 1:1 response, with a resulting increase in the ventricular rate. The drug is no longer as freely used as before chiefly because of the danger of QT prolongation that could lead to torsade de pointes. It is also unavailable in India.

Dosage

For conversion of both sustained supraventricular and ventricular tachyarrhythmias, Quinidine is preferably used orally. The recommended dosage of 400 mg 2 hourly for 4–5 doses is preferred over 400 mg 6 hourly, as the former leads to a more frequent reversion to sinus rhythm. Quinidine can be given intravenously in an emergency situation, e.g. a VT not responding to lidocaine, amiodarone or direct current conversion. Quinidine gluconate is given in a dose of 10 mg/kg intravenously very slowly at a rate of 0.5 mg/kg per minute, the blood pressure and electrocardiogram (ECG) being constantly monitored.

Adverse Effects

The most common adverse effects include nausea, vomiting and diarrhea. CNS disturbances include hearing loss, tinnitus, visual disturbances, confusion, delirium and psychosis. Hypersensitivity responses include hemolytic anemia, thrombocytopenia, fever and rash. Remarkably enough, in our Indian patients these adverse effects are uncommon, the drug being fairly well tolerated. Its cardiovascular effects can indeed be dangerous and should therefore be very closely monitored. It can slow conduction and may produce a sinoatrial (SA) or AV block or a bundle branch block. Quinidine-induced cardiac toxicity can be treated with molar sodium lactate.

Quinidine may produce a QT prolongation and torsade de pointes, a polymorphic ventricular tachyarrhythmia which can cause a syncopal attack and may even be fatal. Syncope due to ventricular tachyrhythms is unrelated to plasma concentrations of quinidine or duration of therapy, though the majority suffer these episodes within the first 2–4 days. In these cases, the drug should be promptly omitted and hypokalemia, which is frequently present should be corrected. The drug of choice in a patient who has syncope from torsade de pointes is magnesium, given intravenously (2 g over 1–2 minutes followed by an infusion of 3–20 mg/minute).[12,13] Drugs that do not prolong the QT interval like lidocaine or phenytoin may also be tried. Atrial or ventricular pacing may act by suppressing depolarization. If pacing is not available, isoproterenol may be used. Quinidine may elevate serum digoxin levels by displacing digoxin from tissue receptors and by decreasing both its total body clearance and volume of distribution.

Procainamide[14]

This is an antiarrhythmic drug very similar to quinidine in its mode of action. It depresses depolarization and prolongs repolarization both in the atria and in the ventricles, facilitates AV conduction through its vagolytic effect and prolongs the QT interval. The drug is chiefly excreted through the kidneys, though it is also partly metabolized by the liver. About 15% is metabolized to N-acetyl procainamide, which also has antiarrhythmic effects and is excreted by the kidneys.

The drug's dosage should therefore be reduced in patients with a low-output state and in those with renal insufficiency. Renal clearance of procainamide is diminished by cimetidine.

Clinical Indications

The main indications for its use are: (1) emergency suppression of ventricular arrhythmias when amiodarone or lidocaine is ineffective, (2) conversion of atrial flutter or fibrillation after digitalis or verapamil or beta blockers have been first used to slow or block AV conduction.

Dosage

Most units in the West at one time used procainamide for the treatment of VT. Today lidocaine or amiodarone has replaced procainamide almost completely in the management of VT. Perhaps its use is in the occasional patient who fails to respond to lidocaine or amiodarone. We have stopped using procainamide for several years. Several intravenous regimes have been advocated. One regime is to give 25–50 mg of the drug intravenously over a 1 minute period. This is repeated every 5 minutes until the arrhythmia is controlled, or hypotension results, or the QT interval is prolonged by more than 50%. Another regime is to give a slow infusion of the drug at a rate of 2–6 mg/minute with a careful monitoring of the blood pressure and ECG. It is wise not to exceed a total dose of 1,000 mg. In less emergent situations, procainamide can be used orally—500 mg every 3–4 hours, the total daily dose being between 2 g and 4 g.

Adverse Effects

Hypotension, which can be precipitous, is the most frequent side effect. Procainamide is a myocardial depressant and can worsen myocardial function in a patient with LV disease. It can also induce ventricular arrhythmias by prolonging the QT interval. It can also suppress conduction in the SA node, or the AV node, or within the conduction system in the ventricles and can lead to various forms of heart block. The syndrome of systemic lupus erythematosus reported on prolonged oral administration of the drug does not occur following emergency administration of the drug. Procainamide should never be used to treat torsade de pointes associated with a prolonged QT interval.

Amiodarone[15,16]

This is a class III antiarrhythmic agent useful in the management of ventricular and supraventricular tachyrhythms in the ICU. It prolongs action potential duration and refractoriness: Though its main action is to block the potassium channel, it also blocks the sodium channel. It also prolongs the QT interval but is less likely to induce torsade de pointes than quinidine, procainamide or disopyramide. It also has a depressant action on the myocardium and can produce a mild alpha and beta blockade. The drug is lipid soluble and is metabolized by the liver. It is not excreted by the kidneys and the dose need not be reduced in patients with renal failure.

The onset of action after intravenous administration is generally within a few hours.[17] Oral medication takes 2–3 days or even 1–3 weeks to produce an effect and is therefore of no use in an emergency situation. Therapeutic serum levels range from 1 mg/mL to 3.5 mg/mL.

Clinical Indications

Amiodarone can suppress a wide range of supraventricular and ventricular tachyarrhythmias.[18] These include AV nodal reentrant tachycardia, junctional tachycardia, atrial flutter, atrial fibrillation, VT and ventricular fibrillation. Its efficacy is 60–80% for most supraventricular tachycardias (SVT) and 40–60% for VTs.[19] It has been shown to be superior to class I antiarrhythmic agents in maintaining sinus rhythm in patients with recurrent atrial fibrillation. In the ICU, this drug is used for VT resistant to lidocaine and in the management of supraventricular arrhythmias. Many units prefer amiodarone to lidocaine in the treatment of VT.

Dosage

A loading dose of 5 mg/kg dose is given intravenously over 20 minutes and is repeated after 30 minutes. This is then followed by a maintenance dose of 10 mg/kg per day for 3–4 days. One should do not exceed a total dose of 1.2 g in 24 hours. The drug is administered in a 5% dextrose infusion as it may precipitate in normal saline.

Adverse Effects

Amiodarone has significant potential toxicity. Cardiac side effects include bradycardia, hypotension, aggravation of tachyarrhythmias in 1–2%[20] and worsening of congestive heart failure in 2%. The drug can prolong the QT interval and should not be given to patients with torsade de pointes.

Noncardiac toxic effects chiefly involve the pulmonary and gastrointestinal (GI) systems. Pulmonary toxicity very rarely can begin acutely within 6–10 days of treatment in the ICU,[21] but generally occurs after a few months of continuous oral therapy. Acute lung toxicity, which can occur within 6 days of intravenous use of the drug, leads to a rapidly progressive interstitial lung disease that may not be reversible. Chronic toxicity is characterized clinically by cough, breathlessness and crackles over the lungs on auscultation. The underlying pathology consists of areas of pulmonary consolidation with progressive respiratory failure. The pathogenesis is believed to be related to an immune-mediated hypersensitivity response of the lung to the drug. Amiodarone should be promptly stopped at the first sign of lung involvement.

The drug can also produce liver cell dysfunction with elevated liver enzymes, GI disturbances and neurological dysfunction. Other potential toxic effects (e.g. corneal microdeposits and thyroid dysfunction) are not observed during use in critical care units. Prolonged use can cause hypothyroidism or rarely hyperthyroidism. A slate blue discoloration of the skin may be observed with chronic use. Patients are advised not to be exposed to bright sunlight

because of photosensitivity. Optic neuritis has been rarely observed, but the causal relationship with amiodarone has not been established.

In spite of its potential toxicity, the drug is indeed extremely useful in a critical care setting for a variety of supraventricular and ventricular arrhythmias.

As far as possible, amiodarone should not be used in combination with quinidine or procainamide as it increases the serum level of these drugs. If digoxin is being used, the dose should be reduced by 25–40%.

Dronedarone

Dronedarone is a new antiarrhythmic drug that is pharmacologically related to amiodarone, but lacks the iodine moiety that is associated with thyroid and pulmonary side effects. Dronedarone is given in a dose of 400 mg twice a day. Its chief use is in patients with paroxysmal atrial fibrillation (AF) maintaining both sinus rhythm and a slow rate successfully. When compared to amiodarone, dronedarone was associated with more recurrences of AF. It should be noted that the PALLAS trial showed that administration of dronedarone in patients with permanent AF was associated with an increase in the rates of heart failure hospitalization, stroke, and death.[22] This drug is contraindicated in: (1) elderly patients with asymptomatic permanent AF; (2) patients with severe LV systolic dysfunction or recent heart failure where it has been shown to increase total mortality.[23-25]

Esmolol[19,26]

Esmolol is a short-acting cardioselective beta blocker with a half-life of approximately 9 minutes after intravenous administration. It has an action similar to other beta blockers—it chiefly prolongs AV conduction, slows the heart rate and reduces contractility. The action starts within 2 minutes of an intravenous loading dose. It is metabolized by red blood cell esterases and is rapidly inactivated so that complete recovery from its physiological effects occurs within 20 minutes after intravenous administration. Its main indication is in the acute or emergency control of the ventricular rate in SVT, atrial flutter and atrial fibrillation.

Dosage

This drug is administered in a loading dose, an intravenous bolus of 500 mg/kg per minute being given over 1–2 minutes. A maintenance dose of 50–200 mg/kg per minute is then continued as a slow intravenous infusion.

Adverse Effects

These are the same as with other beta blockers, only these effects if present disappear within 15–20 minutes. The drug, therefore, has a higher margin of safety compared to other beta blockers, particularly in patients with LV dysfunction. Even so, hypotension, heart block, bronchospasm and acute heart failure may be observed.

Verapamil

Verapamil is a class IV antiarrhythmic agent that blocks the slow calcium channel in cardiac muscle.[26] It thereby reduces the plateau height of the action potential, shortens muscle action potential, and prolongs total Purkinje fiber action potential.[19] In vivo, verapamil prolongs conduction time through the AV node and lengthens functional and effective refractory periods of the AV node. Like all calcium channel blockers, the drug has a negative inotropic effect on ventricular contraction though this is not as marked as that observed with beta blockers. Verapamil also produces significant peripheral vasodilatation; the resulting hypotension induces reflex sympathetic stimulation. The drug produces coronary vasodilatation and decreases myocardial oxygen demand.

The drug acts promptly on intravenous administration. AV nodal conduction delay occurs within a few minutes and is detectable for over 6 hours. The elimination half-life of verapamil is 3–7 hours, 30% being metabolized in the liver, and 70% being excreted by the kidneys.[19]

Clinical Indications

The drug is extremely useful in the treatment of paroxysmal atrial tachycardia, AV nodal entry or reciprocating tachycardia. It should be tried if simple vagal maneuvers fail. However, most units prefer to administer intravenous adenosine as the drug of choice for the above mentioned supraventricular tachyrhythms. Even so, verapamil given intravenously terminates more than 90% of episodes of SVT. The drug is also used to slow the ventricular rate in atrial flutter and fibrillation. It can be used with digoxin for this purpose but should not be combined with beta blockers.

Verapamil has no action on and should not be used for VTs. As a general rule, intravenous verapamil should not be given in any wide QRS complex tachycardias. If the latter happens to be a VT, hemodynamic collapse (severe hypotension and arrest) may occur.

Dosage

For emergency use in critical care units, 5–10 mg is given intravenously over 2–3 minutes, with close monitoring of the blood pressure and ECG. Slowing of the ventricular rate in atrial fibrillation may be maintained if necessary, by the oral use of the drug, or by a continuous infusion of the drug at a rate of 0.005 mg/kg per minute.

Adverse Effects

Hypotension, during or immediately after intravenous administration, can be marked. This effect can be reversed by intravenous calcium gluconate. Because of its negative inotropic action, the drug can further depress cardiac function and cardiac output in a patient with LV dysfunction or in a patient with congestive cardiomyopathy. This adverse effect can be dangerous and at times fatal if the drug is administered to a patient already on beta blockers.[27] Bradycardia, AV block

and asystole can also occur as dangerous side effects; they are more likely to occur when the drug is combined with beta blockers.

Contraindications to the use of verapamil are sinus node dysfunction, AV block without a pacemaker in place, atrial fibrillation occurring against the background of a WPW syndrome with antegrade conduction over an accessory pathway. In the latter situation, verapamil can facilitate conduction through the accessory pathway with a marked rise in ventricular rate that may end with VF and death. The drug is also contraindicated in VTs, all wide QRS complex tachycardias, in hypotensive states and in cardiogenic shock. It is generally contraindicated, as stated earlier, in a patient receiving beta blockers. Verapamil can decrease the excretion of digoxin by 30%; the dose of the latter should therefore be reduced, if it is to be used with verapamil.

Diltiazem

The mechanism of action of diltiazem is the same as verapamil. Intravenous diltiazem is effective in terminating paroxysmal supraventricular tachycardia (PSVT) and in controlling the ventricular rate in patients with atrial flutter and fibrillation. Diltiazem should not be used for VT.

Dosage

An initial bolus of 0.25 mg/kg (20 mg in an average adult) is administered intravenously over 2 minutes. If satisfactory rate control in atrial flutter or fibrillation is not achieved, a further 20 mg is given over 2–3 minutes after a lapse of 15 minutes. The bolus dose is followed by an infusion at 5–15 mg/hour. The infusion should not exceed a period of 24 hours.

Adverse Effects

Adverse effects are as those that are observed with verapamil. The hypotensive and negative inotropic effects are however much less marked as compared to verapamil. Verapamil and diltiazem are best avoided in patients with a sick sinus syndrome or AV block in the absence of a functioning pacemaker.

Adenosine

This is a comparatively new drug used to treat SVT.[28,29] It is administered intravenously and is an extremely effective antiarrhythmic agent. Adenosine interacts with A_1 receptors present on the extracellular surface of cardiac cells and activates K^+ channels. The increase in K^+ conductance shortens the atrial action potential duration, hyperpolarizes the membrane potential and decreases atrial contractility.[19] It delays conduction and induces a block in the AV node. Adenosine is removed from the system by washout, by enzymatic degradation to inosine, phosphorylation to adenosine monophosphate or by re-uptake into the cells.[19] It has a very short elimination half-life of 1–6 seconds. It is worth noting that therapeutic concentrations of theophylline block the action of adenosine. Dipyridamole blocks re-uptake of adenosine and delays its clearance from the circulation; hence, smaller doses of adenosine must be used in patients on dipyridamole. The onset of action of adenosine begins in less than 30 seconds and lasts for 1–2 minutes.

Clinical Use

This drug is used by many as the first choice to terminate acutely occurring SVT such as AV nodal or AV re-entry tachycardias.[30-32] It is particularly indicated when SVT occurs in patients with heart failure, hypotension, WPW syndrome or in patients receiving calcium channel blockers or beta blockers.

Dosage

An intravenous dose of 6 mg is given by a rapid intravenous injection. After 2 minutes, a second dose of 10 mg may be administered in the same manner, if necessary. The dose should be reduced by 50% if the injection is given through a central line or in patients on beta blockers, calcium channel blockers or dipyridamole (see Chapter Tachyarrhythmias in the Intensive Care Unit). Conversion to sinus rhythm occurs in 90–100% of cases.

Adverse Effects

Facial flushing, dizziness, nausea, dyspnea and angina-like chest pain are observed quite frequently. Sinus bradycardia or a temporary AV block may occur. Cardiac asystole for a few seconds may be a worrying feature.

Digoxin

Digoxin is still very frequently used in the ICU both in the management of cardiac failure and in the control of supraventricular arrhythmias.

Digitalis has a significant inotropic action on the heart. It binds to and inhibits Na^+ K^+ adenosine triphosphatase (ATPase) resulting in an increased intracellular Na^+, which is exchanged for extracellular calcium.[33] The increased availability of activated calcium to the contractile proteins of the myocardial cells results in enhanced contractility. The action of digoxin on Na^+ K^+ ATPase activity also alters the transmembrane potential of other cells affecting the refractory period, conduction velocity and excitability. Various cell types may be affected differently accounting for different effects on the atria, on the AV node and conducting tissues and on the ventricles. Digitalis (including digoxin) enhances the parasympathetic, and diminishes the sympathetic effects on the heart. It also acts as a peripheral vasoconstrictor.[34]

The main action of digitalis glycosides in clinical practice is an inotropic action on the heart and a prolongation of AV conduction. The latter is due to varying degrees of block in the AV node. This effect is made use of in slowing the ventricular rate in atrial flutter and fibrillation and in inhibiting re-entrant SVT.

Pharmacokinetics

Digoxin is widely distributed in the tissues and the serum half-life is fairly long (36–48 hours). Intravenous digoxin acts within 1–2 hours of administration. Therapeutic blood levels of digoxin are between 0.8 ng/mL and 2 ng/mL. Unfortunately, the drug has a relatively narrow therapeutic ratio, and toxicity may occur even when serum levels are within the therapeutic range. The drug is primarily cleared by the kidneys. Interactions between digoxin and other drugs are frequent. Impaired renal function and drug interactions, which raise serum digoxin levels dangerously, contribute to the frequent occurrence of digitalis toxicity observed in the ICU.

Clinical Indications

These chiefly include: (1) cardiac failure—both LV failure and congestive cardiac failure; (2) supraventricular tachyarrhythmias—atrial flutter, atrial fibrillation and re-entrant SVT.

Dosage

Emergency slowing of the ventricular rate in supraventricular tachyrhythms, or a quick inotropic action in LV failure, necessitates intravenous administration of the drug. 0.25 mg (or in exceptional instances 0.5 mg) is given intravenously over 5 minutes. 0.25 mg is then repeated 4–6 hourly till a digitalizing dose of 0.75–1 mg is reached over a 24 hour period. It is wise not to exceed this dose, at least not in patients in our country. Patients with atrial flutter or fibrillation may require a larger dose of 1.5 or even 1.75 mg in 24 hours. A maintenance dose of 0.25 mg orally daily for 5–6 days in a week generally suffices. In the presence of renal failure, the loading and maintenance doses need to be sharply reduced. Frequent digoxin levels may need to be done and digoxin levels should be kept below 2.0 ng/mL. In the elderly, intravenous digoxin should be given with caution. We prefer to give half the loading dose followed by a maintenance dose of 0.125 mg orally daily for 5 days in a week.

Toxic Effects

Digitalis is a toxic proarrhythmic drug particularly in the presence of hypokalemia, hypomagnesemia and renal insufficiency. The simultaneous use of quinidine alters the renal clearance and the volume of distribution of digoxin. In fact, therapeutic levels of quinidine may nearly double the serum concentration of digoxin. The dose of digoxin should be halved when using quinidine. Amiodarone and verapamil have similar but lesser effects on digoxin levels in the blood.

Digitalis-induced arrhythmias and their management have been discussed in an earlier chapter. Nausea, vomiting, and visual disturbances (colored vision) are also observed in patients in the ICU and may precede or accompany rhythm disturbances caused by digoxin. Digoxin is contraindicated in the presence of AV block, in severe hypokalemia or hyponatremia, and in hypertrophic cardiomyopathy.

NEWER ANTIARRHYTHMIC AGENTS[5,35]

Newer Class IC Antiarrhythmic Drugs

Flecainide and propafenone are class IC antiarrhythmic agents used to treat ventricular tachyarrhythmias. The main risk associated with their use is the precipitation of life-threatening ventricular arrhythmias. These drugs can suppress the sinus node and impair AV and infra-nodal conduction in patients with conduction disease. They also depress systolic LV function. Flecainide is given at 50–200 mg orally twice a day; many elderly patients only require 50 mg twice a day. The starting dose of propafenone is 150 mg every 8–12 hours.

It is of interest to note that ventricular premature beats were believed to lead or rather predict sudden cardiac death in patients with myocardial infarction who developed a cardiomyopathy. The CAST study was designed to assess the impact suppression of these ectopic beats in this high-risk population.[36,37] It was observed that patients, who received the above newly introduced antiarrhythmic agents, had a 2.5-fold higher mortality than patients in the control arm of the trial forcing the premature termination of this study.

Newer Class III Antiarrhythmic Drugs

Sotalol is a nonspecific beta adrenergic receptor blocker with potassium channel blocking properties. It is used in the treatment of ventricular arrhythmias and atrial fibrillation. Oral dosing is usually 80–160 mg twice a day. The most dangerous side effect is a prolongation of the QT interval that can lead to torsade de pointes. The drug can aggravate airways obstruction in patients with asthma or chronic obstructive pulmonary disease.

Ibutilide is a short-acting potassium channel blocker given intravenously for the quick termination of atrial fibrillation or flutter. Ibutilide is given as an intravenous bolus in a dose of 1 mg over 10 minutes or until conversion, whichever occurs first. The major side effect is precipitation of sustained ventricular arrhythmias. The patient should be monitored in the ICU continuously with resuscitative equipment at hand.

Dofetilide is another class III antiarrhythmic drug excreted by the kidneys. The dosage is determined by creatinine clearance (CrCl) and adjusted according to changes in the corrected QT (QTc) interval. Initial dose of dofetilide is 500 µg twice a day if the CrCl is more than 60 mL/minute, 250 µg twice a day if the CrCl is 40–60 mL/minute and 125 µg twice a day if the CrCl is 20–40 mL/minute. It has been found safe in patients with cardiomyopathy. The dosage needs careful adjustment with continuous patient monitoring.

CHAPTER 26

Hypertensive Emergencies and Aortic Dissection in the ICU

HYPERTENSIVE EMERGENCIES

INTRODUCTION

The incidence of hypertension is increasing globally. Population data suggest that 97.2 million individuals worldwide have hypertension[1] and 30% of hypertensive individuals are unaware of this diagnosis. This chapter first briefly introduces the concept of hypertensive urgency and then focuses on hypertensive emergencies, also termed hypertensive crisis.

Hypertension can exist without evident acute or chronic target organ dysfunction. Hypertensive urgency is characterized by an elevated blood pressure (BP), systolic often greater than 180 mm Hg, diastolic greater than 115 mm Hg without evidence of any acute end-organ damage. Hypertensive urgency may be associated with chronic stable complications such as renal insufficiency, ischemic heart disease (IHD) [stable angina, past history of myocardial infarction (MI)], and/or cerebrovascular disease in the form of a history of past transient ischemic episodes or a past history of a cerebrovascular accident. There is no threat of an immediate, impending acute insult. Hypertensive urgency may be the result of improper treatment or lack of compliance.

Hypertensive emergency, also called hypertensive crisis, is defined as an acutely elevated BP associated with acute end-organ damage. The organs chiefly involved are the kidneys, the heart and the central nervous system (CNS). Unless properly treated there is a significant morbidity and mortality attached to this emergency within an immediate short span of time. The evolution of a hypertensive crisis is dependent both on the degree of rise in BP and the time course over which this BP has risen. In patients who are previously hypertensive, the blood pressure in an acute crisis may well be greater than 210 mm Hg systolic and greater than 120–130 mm Hg diastolic. In previously normotensive individuals, as, also in pregnant females and in children, hypertensive crisis may occur with a comparatively lesser or even minor increase in BP.

PATHOPHYSIOLOGY OF HYPERTENSIVE CRISIS

A sudden sharp increase in the BP is the initiating feature that transforms simple hypertension to an acute hypertensive crisis. BP is the product of the cardiac output and peripheral resistance. The initial sharp rise in BP is due to a sharp increase in vascular tone with a corresponding increase in peripheral vascular resistance. There is evidence to suggest that the sharp increase in BP leads to increased mechanical stress on the arteriolar wall with a disruption of endothelial integrity.[2] Disruption of endothelial integrity results in diffuse microvascular lesions, characterized by a fibrinoid necrosis of the arteriolar walls, a consistent histological feature of hypertensive crisis.[3,4] Other factors may well contribute to the evolution of an acute hypertensive crisis. Increase in peripheral vascular resistance occurs in part from activation of the renin-angiotensin-aldosterone system (RAAS). Angiotensin II may activate genes for the proinflammatory cytokine interleukin and nuclear factor κB thereby directly injuring the vessel wall.[5,6] Hormones such as catecholamines, vasopressin, endothelin and immunological factors may also contribute to the increase in vascular tone. The end result of

these peripheral vascular changes is ischemia to vital organs such as the brain, kidney and the heart.

CRITICAL CARE IN HYPERTENSIVE EMERGENCIES

Hypertensive emergencies invariably need critical care. The danger caused by a sudden rise in BP to high levels is related as already stated to disturbance in structure and function of important organ systems. Equally important is the potential hazard of a sudden increase in BP in specific critical situations such as in the perioperative or immediate postoperative phases of intracranial surgery, open heart surgery or other vascular surgeries. Thus, a sudden rise of BP during or after intracranial surgery or following trauma to the head is fraught with risk of increasing cerebral edema with all its attendant complications. A hypertensive crisis, perioperative or postoperative following open heart surgery, subjects the heart to an unnecessary increase in afterload and can trigger cardiac failure and pulmonary edema. A rise in BP in the immediate post-coronary artery bypass graft (CABG) phase can also accentuate myocardial ischemia and can precipitate MI. The risk of increased bleeding due to postoperative hypertension is also ever present, particularly following open heart surgery and vascular surgery.

Patients with hypertensive crisis needing critical care can be grouped as follows—

- An acute hypertensive crisis causing acute structural damage and functional changes in the following major organ systems—
  - *Central Nervous System—problems involving the CNS* include hypertensive encephalopathy, cerebral hemorrhage, subarachnoid hemorrhage, cerebral *infarction*, stroke-in-evolution.
  - Cardiovascular System—acute hypertensive crisis can precipitate unstable angina (UA), MI, acute left ventricular failure, congestive heart failure, aortic dissection.
  - Renal System—malignant hypertension with rapidly evolving renal destruction and failure are the most dreaded features of severe accelerated hypertension.
- Hypertensive crisis posing a potential hazard in specific critical situations—
  - After intracranial surgery (greater risk of cerebral edema and bleeding).
  - After trauma to head—again, a greater risk of cerebral edema and bleeding.
  - After open heart surgery (risk of MI, acute heart failure, bleeding).
  - After vascular surgery (risk of bleeding).
  - After other major surgery (risk of bleeding, risk to sutures).
- Eclampsia—this is a special situation in pregnancy when sudden increase in BP is associated with seizures and albuminuria. There is a great risk of multiorgan failure particularly involving the CNS and kidneys.
- Uncommon conditions causing a sudden dangerous rise in BP—
  - Pheochromocytoma often causes paroxysmal hypertension. Even so, the commonest cause of paroxysmal hypertension in clinical practice, occurs against a background of mild to moderate essential hypertension.
  - Drug reactions in patients on monoamine oxidase (MAO) inhibitors.
  - Rare instances in our country of acute hypertension in cocaine addicts and in lead poisoning and encephalopathy.
  - Sudden withdrawal for whatever reason of potent antihypertensive drugs.

APPROACH TO HYPERTENSIVE EMERGENCIES

Hypertension from any cause can be complicated by an evolution into an acute crisis. The commonest cause of an acute hypertensive crisis is essential hypertension. Hypertensive emergencies can also occur in secondary hypertension and in individuals who give no history of hypertension, as in pheochromocytoma, acute glomerulonephritis, toxemia of pregnancy and eclampsia. Cocaine addicts are also known to present with an acute hypertensive crisis.

An important feature in the history is to determine whether the patient has had a background of hypertension and if so, the duration of the hypertension. If there is a history of long standing hypertension then the underlying etiology is generally essential hypertension. The possible factors precipitating an acute crisis in a patient need to be carefully evaluated. Emotional stress, physical fatigue, excessive ingestion of salt, administration of corticosteroids or the occurrence of secondary renovascular problems are important causes of an acute crisis in some patients. Not uncommonly no underlying triggering factors can be found for a precipitous rise in BP.

The management of a hypertensive emergency rests on quick assessment and immediate treatment. Quick assessment consists of a relevant history and physical examination. The urgency of the situation at times may demand measures to control the hypertensive crisis as the first and initial step.

Patients with hypertensive emergency present with a variety of symptoms, the most common being headache. It is usually sudden in onset, located in the occipital or frontotemporal region. Symptoms may relate to the CNS and include disturbances in vision, transient ischemic attacks, stroke, stroke-in-evolution, confusion, drowsiness and seizures. Symptoms related to the cardiovascular system (CVS) include cardiac pain and breathlessness and to the renal system include nocturia, polyuria, and hematuria. Nausea and vomiting frequently occur with an acute rise in BP, as in patients presenting with hypertensive encephalopathy. The physical examination in an acute emergency should be brief and is conditioned to an extent by the nature of the presenting illness. BP should be measured in both arms; the diastolic BP

in an acute crisis is generally greater than 120 mm Hg. A point of note is that calcification of the vessel walls may prevent compression of the vessel wall by the BP cuff, so that in these patients there appears to be a pseudo or false increase in the BP. Pseudo-hypertension can occur with severe atherosclerosis, Monckeberg's medial calcification and metastatic calcification occurring in some patients with end stage renal disease. The arteries in these instances are thick, almost hard when palpated. A palpable radial artery after proximal compression of the vessel (Osler's maneuver) suggests this diagnosis.

Examination of the CVS should include evidence for left ventricular hypertrophy (seen in long standing hypertension), evidence of left ventricular failure (a diastolic gallop with basal crackles) and the presence or absence of a carotid bruit. All major pulses should always be palpated for evidence of any inequality.

A brief CNS examination should include a rapid assessment of cognition and memory, of motor function, of focal signs and of the tendon and plantar reflexes. A fundus examination is mandatory as it reveals the severity of hypertension (presence of exudates and hemorrhages), the duration of hypertension [sclerotic vessels with arteriovenous (A-V) nicking] and the presence of malignant hypertension as judged by papilledema.

Examination of the abdomen should include careful palpation for enlarged ballotable kidneys as is observed in polycystic kidneys and for clinical evidence of an aortic aneurysm.

It is important to assess priorities in management. Though control of hypertension is of vital importance, the presence of continuous seizures should prompt the urgent use of antiepileptic drugs. Similarly, the use of aspirin or anticoagulants in a patient with a stroke or stroke in evolution should be delayed till such time as imaging studies have excluded an intracerebral hemorrhage.

Emergency laboratory investigations are often of marginal help. A routine blood count, erythrocyte sedimentation rate (ESR) and urine examination are necessary. The urine often shows mild proteinuria, red blood cells and occasional casts. Gross proteinuria points to glomerulonephritis. Serum electrolytes, serum bicarbonate, serum creatinine, prothrombin time, activated partial thromboplastin time (PTT), a pregnancy test when appropriate, toxicological screening of urine and blood (especially for lead and cocaine) also when appropriate, may be necessary.

A chest X-ray and electrocardiogram (ECG) will help further assess cardiac function in relation to a hypertensive crisis. Evidence of frank cardiac failure should warn the intensivist against the use of a beta-blocker. Special imaging tests include a magnetic resonance imaging (MRI) for CNS lesions and for possible aortic dissection. Ultrasonography (USG) of the abdomen will determine kidney size and detect an aortic aneurysm. Echocardiography is of use in assessing wall motion abnormalities, ejection fraction and the presence of clots within the heart. There should be a protocol, which allows a sequential work-up based on immediate priorities; these would depend on the nature of the crisis and the presenting features.

MANAGEMENT OF HYPERTENSIVE EMERGENCIES

Patients with an acute hypertensive crisis often have BP greater than 220 mm Hg systolic and greater than 120–130 mm Hg diastolic. They are treated in an intensive care unit with monitoring of the BP by arterial cannulation or through the use of automated cuff measurements. Invariably in an acute crisis, drugs should be used parenterally to reduce the BP. Marked fall in the BP should be avoided. In many cases, it may be unwise or even harmful to reduce the BP to normal levels for fear of a sharp reduction in the coronary, cerebral and renal circulation. The speed at which BP should be reduced depends on the nature of the emergency or crisis.

In most but not all clinical situations, the BP is reduced by 20–25% in the first 15 minutes–2 hours.[7] Once the BP is stabilized at this level, it is further reduced to 160/100 mm Hg over the next 3–6 hours. If the patient is known to have been normotensive before the acute crisis, the blood pressure could be brought down to normal levels over the next 24–48 hours. Otherwise, if the patient is a known hypertensive, it is prudent to allow the BP at 140–150/90–100 mm Hg. The method of reduction described above allows CNS blood flow autoregulation to be generally well maintained.

There are however clinical situations, which require special consideration—

- In ischemic cerebral infarction or a stroke-in-evolution the BP should not be reduced unless it is above 220/120 mm Hg or the patient is a fit candidate for thrombolytic therapy.
- In patients with carotid artery stenosis, a past history of IHD, or of a cerebrovascular accident, or in patients with established chronic renal insufficiency, the BP should be brought down even more gradually than stated earlier.
- Fulminant pulmonary edema due to acute left ventricular failure may require a more rapid reduction in BP. The same directive applies to patients with active severe UA and patients in acute congestive cardiac failure.
- Hypertensive encephalopathy characterized by seizures, or mental obtundation, or coma due to cerebral edema requires an urgent more rapid reduction of BP.
- Acute dissection of the aorta is one condition which requires a very rapid reduction of the blood pressure to preferably 100 mm Hg systolic, within a period of 15–30 minutes.

Drugs Used in Hypertensive Crisis[8]

The drugs used parenterally to treat hypertensive crisis are—

- Intravenous (IV) nitroglycerin and IV nitroprusside, which act as vasodilators.
- IV labetalol, which is an α and β adrenergic blocker.
- IV nicardipine, a calcium channel blocker.
- Esmolol given IV as a short acting β_1 antagonist.
- IV enalapril, an angiotensin-converting-enzyme (ACE) inhibitor.

- Phentolamine, which is an α adrenergic blocker, chiefly used to counter an acute hypertensive crisis caused by a pheochromocytoma.
- Fenoldopam, which is a strong dopa agonist and which lowers BP by decreasing peripheral vascular resistance. We have no experience with this drug.
- Nifedipine sublingually (squeezed from a punctured capsule) is the only non-parenteral drug that can sharply reduce BP.[8] It is best not to use more than 5 mg sublingually as the fall in BP though temporary may be dramatic and uncontrolled. Though anecdotal reports of MI and arrhythmias have been reported following sublingual nifedipine, we have never encountered problems when the drug is used in the dose stated above.

The dosage, use, adverse effects of drugs in parenteral use have been summarized in Table 1.

Once a marked increase in BP is controlled by IV therapy, oral therapy using an appropriate single drug or a combination of drugs is given to maintain control. A careful transition from IV to oral medication is desirable. Calcium channel blockers, labetalol, beta-blockers, ACE inhibitors are commonly used oral preparations given singly or in combination. In fact, when the emergency is not very acute, and the BP is not unduly raised, oral medication (which should exert BP control over 12–24 hours) may be preferred to parenteral medication.

The ideal parenteral drug should be quick acting, effective and rapidly reversible, should not exhibit tachyphylaxis and should have minimal sideeffects on other organ systems. No drug fulfills all these criteria ideally. The quickest way to bring the BP down sharply is the use of IV nitroprusside, which acts through a direct vasodilator action on the arteriolar, capillary

Table 1: Parenteral drugs used in the management of hypertensive crisis

Drugs	*Dose*	*Onset of action*	*Duration of action*	*Adverse effects*
Drugs with Rapid Action				
Sodium nitroprusside	0.25–10 µg/kg/min as IV infusion	Immediate	1–3 minutes	Hypotension, nausea, vomiting, muscle twitchings, cyanide poisoning with prolonged excessive use
Nitroglycerine	5–100 µg/min as IV infusion	2–5 minutes	1–3 minutes	Tachycardia, headache, flushing, vomiting, methemoglobinemia
Diazoxide	50 mg IV bolus repeated at 5–10 minutes intervals, or 15–30 mg/min IV infusion	1–2 minutes	6–8 hours	Hypotension, fluid retention hyperglycemia, tachycardia
Hydralazine	10–20 mg IV 10–50 mg IM	1–20 minutes 20–30 minutes	3–6 hours	Tachycardia, flushing, headache, vomiting, precipitation of angina
Phentolamine	5–15 mg IV	1–2 minutes	10–30 minutes	Tachycardia, flushing
Trimethaphan	1–4 mg/min IV infusion	1–5 minutes	5–10 minutes	Orthostatic hypotension, bowel or bladder paresis, blurred vision, dry mouth
Esmolol	500 µg/kg/min for 4 minutes; then 150–300 µg/kg/min IV	1–2 minutes	8–10 minutes	Hypotension
Labetalol	20–80 mg IV bolus every 10 minutes 2 mg/min IV infusion	5–10 minutes	3–6 hours	Vomiting, dizziness, nausea, postural hypotension, precipitation of cardiac failure
Propranolol	1–5 mg IV bolus; 3 mg/hour IV infusion	1–2 minutes	3–6 hours	Bronchospasm, hypotension
Nicardipine hydrochloride	5–15 mg/hour as a loading infusion; 3–8 mg/hour as a maintenance infusion IV	1–3 minutes	15–40 minutes	Hypotension, headache, flushing
Enalaprilat	0.625–1.25 mg IV bolus every 6 hours	10–15 minutes	6–8 hours	Hypotension, cough, hyperkalemia, renal insufficiency
Slower Acting Drugs				
Reserpine	1 mg IV; 2–2.5 mg repeated after 4–6 hours	2–4 hours	Few weeks	Drowsiness, Parkinsonian-like rigidity, reactivation of peptic ulcer, nasal obstruction, bronchospasm
Alpha methyldopa	250–500 mg IV 6 hourly	1–3 hours	90–120 minutes	Drowsiness

and venous walls. The drug is potentially dangerous and therefore merits a more detailed description of its use. Its prime use is in patients with hypertensive encephalopathy where the BP may be greater than 250/130 mm Hg. A number of patients in our experience are extremely sensitive to this drug. It should always be given through a microdrip starting with 0.25 ug/kg per minute. A 60 kg patient would receive 15 ug/minute which would work out to 8–9 microdrops/minute. The BP should be continuously monitored preferably through cannulation of the radial artery. If necessary, one can increase the flow rate by five microdrops at 3–4 minutes interval. The blood pressure can occasionally crash to unrecordable levels. Fortunately, the effect of the drug is short lived, so that the BP starts to rise within a few minutes of stopping the drug. If severe hypotension does not quickly and spontaneous recover a titrated dose of noradrenaline is given in a separate infusion.

The drug today is not as frequently used as before for fear of causing sudden severe hypotension and for fear of cyanide poisoning (suspected when the serum lactate is raised and when there is a fall in pH) and thiocyanate toxicity. It is best not to use the drug for more than 48 or at most 72 hours.

Preparation 50 mg of the drug is added to 500 mL of 5% dextrose, so that 1 mL (60 microdrops) of this constituted solution contains 100 ug. The solution should be protected from light by wrapping it in a dark cloth. It should be freshly prepared and promptly used. Normally it is faint brown in color and should not be used if the color changes to dark brown.

Treatment Recommendations in Hypertensive Crisis Based on Etiology

Cerebral Infarction

Studies show that the areas surrounding the infarcted region are ischemic but potentially can be restored to function if reperfused. This is referred to as the ischemic penumbra. Also, in an acute cerebral infarct autoregulation is impaired and cerebral blood flow is not preserved in a predictable manner. Acute reduction of BP in these circumstances could potentially increase the area of infarct with unfortunate clinical consequences.

The current recommendations[9] are—

- To refrain from reducing the BP in an acute cerebral infarct except when the systolic BP is over 220 mm Hg and diastolic greater than 120 mm Hg. The pressure in the above circumstance is reduced by 15–25% over 24 hours.
- In patients who are considered appropriate for thrombolytic therapy, the BP must be reduced to less than 185 mm Hg systolic and less than 110 mm Hg diastolic.

Subarachnoid Hemorrhage[10]

Untreated severe hypertension can be dangerous. The recommendation is to reduce the hypertension by 20–25% over the first 6–12 hours but not less than 160–180/100 mm Hg.[10] Labetalol is the preferred agent as there are no adverse effects on the intracranial pressure or cerebral perfusion pressure. Oral nimidopine within 4 days of the acute event is believed to decrease vasospasm and cerebral ischemia. IV nitroglycerine or IV nitroprusside are not usually first line drugs as they could cause a further increase in cerebral volume and intracranial pressure because of their vasodilator effect.

Intracranial Hemorrhage

A recent consensus[11] states that—

- The blood pressure should be lowered by IV medication when the systolic BP is greater than 200 mm Hg or the mean arterial pressure (MAP) greater than 150 mm Hg.
- If intracranial hypertension is suspected, aggressive lowering of BP with continuous or intermittent IV medication is to be considered when the systolic BP is greater than 180 mm Hg or the MAP greater than 130 mm Hg.
- If there is no suspicion of increased intracranial pressure and the systolic BP is greater than 180 mm Hg and the MAP greater than 130 mm Hg, the BP should be lowered to a level of 160/90 mm Hg or a MAP of 110 mm Hg.

There is no consensus on the antihypertensive agent of choice. Labetalol is often used, though it may lead to worsening bradycardia. Vasodilator therapy is also often used in the presence of increased intracranial pressure. These patients have high circulatory catecholamines in the blood. If vasodilators are not effective, a beta-blocker is given in addition. An ACE inhibitor IV enalaprilat is also a good choice to control the BP. Once the sharp increase in BP is brought under control, oral medication in the form of a calcium channel blocker or an ACE inhibitor or labetalol singly or in combination can be given to maintain control.

Cerebral Trauma

In most trauma centers intracranial pressure monitoring has become a necessary standard of care. Current recommendations are to maintain a cerebral perfusion pressure of 70 mm Hg and a MAP above 90 mm Hg. When choosing an antihypertensive drug, a major consideration is its effect on intracranial pressure. A combination alpha- and beta-blocker (labetalol) or nicardipine may be preferred when there is increased intracranial pressure.[12] In the absence of intracranial hypertension vasodilators may be preferred.

Use of antihypertensives in malignant hypertension and hypertensive encephalopathy is given under the separate description of these entities.

MALIGNANT HYPERTENSION

Malignant hypertension is characterized by severe hypertension with hypertensive neuroretinopathy. The fundus examination classically shows flame shaped hemorrhages, cotton-wool exudates and papilledema. Some patients may just show severe papilledema. This syndrome is associated with nephropathy progressing to renal failure, microangiopathic hemolytic anemia and cardiac failure. Critical care is often needed in the presence of rapidly deteriorating

renal function, cerebrovascular accident or cardiac failure. Malignant phase hypertension is invariably associated with a marked increase in renin activity even when the underlying hypertension is essential.

The objective is to treat severe hypertension aggressively in order to prevent increasing ischemic end-organ damage. To protect cerebral function, the BP should be reduced by about 20% in the first hour and then further reduced to 160/100 mm Hg over the next 8–12 hours. The urine output, cerebral, renal and cardiac functions need careful monitoring. Nitroprusside in an IV infusion is often used to achieve this objective. Many patients are exquisitely sensitive to this drug, so that the drug to start with should be infused at not more than 5 μg/minute and titrated further to achieve BP control. Alternatives to nitroprusside are labetalol, nicardipine, fenoldopam. A gradual transition to oral drugs can be made once BP control is achieved.

It is not uncommon for renal function to deteriorate even further once the BP is controlled. Renal function, however, generally starts to improve after a period of 2 months; recovery at times is possible even after 1–2 years. In the interim period, some patients may require dialysis, particularly when the serum creatinine rises to greater than 4.5 mEq/L. Recovery of renal function is more likely to occur when on USG the combined length of both kidneys is greater than or equal to 20 cm and less likely if the combined length is less than or equal to 14 cm. Unfortunately, a number of patients progress to end-stage renal failure, requiring permanent dialysis even when the BP is controlled. This is particularly so when the underlying cause of malignant hypertension is chronic glomerulonephritis.

Relatively asymptomatic patients with malignant hypertension may present just with neuroretinopathy. The BP in these individuals can often be controlled by oral medication. Calcium channel antagonists are safe. ACE inhibitors can be used with caution, guarding against hyperkalemia, particularly in patients with renal insufficiency.

HYPERTENSIVE ENCEPHALOPATHY

Hypertensive crisis may manifest as hypertensive encephalopathy, a dangerous yet reversible condition, if promptly and appropriately treated.

In hypertensive encephalopathy the MAP exceeds the limits of autoregulation, so that edema of the brain results from extravasation of fluid and plasma proteins. The clinicopathological entity that ensues is termed reversible posterior leukoencephalopathy, a condition caused by vasogenic subcortical edema without infarction.

It is to be noted that hypertensive encephalopathy is just one of the many other medical conditions that can result in reversible posterior leukoencephalopathy.[13]

Clinical Features

The clinical features consist of severe headache, drowsiness, obtundation, visual disturbances, including an inability to see, mental confusion, speech disturbances, and most important of all, seizures. The latter may be the sole presentation of this disorder. Focal signs are generally absent unless there has been an intracerebral bleed. However, papilledema is invariably present; its absence should raise doubts on the diagnosis.

Box 1: Differential diagnosis of hypertensive encephalopathy

- Intracerebral or subarachnoid hemorrhage
- Cerebral infarction
- Subdural hematoma
- Mass lesion (e.g. trauma)
- Seizure disorder
- CNS vasculitis
- Drug poisoning

The condition is completely reversible within 24–48 hours, if the BP is appropriately controlled, in contrast to the persistence of obtundation, mental confusion observed in an intracerebral bleed. The syndrome generally occurs against a background of severe hypertension but even a modest elevation of BP can lead to encephalopathy in children, particularly against the background of glomerulonephritis.

Among routine investigations, imaging of the brain is vital to exclude an intracranial hemorrhage, subarachnoid hemorrhage or a massive cerebral infarct. An MRI of the head in hypertensive encephalopathy reveals edema in the occipital and parietal lobes (posterior leukoencephalopathy); edema in other regions of the cerebral hemispheres and occasionally brainstem involvement may also be observed.

Treatment consists in appropriately lowering the BP in the clinical setting of cerebral edema and ischemia. The MAP should initially reduced by 20% in the first 2 hours and further reduced to 150/100 mm Hg over the next 4–6 hours. The diagnostic feature of hypertensive encephalopathy is complete recovery within 12–24 hours of reduction of BP. If hypertensive encephalopathy is untreated or inappropriately treated, coma and death may result.

The differential diagnosis of hypertensive encephalopathy is given in Box 1.

HYPERTENSIVE CRISIS IN ECLAMPSIA[14]

The diagnosis of eclampsia requires the presence of seizures, edema, proteinuria and hypertension in pregnancy. An MRI of the head shows edema within the occipital and parietal lobes (posterior reversible encephalopathy syndrome or posterior leukoencephalopathy). This resolves with successful treatment of the disorder. Eclampsia should be differentiated from toxemia of pregnancy (pre-eclampsia), wherein seizures are absent and where a prompt reduction in BP may well prevent morbidity and transition to eclampsia. The antihypertensives best suited to the pregnant state include hydrazaline and alpha methyldopa. Between 10–40 mg hydrazaline is best given orally or intravenously every 6 hours. Alpha methyldopa is given in a dose 500 mg four times a day. Calcium channel blockers can be added to this regime if necessary.

Magnesium sulfate administered intravenously is extremely useful for control of seizures. It also has an antihypertensive effect. A loading dose of 4–6 g is given intravenously over 20–30 minutes. This is followed by 1.5–3 gm/hour given intravenously. A plasma magnesium level of 4–6 mEq/L is considered to be within the therapeutic range. Once seizures and hypertension are reasonably controlled, the fetus should promptly be delivered.

PERIOPERATIVE AND POSTOPERATIVE HYPERTENSION

Some hypertensive patients, ordinarily well controlled, may develop a sharp rise in BP just before surgery. Elective surgery is preferably postponed till the BP again settles. If postponement is not possible, BP should be reduced to less than 160/100 mm Hg before noncardiac surgery. It is to be noted that perioperative hypertension is an important risk factor for postoperative hypertension.

In hypertensive patients with existing but stable end-organ damage, marked fluctuations in blood pressure during anesthesia and surgery may lead to worsening myocardial ischemia, MI, acute renal failure or a cerebrovascular accident. A sharp rise in BP during surgery is best controlled by a titrated IV infusion of nitroglycerin.

Patients who have been receiving a beta-blocker should be continued on the beta-blocker postsurgery, else there is often a rebound hypertension with marked tachycardia. After major surgery severe postoperative pain and hypoxia are two factors that can result in a sharp elevation in the BP, aggravating or inducing end-organ damage, particularly in known hypertensives. Relief of pain and hypoxia generally results in BP control. BP control is important as it reduces the risk of postoperative bleeding, premature graft closure in patients who have undergone coronary artery bypass surgery, and the risk of end-organ damage. A titrated IV infusion of nitroglycerin is the drug of choice in the postcoronary bypass hypertensive patient.

Acute Hypertension in Patients on MAO Inhibitors

Ingestion of food containing tyramine or sympathomimetic amines in patients on MAO inhibitors can lead to an acute hypertensive crisis. Tyramine is metabolized by an alternative pathway to octopamine, which release catecholamines from peripheral sites causing acute hypertension. This episodic hypertension is dangerous, particularly in known hypertensives. Fortunately, these episodes are self limited and last just for 4–8 hours. Tyramine containing foods are bananas, coffee, chocolate, soya sauce, avocadoes, chicken liver, unpasteurized cheese, Chianti wine and certain beers. These foods should be strictly avoided by patients on MAO inhibitors.

Hypertensive crisis seen in pheochromocytoma is dealt with under Endocrine Emergencies, and hypertensive crisis in eclampsia is further dealt with in the Section Critical Care in Pregnancy.

DISSECTION OF THE AORTA

INTRODUCTION

Aortic dissection is a catastrophic emergency most frequently associated with hypertension. Dissection occurs through a tear in the intima, and this takes place either in the ascending aorta or at the beginning of the descending aorta, distal to the origin of the left subclavian. Blood dissects the aorta between the intima and the media for a varying length, with catastrophic results. The condition is more common in men than in women, and the mortality is over 50% in the first 48 hours, and over 70% within the first week. Rarely aortic dissection can occur in the absence of hypertension in patients with a congenital weakness in the aortic wall as in Marfan's syndrome, or in aortic cystic medionecrosis.

CLASSIFICATION

A classification of aortic dissections based on approach to therapy, delineates three types: Types A, B and C, which have been illustrated in Figure 1.

A more current classification is that proposed by the Stanford group of workers.[1] This classification delineates just two types—(1) Type A and (2) Type B. In Type A, the ascending aorta is involved, irrespective of the site of intimal tear. 15% of tears in the transverse aorta and 5% of tears in the descending aorta also involve the ascending aorta. In Type B, only the descending aorta beyond the left subclavian is involved. The risk of sudden death is highest in Type A as the dissection can cause tamponade, aortic insufficiency, congestive heart failure and coronary occlusion. Type B dissections carry less risk and therefore can be managed conservatively.

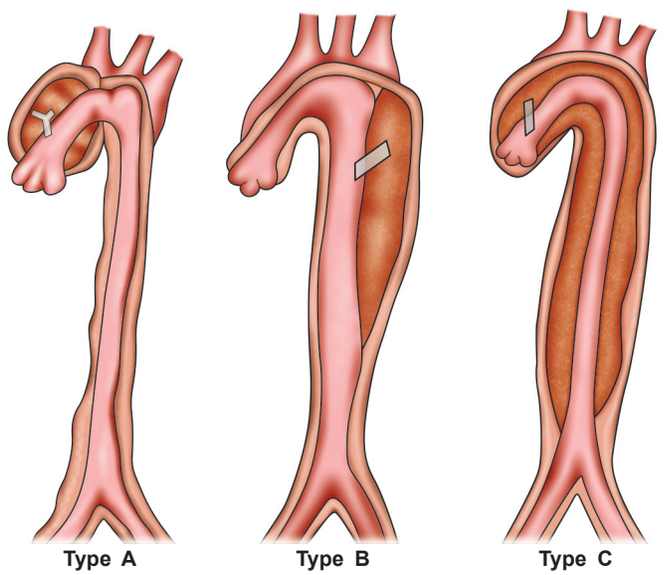

Fig. 1: Classification of aortic dissections. Type A dissection: Dissections proximal to origin of left subclavian artery. Type B dissection: Tear distal to origin of left subclavian artery with no involvement of the ascending aorta. Type C dissection: Dissection extends both proximally and distally to origin of left subclavian artery. The current standard classification recognizes two types: (1) Type A, when the ascending aorta is involved, irrespective of the site of tear; (2) Type B, when only the descending aorta distal to the origin of the left subclavin artery is involved

CLINICAL FEATURES AND DIAGNOSIS[2,3]

Excruciating pain starting most often in the back is the presenting feature. The pain is also felt in the front of the chest and may radiate to the shoulders and the left arm, or to both arms. Invariably the patient is admitted to the intensive care unit with a diagnosis of acute MI. The correct diagnosis depends on a high index of suspicion. The clinical features of shock often accompany the agonizing pain, but a noteworthy feature in a number of these patients is the persistence of hypertension in the presence of other shock-like features.

Clinical features that must be carefully searched for are—

- An inequality of pulses in the upper limbs, or the disappearance of the pulse in an upper limb or even a lower limb.
- The appearance of a rough systolic murmur at the base, or over one or both carotids.
- Pulsations over one or the other sternoclavicular joint.
- The development of a diastolic murmur of aortic incompetence. At times, a soft systolic or even continuous murmur is heard over the middle of the back in extensive dissection of the thoracic aorta.
- Focal neurological signs, if dissection involves the carotid or vertebral arteries, with compression of the lumen of these vessels.
- The absence of classical ECG changes of myocardial infarction, and no rise in creatinine kinase isoenzyme (CK-MB) or troponin levels in blood, in spite of severe pain compatible with MI.
- Extremely wide radiation of pain, which may be felt over the lower thoracic spine, the small of the back, in the abdomen, and even involving the lower extremities. This should suggest a possible extensive dissection.

A hemorrhagic left-sided pleural effusion, when associated with the clinical features of an acute MI should also suggest the diagnosis of an aortic dissection. The pleural effusion is due to a slight leak of the dissection into the pleura, or at times due to pleural irritation.

About one-third of patients with dissection of the aorta present with manifestations of compromised flow to a major branch of the aorta. This is due to compression or thrombosis of the true lumen of a major branch as a result of pressure from the blood within the expanded false lumen. When the carotids and vertebrals are involved, the presentation is with a neurological deficit or a stroke; involvement of the subclavian causes ischemia to the upper limb; involvement of the mesenteric artery results in intestinal ischemia; involvement

of a renal artery results in renal failure or hypertension and of the iliofemoral vessels in lower limb ischemia.

Sudden death can occur from rupture of the dissected aorta into the pleura, the pericardium (causing cardiac tamponade), the retroperitoneum or into the abdomen.

INVESTIGATIONS

An X-ray of the chest shows a widened mediastinum in 50% of cases. A double contour of the arch at the start of the descending aorta, may occasionally suggest the diagnosis. A small left sided pleural effusion may occasionally be observed when the adventitia oozes red blood cells from the dissecting hematoma. A progressive widening of the mediastinal shadow strongly suggests the diagnosis.

Echocardiography Transesophageal echocardiography (with the probe within the esophagus) is a very useful non-invasive method of demonstrating a dissection, and also of demonstrating the intimal flap, which points to the site of the dissection.[4]

A computed tomography (CT) scan or an MRI of the thorax invariably proves a dissection, clearly demonstrating the double lumen in the aorta, and often pointing to the site or origin of the dissection (Figs 2A and B).[5]

Most surgeons before surgery prefer to have an anatomical display of the dissection through an aortography. This indeed is not required if all the necessary information is available through echocardiography and a CT or MRI of the chest. What is more, if the intimal flap has been sealed off (which may happen within a few days of the dissection), an aortogram may not be able to pick up the dissection. In such patients, if the diagnosis is highly suspect, it is mandatory to do a CT or MRI of the chest, if these investigations have not been done.

MANAGEMENT[6,7]

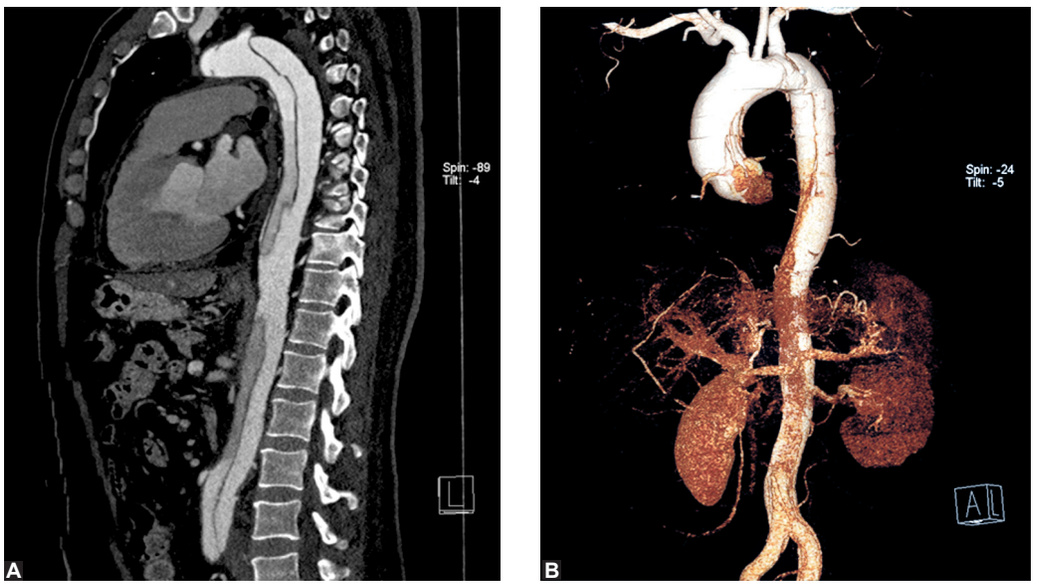
The patient under intensive care should be continuously monitored with regard to vital signs, ECG, relevant investigations on the blood, and serial X-rays of the chest. The BP should be constantly monitored. The principles of management are (Box 2)—

- *Complete bed rest.*
- *Relief of pain* with morphine, buprenorphine or pethidine. Small bolus doses (2–5 mg of morphine) should be given intravenously, and repeated as and when necessary.

Box 2: Principles of management of aortic dissection

- Complete bed rest
  Relief of pain with morphine (2–4 mg IV), or buprenorphine (0.2–0.4 mg IV), or pethidine (75–100 mg IM)
- Quick reduction of blood pressure—In hypertensive patients systolic BP should be maintained between 100–120 mm Hg; in non-hypertensive patients, keep systolic BP around 90 mm Hg. A combination of IV nitroprusside and IV propranolol (0.5–1 mg every 15–30 minutes till beta-blockade achieved), is commonly used. Many units now prefer to use IV labetalol (see text) instead of the above combination
- Medical therapy continued with in the following cases—
  - In patients with uncomplicated Type B dissection (dissection distal to origin of left subclavian artery, with no involvement of the ascending aorta), who have responded well to medical therapy (relief of pain, control of BP), and are hemodynamically stable
  - In patients with stable, chronic dissection (2 weeks or more after onset)
  - Failure of opacification of double lumen on aortography
- Definitive surgical therapy for aortic dissection in selective cases

Abbreviations: IV, intravenous; IM, intramuscular; BP, blood pressure.



Figs 2A and B: Aortic dissections

- *Reduction of blood pressure* This is imperative in all hypertensive patients. The pressure should be quickly and sharply reduced to a systolic of about 100 mm Hg provided tissue perfusion is adequate. It should never exceed 120 mm Hg. In the rare instances when the patient is not hypertensive, the systolic BP should be kept around 90 mm Hg. It is preferable to use intravenous infusions of nitroprusside to lower the blood pressure and to maintain it at the desired level. The method of infusion has already been described earlier. It is important to combine the use of nitroprusside with a beta-blocker. This is because sodium nitroprusside increases the dP/dT, which is a measure of the velocity of left ventricular ejection. An increase in the velocity of left ventricular ejection is an undesired effect in aortic dissection, and can be countered by a beta-blocker, which reduces dP/dT—an advantage in dissection. For an acute or rapid reduction in dP/dT, propranolol is given intravenously in a dose of 0.5–1 mg every 15–30 minutes till satisfactory beta-blockade occurs. For the maintenance of beta-blockade in a stable dissection, propranolol is given orally in a dose 20–40 mg thrice daily.

Many units in the West prefer the use of labetalol to nitroprusside in control of hypertension in aortic dissection. The drug is a selective alpha-blocker and a non-selective beta-blocker, and thereby reduces dP/dT and the systolic BP by beta-blockade and vasodilation. A bolus injection of 0.25 mg/kg is given intravenously over 2 minutes and repeated every 10–15 minutes. The drug can also be given through a continuous infusion at 1–2 mg/minute.

Esmolol, a very short acting β_1 selective receptor blocker is also very useful in the prompt control of acute hypertension in aortic dissection. It is given as an IV bolus in a dose of 500 µg/kg per minute over 11 minutes and then as an infusion of 150–300 µg/kg per minute. The infusion is titrated to keep the systolic BP at 100 mm Hg.

If labetalol and esmolol are unavailable, sodium nitroprusside combined with propranolol or metoprolol are equally effective.

Oral antihypertensives like alpha methyldopa, ACE inhibitors or calcium channel blockers may be used in addition, once the BP has been urgently brought down to a desired level (about 100 mm Hg systolic) with IV parenteral therapy.

Patients who do not tolerate beta-blockade [patients with asthma, congestive heart failure and chronic obstructive pulmonary disease (COPD)] can be treated with trimethaphan, a ganglion blocking agent for a quick reduction in BP. The drug is given in a dose of 1–2 mg/minute in a slow IV infusion for 24–48 hours. The head end of the bed is elevated to maximize the orthostatic hypotension the drug induces and the BP is monitored and maintained around 100 mm Hg systolic. The use of trimethaphan is associated with rapid tachyphylaxis and with unpleasant sideeffects due to ganglion blockade. We have no experience with the drug.

Box 3: Indications for definitive surgical therapy in aortic dissection (surgical expertise and experience mandatory)

- Type A Dissection (dissection starting in proximal aorta)
- Type C Dissection (dissection extends both proximal and distal to origin of left subclavian artery)
- In presence of aortic insufficiency
- Impending rupture of aneurysm (even in Type B variety)
- Compromised blood flow to a major branch of the aorta
- Large hemorrhagic pleural effusion
- Cardiac tamponade
- Failure to control hypertension or pain with medical therapy

Lowering the BP produces dramatic relief in back and chest pain. Once the pain is relieved and the BP lowered, the patient may be sent for a CT or an MRI of the chest, or if needs be for an emergency aortography. An echocardiography can easily be done at the bedside. Esophageal echocardiography as mentioned earlier, is of great help. It must be done expertly without causing a rise in the BP during passage of the probe into the esophagus.

Medical therapy is continued for a Type B tear, i.e. a tear distal to the origin of the left subclavian in which the ascending aorta is uninvolved, provided there is relief of pain, control of BP and a stable clinical state. Other indications for medical therapy are a stable, chronic aneurysm (onset more than 2 weeks), failure of opacification of a double lumen on aortography, and the unavailability of surgical expertise.

The first requisite for surgical therapy is surgical expertise and experience with the problem.[7] If this is available, the indications for surgery include a Type A dissection (dissection starting in and only involving the proximal aorta), Type C dissection (where dissection extends both proximal to the origin of the left subclavian, and also extends distal to it). Other indications for surgery are aortic insufficiency, impending rupture of the aneurysm (even in the Type B variety), a large hemorrhagic pleural effusion, cardiac tamponade, and inability to control pain or reduce hypertension with drug therapy. Indications for definitive surgical therapy are listed in Box 3. Surgical therapy involves resection and graft replacement. Successful medical or surgical therapy should be followed-up by the continued use of antihypertensive drugs which should include a beta-blocker.

CHAPTER 27

Pulmonary Embolism

INTRODUCTION AND IMPORTANCE[1]

Pulmonary embolism (PE) is the third most common cause of mortality after coronary artery disease and stroke. It is the commonest cause of death in the puerperium and postoperative period. Despite its importance, it remains underdiagnosed in our country and hence in a sense neglected. Indeed, up to 80% of pulmonary emboli found at autopsy had not been suspected antemortem. This must be one of the most staggeringly poor diagnostic rates for any disease in all of medicine. Despite all the advances in diagnosis, this appalling diagnostic rate has not changed over the last four decades. Sadly, physicians cannot diagnose what they do not suspect and this is the crux of the problem with PE as we shall discuss later in the chapter.

The problems in PE in the intensive care unit (ICU) are twofold—

1. It can occur as a complication in patients who are already critically ill with diverse medical and surgical problems. The manifestations may be subtle, and the diagnosis in these patients is difficult to make, and at times difficult to confirm. The usual modes of treatment in many of these critically ill patients are hazardous. The importance of being reasonably certain of the diagnosis, before starting potentially hazardous therapy is therefore evident.
2. Patients with PE may also present with acute cardiorespiratory failure. When this occurs against a background of recovery from recent surgery, the diagnosis is generally obvious, and the management well-defined. When acute cardiorespiratory failure due to PE occurs against a background unrelated to surgery, the diagnosis may be often missed with disastrous consequences.

Pulmonary embolism is believed to affect 600,000 patients annually in the US. Of these, 200,000 die from their PE. It is responsible for at least 15% of all hospital deaths in some hospital mortality series from the US. It is unfortunately, still the general belief that PE within or outside the ICU is comparatively uncommon in India when compared to the West. This is untrue; the incidence of PE is about the same. In our critical care unit, the incidence of PE is very close to that observed in the West. In 2006, Kapadia SR and colleagues from Sir Ganga Ram Hospital, New Delhi[2] noted that PE occurred in as many as 40% of 1,552 consecutive Indian patients with symptomatic deep vein thrombosis (DVT); 47% of patients with PE judged from a high-probability lung perfusion scan were asymptomatic. Considering that many patients with DVT are asymptomatic, the incidence of both DVT and PE would be much higher than is apparent. Increasing awareness will perhaps provide a much clearer idea about the prevalence of venous thromboembolism in India, which is certainly much higher than what is generally believed.

SOURCES OF PULMONARY EMBOLISM

The two main sources of embolism are venous thrombosis in the lower limbs, thrombi within the right atrium in patients with atrial fibrillation, and other supraventricular arrhythmias. Thrombi within the right ventricle causing PE can occur following septal infarction or a right ventricular (RV) infarction.

Conditions that lead to venous stasis, endothelial cell damage and a subclinical hypercoagulable state, predispose to venous thrombosis. Venous thrombi in the legs leading to thromboembolism are most frequent in the popliteal veins above the knee, and in the femoral vein within the thigh. Rarely, thrombi within the pelvic veins may also lead to PE.

Deep vein thrombosis in the calves is common; generally, these thrombi extend upward into the popliteal veins before thromboembolism occurs.

Risk factors of venous thrombosis in the lower limbs include trauma to a limb, generalized trauma, immobilization of a limb, complete bed rest, sitting for long periods, as in air, train or vehicular travel, congestive heart failure, recent surgery, pregnancy, pelvic disease and recent myocardial infarction. Femoral and popliteal vein thromboses with thromboembolism are important complications of total hip or knee replacement surgery. Both oral contraceptives and postmenopausal hormone replacement therapy increase the risk of venous thromboembolism. The pulmonologist must not forget that chronic obstructive pulmonary disease (COPD) is an important risk factor both for DVT and PE. Cancer promotes the production of procoagulant factors and is an important risk factor in venous thrombosis and thromboembolism. Occassionally, venous thrombi in the legs and thromboembolism is a manifestation of an occult cancer, in particular, cancer of the pancreas, ovary and a primary cancer of the liver. Any acute critical illness requiring intensive care may perhaps be associated with an increased incidence of venous thrombosis. Current data have identified heavy smoking and hypertension as new independent risk factors for DVT.

In patients who present with venous thrombosis with or without thromboembolism, and who have no risk factors, it is important to test for hypercoagulable states, either genetic or acquired. There have been major advances in our knowledge of the molecular markers of thrombophilic states. The two most important are the Leiden mutation of Factor V, which confers a resistance to activated protein C, and the G20210A mutation of prothrombin. Both these occur in about 4% of the Caucasian population. Other rarer genetic defects include antithrombin deficiency (0.02%), protein C deficiency (0.2%), and protein S deficiency (0.1%). Similar data from Indian populations are needed but at present lacking. Intriguingly, Factor V Leiden and prothrombin mutation are stronger risk factors for DVT than PE. Occasional patients are heterozygous for two of these anomalies and then carry a much greater thrombotic risk. Conversely, certain genetic traits offer protection. This includes the O blood group which appears to reduce the risk of DVT even in carriers of Factor V Leiden. Elevated level of homocysteine is also an independent risk factor though the genetics of transmission are not as yet clear. A detailed genetic prothrombotic screen should be mandatory in patients with a history of DVT or PE occurring without any other traditional risk factor; in those with a positive family history; those with recurrent episodes of thrombosis; patients with their initial thrombotic episode at a young age; and in patients with arterial and venous thrombosis or thrombosis in unusual sites.

Acquired factors causing thrombophilia include the presence of lupus anticoagulant and antiphospholipid antibodies, which predispose chiefly to venous but also to arterial thrombosis (Box 1).

Box 1: Important risk factors for deep vein thrombosis and pulmonary embolism

- *Surgery—*
  - Major abdominal, pelvic surgery
  - Hip, knee surgery
  - Trauma
  - Fractures
  - Spinal cord injury
- *Immobilization—*
  - Hemiplegia
  - Paraplegia
  - Prolonged recumbency
- *Obstetrics—*
  - Pregnancy
  - Puerperium
- *Airplane, train, car travel*
- *Hormonal treatment—*
  - Oral contraceptives
  - Hormone replacement therapy
  - Tamoxifen, raloxifene
- *Cardiorespiratory—*
  - Congestive cardiac failure
  - Atrial fibrillation, supraventricular tachycardia
  - Myocardial infarction: septal infarct, right ventricular infarction
  - Cardiomyopathy
  - Bacterial vegetations on the tricuspid valve
  - Chronic obstructive pulmonary disease
- *Past history of DVT/PE*
- *Malignancy—*
  - Abdominal, pelvic
  - Advanced, metastatic
  - Concurrent chemotherapy
- *Inflammatory bowel disease*
- *Nephrotic syndrome*
- *Obesity*
- *Genetic factors —*
  - Factor V Leiden disease
  - Protein C and Protein S deficiency
- *Acquired thrombophilia*
- *Lupus anticoagulant*
- *Antiphospholipid antibody syndrome*

Venous thrombosis in the upper limbs is uncommonly associated with PE. However, if the patient has had a central venous line for many weeks or has a Hickman's catheter, there is a definite risk of thrombus formation in the central vein, even if the central line has been changed periodically. Occasionally, massive fatal PE resulting from such a thrombus may be seen.

Very rarely in the ICU, a catheter tip of a central venous line is sawed off by the bevel or the point of the large needle through which the catheter is introduced. This tip may travel to the lung and produce PE.

Fat embolism after fractures and crush injuries should always be kept in mind. Air embolism following accidental injection of a large bolus of air (or following entry of air from other causes) into the systemic venous circulation, or tumor

emboli particularly in hypernephromas, or from other tumor tissue gaining access to the venous circulation, may also be occasionally observed.

PATHOPHYSIOLOGY

The clinical features of PE are due to three possible pathophysiological changes—

- *Acute circulatory compromise* due to an obstructed pulmonary circulation. This occurs with massive embolism or when numerous thromboemboli block a large cross-section of the pulmonary circulation (>60–70% of the circulation). This circulatory compromise is characterized by pulmonary hypertension (PH), RV dilatation and dysfunction, right-sided heart failure and a low cardiac output, which when marked leads to cardiogenic shock. The dilated right ventricle causes a septal shift to the left, resulting in underfilling of the left ventricle, a decreased systemic cardiac output and myocardial ischemia from reduced coronary perfusion.
- *Gas exchange abnormalities* generally characterized by a low PaO_2 with a lowered $PaCO_2$ High V/Q areas are responsible for increased dead space ventilation. Tachypnea and an increased minute ventilation allow a normal, and often a lower than normal $PaCO_2$ to be maintained. If the dead space is markedly increased, and the minute ventilation does not increase proportionately, the $PaCO_2$ may rise. The alveolar PCO_2 is characteristically slightly lower than the arterial $PaCO_2$.

  Normal arterial blood gases do not exclude PE. In fact, arterial hypoxemia is generally never marked, except in massive embolism associated with a shock-like state. The PaO_2 is rarely less than 55 mm Hg. A lowered PaO_2 is due to ventilation-perfusion mismatch resulting from atelectasis, and to redistribution of pulmonary blood flow, which causes a fall in the V/Q ratio in areas of the lung that are unobstructed by pulmonary emboli.
- *Pulmonary infarction may* occur but is not commonly observed in PE. Patients with congestive heart failure are more prone to develop pulmonary infarction because of pre-existing raised pulmonary venous pressure.

  The clinical manifestations of thromboembolism often appear to be far more serious than what is expected from the degree of vascular occlusion. In critically ill patients in the ICU, this could be due to two causes: (1) a poor pre-existing cardiopulmonary reserve; (2) release of vasoactive and bronchoconstrictive mediators from platelets and perhaps from other sources, following embolism. This potentiates PH, accentuates ventilation-perfusion disturbances, and adds to the already existing tachypnea.

PULMONARY EMBOLISM SPECTRUM

The outcome following PE is a function of the size of the PE and the underlying cardiopulmonary status. A small PE may be poorly tolerated and tip the balance in a patient with advanced COPD while an otherwise fit young person might tolerate the effects of a larger PE without compromise. There is a spectrum in the severity of the PE, from mild to massive. At one end, the patient with mild PE may remain asymptomatic with the PE detected incidentally. In the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study,[3] there were 20 such patients who had mild PE, which was not initially diagnosed and hence not treated.

The mortality in these patients, even when untreated, was only 5%. At the other end of severity is a massive PE, which can cause almost immediate cardiorespiratory arrest. A massive PE is one that results in hemodynamic instability. Overall, these PEs are rare; in the PIOPED II series,[4] only 10% of all PEs could be classified as massive. The majority of PEs fall in between these two groups. This category includes submassive PE. These are patients with a sizeable clot burden, no hemodynamic instability when they first present, but show echocardiographic evidence of right heart dysfunction. These patients will be discussed in more detail later.

CLINICAL FEATURES: PULMONARY EMBOLISM SYNDROMES

The symptoms of PE are nonspecific and include dyspnea, chest pain, fever, cough, hemoptysis and apprehension. The signs are equally nonspecific and include tachypnea, tachycardia, auscultatory crackles, a pleural rub and an accentuated pulmonary component of the second heart sound. Evidence of an associated DVT must be carefully looked for, though this is often not clinically obvious. Because the symptoms and signs are nonspecific, attempts have been made to combine them into scoring systems. The best validated is that of Wells,[5] which can immediately be applied at the bedside on first seeing a patient. It gives the patient points based on previous PE/DVT; heart rate greater than 100/minute; recent surgery or immobilization; clinical signs of DVT; alternative diagnosis less likely than PE; hemoptysis and cancer. This scoring system can be applied to inpatients and outpatients and has recently been externally validated. Adding on D-dimer further increases the accuracy of this clinical prediction system (Table 1).

The presentation of PE in the ICU is varied. The clinical syndromes are as follows—

1. Sudden death.
2. Shock, with a low output hypotensive state. Severe chest pain (indistinguishable from the pain of acute myocardial infarction) may or may not be associated with the shock-like state.
3. Acute right heart failure, with increase in the central venous pressure (CVP), prominent "a" waves in the jugular veins, and auscultatory evidence of PH.
4. Acute respiratory failur, with dyspnea, tachypnea, and at times, cyanosis.
5. Features of (2), (3) and (4) are combined in massive embolism: various combinations are observed depending on the interval after acute embolism. Shock often predominates in the earliest phase and is associated with a

Table 1: Wells clinical prediction rule for pulmonary embolism

Clinical feature	*Points*
Clinical symptoms of DVT	3.0
Other diagnosis less likely than PE	3.0
Heart rate greater than 100 beats per minute	1.5
Immobilization or surgery within past 4 weeks	1.5
Previous DVT or PE	1.5
Hemoptysis	1.0
Malignancy	1.0
Total	

Abbreviations: PE, pulmonary embolism; DVT, deep venous thrombosis.
Risk score interpretation (probability of PE):
>6 points: high risk (78.4%)
2–6 points: moderate risk (27.8%)
<2 points: low risk (3.4%)

Box 2: Syndromes associated with pulmonary embolism

- Pulmonary infarction syndrome
- Isolated dyspnea syndrome
- Syndromes associated with massive pulmonary embolism manifesting as—
  1. Sudden death
  2. Shock and/or prolonged syncope
  3. Acute right heart failure
  4. Acute respiratory failure
  5. Severe bronchospasm and pulmonary edema
  6. Combination of (2), (3), (4) and (5)
- Subtle features like unexplained tachycardia, increasingly unstable circulatory state, supraventricular arrhythmia, unexplained tachypnea, postural hypotension or syncope

Box 3: Diagnostic tests for pulmonary embolism

- Chest radiograph
- Electrocardiogram
- D-dimer
- Lower limb venous compression ultrasonography
- Arterial blood gases

- Helical CT pulmonary angiography
- Pulmonary angiography

raised CVP, hypotension and hypoxic respiratory failure. If recovery ensues, features of PH become more evident.

6. Rarely, massive PE causes acute pulmonary edema or overwhelming bronchoconstriction.
7. Less massive, frequent, multiple, small emboli in already critically ill patients may show very subtle features. These include tachycardia, an increasingly unstable circulatory state, and supraventricular tachycardia. Tachypnea (at times episodic), faintness or actual syncope, particularly on changing from the supine to the sitting posture, may also be observed. There may be an unexplained fall in the PaO_2 or an increase in an already existing hypoxia. Sometimes, a rapid deterioration in the clinical state of a seriously ill individual, a low-grade fever, a high ESR without apparent cause; or unexplained icterus may be related to silent PE. All these subtle features described above unfortunately lack specificity and sensitivity and may well be due as much to the critical illness per se, as to a complicating PE.
8. Pulmonary infarction. Pulmonary infarction is not frequently observed. When it does occur, its significance should not be missed. Hemoptysis, pleural pain and an unexplained occurrence of a pleural effusion in a critically ill patient suggest embolism. One or more shadows within the lung, or other radiological features compatible with PE should also prompt a correct clinical diagnosis.

Clinical evidence of accompanying venous thrombosis in the lower limbs and the presence of atrial fibrillation are the strongest pointers to a possible PE. Among the significant features to be looked out for in the clinical diagnosis of DVT, are tenderness and swelling of the calf muscles; pain in the calf on dorsiflexion of the foot (Homan's sign), rise in the skin temperature of one limb, edema of the leg or foot, and delayed cooling of an exposed lower limb (Provan's sign). One or more of these signs are positive in 50% of patients with PE. *However, absence of clinical signs in no way excludes femoral, popliteal or deep vein thrombosis (Box 2).*

DIAGNOSTIC TESTS (BOX 3)[6,7]

Chest Radiograph (Figs 1 and 2)

The chest radiograph can be normal though this is rare with massive PE. In the PIOPED series[4] of massive PE, only 16% of patients had a normal chest radiograph. Focal oligemia, if carefully looked for, will be noted in 40–80% of patients. Plate-like atelectasis, basal wedge-shaped shadows and pleural effusions are other distinctive but nonspecific radiological manifestations. The presence of pre-existing cardiopulmonary disease makes appreciation of these features even more difficult. The chest radiograph is also invaluable in patients with PE for differential diagnosis of other conditions like pneumonia, left ventricular failure or pneumothorax.

Electrocardiogram[8]

The electrocardiogram (ECG) is usually normal in smaller PE. In massive PE, a normal ECG is uncommon but did occur in as many as 30% of PIOPED patients with major PE. Transient ST-T changes are the commonest ECG manifestations and may

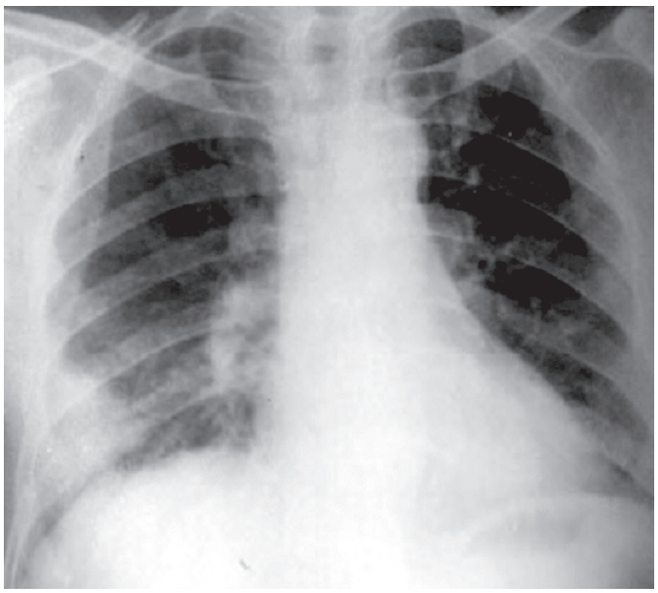

Fig. 1: Chest X-ray demonstrates a wedge-shaped opacity in the right lower zone with its apex pointing to the hilum representing a pulmonary infarct. Note the enlarged and prominent right pulmonary artery (Westermark sign)

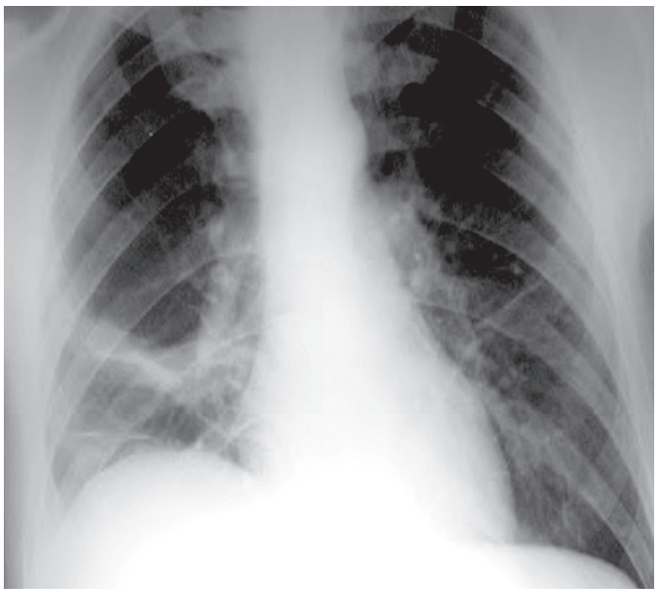

Fig. 2: Pulmonary infarct. Chest X-ray demonstrates a linear band in the right lower zone with an elevated right dome of diaphragm. The linear band represents an infarct with elevation of the right dome due to underlying volume loss. An atelectatic band is also seen in the left lower zone representing an infarct

occur in 50–70% of patients. A $S_1Q_3T_3$ pattern may be seen, along with transient right bundle branch block (RBBB) or atrial fibrillation. Anterior lead T-wave inversion is the pattern that best correlates with the severity of the PE, occurring in 90% of massive compared to 20% of nonmassive PE.

D-Dimer

D-dimer is a breakdown product of cross-linked fibrin and is sensitive marker of acute thrombosis. A normal D-dimer in a low clinical probability setting is an accurate way of ruling out PE. On the other hand, though the D-dimer is very specific for fibrin, the specificity of this test for PE is poor, because fibrin is produced in a variety of conditions including inflammation, infection, necrosis and cancer. Hence, a D-dimer above 500 μg/L has a poor positive predictive value for PE and cannot reliably rule in the disease. But a D-dimer level below this cut-off value reliably rules it out, especially in a low probability setting. Nuclear scanning or spiral computed tomography (CT) angiography may not be needed in this group. There are presently four different assays available and it is important to use the highly sensitive enzyme-linked immunosorbent assay (ELISA) or automated turbidimetric assay to get the most sensitive results. Results are generally available at the bedside in an hour, making this a cost-effective and useful screening test.

Lower Limb Venous Compression Ultrasonography[9]

In studies using venography as the gold standard for detecting proximal DVT, lower limb venous compression ultrasonography, an entirely noninvasive test, had a sensitivity of 97% and a specificity of 98% for symptomatic, proximal DVT. The absence of full compressibility of the deep vein on applying pressure through the ultrasound probe is the single best validated diagnostic criterion. The advantage of this test is that it is noninvasive and can be performed at the bedside. The finding of DVT by ultrasonography in a patient with suspected PE is sufficient evidence to commence anticoagulant therapy without any further testing. Approximately, 50% of PE suspects will have evidence of DVT on sonography, and further invasive and costly tests are not required in these patients. The exact position of ultrasonography in the diagnostic algorithm of PE is still being refined.

Arterial Blood Gases

Hypoxia is usual but not universal following a major PE. Approximately, 20% of patients with proven PE will have a normal arterial oxygen pressure and alveolar arterial oxygen gradient.

Echocardiography[10] (Flowchart 1)

Echocardiography is an enormously useful test to detect the presence and severity of RV pressure overload. RV dysfunction (RV dilatation, hypokinesia) on ECHO helps in stratification of these patients. If present, it denotes greater than 50% obstruction to the pulmonary circuit. Other echocardiographic findings include: increased RV/LV diameter ratio, paradoxical septal motion, pulmonary artery dilatation and evidence of tricuspid regurgitation. The sensitivity of these signs which are often combined is between

  - 2 or more moderate + 1 large mismatched perfusion lung scan defect
    or
  - 4 or more moderate mismatched perfusion lung scan defects
- Intermediate probability—
  - Borderline high or borderline low
  - Not falling into high, low or normal categories
- Low probability—
  - Nonsegmental perfusion defects only
    or
  - 1 moderate mismatched segmental perfusion defect with normal chest X-ray
    or
  - Any perfusion defect with a larger abnormality on chest X-ray
- Normal—
  - No perfusion defects
  - Perfusion outlines exactly the same as shape of lungs on chest X-ray

40% and 70% in patients with clinically suspected PE and their specificity approaches 90%. Thus, echocardiography has emerged as a first-line test in patients with suspected massive PE. *It is extremely useful in the differential diagnosis of shock due to massive PE from cardiogenic shock, cardiac tamponade, valvular heart disease and aortic dissection*. Indeed, absence of PH and/or RV dilatation and hypokinesia makes PE as the cause of shock unlikely. In a small subset of patients with PE, transthoracic echocardiography allows a direct visualization of the clot in the right heart chambers or in the right main pulmonary artery.

Ventilation/Perfusion Lung Scintigraphy

The landmark PIOPED study[3] showed us that V/Q scanning retains its importance. The perfusion scan is done by injection of albumin macroaggregates labeled by technetium-99m. The macroaggregates are trapped in approximately 0.1% of the pulmonary capillary circuit and may be imaged by a gamma camera. Any disease that narrows the airways or fills the alveoli will result in hypoxic pulmonary vasoconstriction; hence, this pattern is not highly specific for PE. If the perfusion defect is large or segmental, it makes the diagnosis more likely. The addition of ventilation scintigraphy by xenon-133 or aerosolized technetium-99m further increases the specificity. This so-called mismatched defect, i.e. perfusion defect with normal ventilation, is highly predictive of PE. Based on revised data from the PIOPED study, lung scans are currently classified into normal, high probability and nondiagnostic. The high negative predictive value of a normal lung scan has been confirmed by several studies including a large outcome study. Equally useful is the positive predictive value of a high probability scan (around 90%) and this is sufficient evidence to rule in PE and proceed with treatment without subjecting the patient to further testing. Recent evidence suggests that a chest radiograph may replace the ventilation scan and be combined with a perfusion scan to give excellent overall agreement of 88% and positive predictive value of 86% for a scintigraphic mismatch. Unfortunately, in the latest study from Wells and his group,[11] only 41% of all V/Q scans fell into the normal or high probability group. The majority were nondiagnostic. These scans carry a 30% likelihood of PE and hence the majority (around 60%) of patients who undergo V/Q scanning will need to undergo further tests to rule in or rule out suspected PE. *For this reason and because it is inconvenient and often impossible to transport a critically ill patient to the nuclear medicine department, the ventilation scintigraphy scan is rarely used for diagnosis of PE in the ICU. Nevertheless, one must be aware of this diagnostic modality (Box 4).*

Helical CT Pulmonary Angiography[12] (Figs 3 and 4)

This noninvasive test offers excellent imaging of the pulmonary vasculature. It has by and large replaced V/Q scanning as a diagnostic modality for PE and has nearly (if not

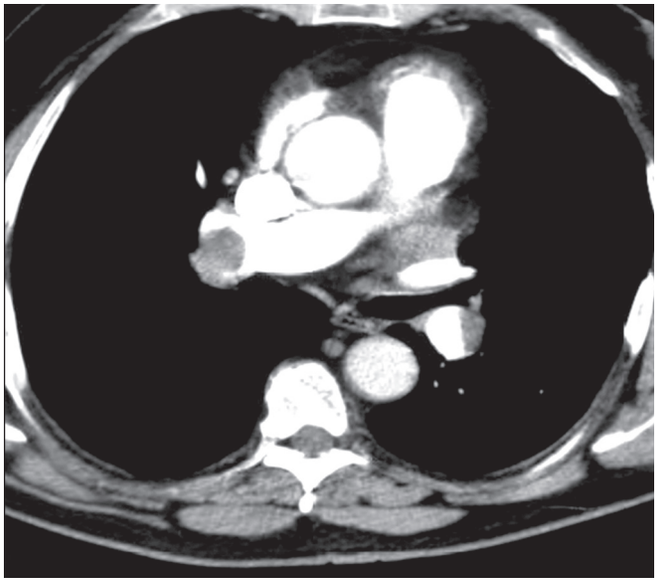

Fig. 3: Bilateral pulmonary emboli. Computed tomography angiography demonstrates pulmonary emboli in both pulmonary arteries

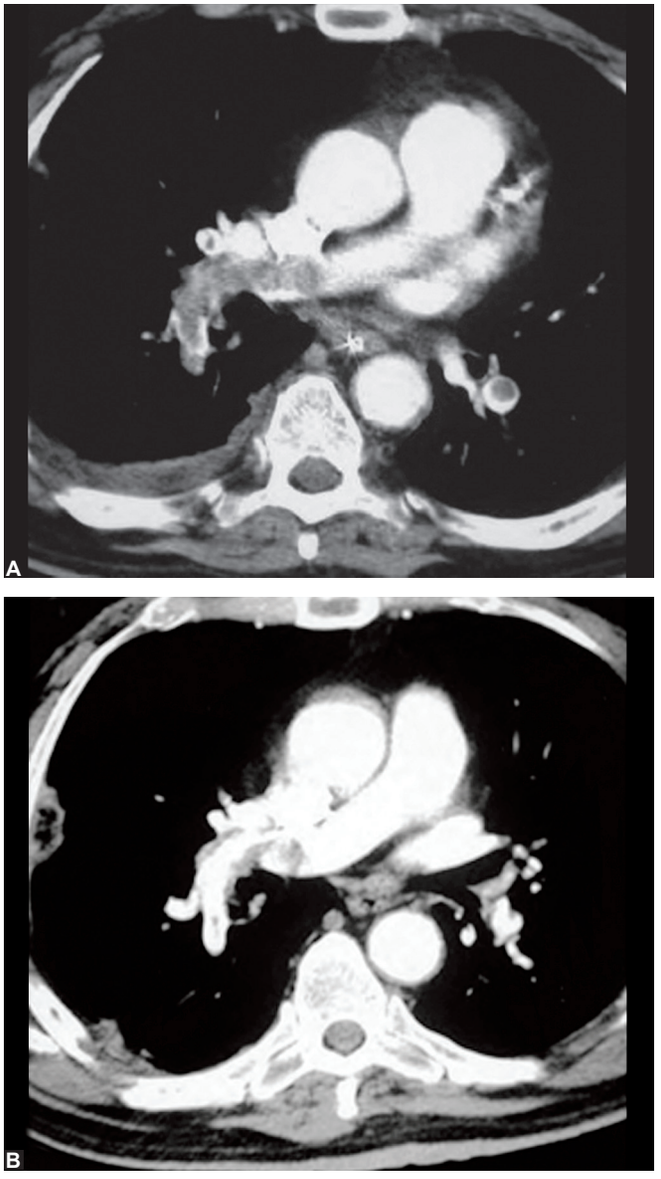


Figs 4A and B: Pulmonary emboli. Computed tomography angiography demonstrates a large embolus in the right pulmonary artery and a smaller embolus in the left pulmonary artery

completely) eliminated the need for invasive pulmonary angiography. Newer and still evolving technology used in helical CT pulmonary angiography has further increased the sensitivity and specificity for detecting PE, the sensitivity ranging from 83% to 100% and specificity from 89% to 97%. This sensitivity and specificity favors comparably with that observed in invasive pulmonary angiography. The advantages of CT angiography when compared to V/Q screening and invasive pulmonary angiography are summarized below—

- Computed tomography angiography is noninvasive, convenient and can be performed safely and quickly in critically ill patients, particularly those in shock and/or in acute right heart failure.
- Studies comparing CT angiography to V/Q scanning suggest that CT angiography is a better test because of more frequent definitive confirmation of pulmonary emboli.
- In a critically ill individual, there is often a large differential diagnosis to PE. A CT angiography offers evidence of other causes as well as that of PE, which neither a V/Q scan nor invasive pulmonary angiography can provide.
- Computed tomography angiography of the legs and pelvis could be performed with the same contrast injection used to image the pulmonary vasculature. Detection of DVT in the femoropopliteal veins is as accurate as with ultrasonography. This procedure could also detect clots in the iliac, renal and caval veins, which are ultrasonographically inaccessible. The major limitation of helical CT pulmonary angiography is the inability to diagnose subsegmental branch emboli, with sufficient certainty. However, invasive pulmonary angiography also has significant limitations in detecting isolated subsegmental emboli. The only other major limitation of helical CT pulmonary angiography compared to V/Q scanning is the need to use contrast material, precluding its use in patients with renal failure and in patients allergic to the dye. It is also inadvisable to use this modality in pregnant women.

What does then one do in a patient with renal failure or in a pregnant woman clinically suspected of serious PE? If DVT or atrial fibrillation is present, one should proceed on the assumption that one is dealing with PE. In the presence of hemodynamic instability, a 2D-ECHO is of immense help. The presence of RV dilatation and PH points to PE.

Pulmonary Angiography

The role of pulmonary angiography in the diagnosis of PE is now sharply reduced. Perhaps, a helical pulmonary CT

angiography might miss out on subsegmental pulmonary emboli which an invasive CT angiography would detect. But is it necessary to diagnose with certainty subsegmental emboli? Data from three large studies suggests that underdiagnosing subsegmental emboli by avoiding pulmonary angiography does not affect the clinical outcomes of recurrent embolism or death.[13] A clinical outcome approach is as safe as the PIOPED approach, less expensive, more convenient, less fraught with immediate risks to the patient and more acceptable to the patient and the physician.

PRINCIPLES OF MANAGEMENT

- *Use of anticoagulants or the use of thrombolytic therapy for the purpose of dissolution of thrombi obstructing the pulmonary circulation. This therapy also helps in dissolution of thrombi in the leg veins, and prevents further embolization.*
- *Cardiorespiratory support in patients with major or massive embolism.*
- *Preventive measures.*

USE OF ANTICOAGULANTS[14]

Unfractionated Heparin

Heparin forms the mainstay of treatment. Unfractionated heparin is started after the diagnosis is made. Around 5,000–7,500 units are given intravenously as a bolus dose, followed by a continuous microdrip infusion at the rate of 1,000 units/hour. The dose is adjusted so as to keep the activated partial thromboplastin time (APTT) to about twice the normal value. Initially, this is measured every 6 hours, and then once or twice daily.

It is important to ensure that the requisite rise in the APTT is quickly achieved, and constantly maintained. If the APTT done after the first 6 hours has not risen to the desired therapeutic range, the 24 hour dose of heparin is increased by 2,000–4,000 units, and the APTT is repeated after 6 hours. Conversely, if the APTT is greater than the therapeutic range of 2.5 times the normal value, the 24-hour dose of heparin is reduced by 2,000–4,000 units, followed by a repeat APTT after 6 hours.

Proper heparinization leads to a decrease in the rate of further embolization to less than 5%. Till recently, it was recommended that warfarin (a vitamin K antagonist) should be introduced only after 5–6 days of IV heparin by which time the APTT is raised to twice the control. Once introduced, warfarin is given daily in a titrated dose to raise the international normalized ratio (INR) between 2 and 3. Parenteral heparin is omitted when this target INR is achieved, and warfarin continued so that the INR is maintained between 2 and 3. It was believed that if warfarin is introduced early in an active thrombotic state, there is a fall in Protein C and Protein S, with an increase in the thrombogenic potential. An overlap with heparin was believed to prevent this.

However, the current American College of Chest Physicians (ACCP) recommendation[13] for the treatment of both deep vein thrombosis and PE is that a vitamin K antagonist (warfarin) should be started early, on the same day as parenteral heparin. Parenteral anticoagulation with heparin should be continued for a minimum of 5 days and until the INR is 2.0 or above for at least 24 hours.

Heparinization can be achieved by IV unfractionated heparin (UFH) as mentioned above, by subcutaneous UFH, by low molecular weight heparin (LMWH) or by fondaparinux. The ACCP 2012 guidelines suggested the use of LMWH or fondaparinux (a factor Xa inhibitor) over IV UFH and over subcutaneous UFH both for the prevention and treatment of DVT and PE.

If there are contraindications to anticoagulation, the guidelines recommend the use of an inferior vena cava (IVC) filter if there is DVT, and pneumatic compression of the legs as prophylaxis for DVT. The ACCP recommends against the use of an IVC filter in addition to anticoagulation. The use of the IVC filter is discussed at length later in this chapter.

Low Molecular Weight Heparin

The low molecular weight heparins (LMWHs) in common use are enoxaparin and dalteparin. The dose of enoxaparin (Clexane), the first LMWH to be introduced for prevention of DVT, is 40 mg subcutaneously daily; for the treatment of DVT or of PE, the dose is 1 mg/kg 12 hourly or 1.5 mg/kg daily.

The dose of dalteparin (Fragmin) for prevention of DVT is 2,500–5,000 units subcutaneous daily. For treatment of DVT and PE, the dose is 200 units/kg daily.

The LMWH has several pharmacokinetic and practical advantages over UFH. These are summarized as follows—

- Ease of use without need for routine monitoring of prothrombin time (PT) or INR.
- More predictable anticoagulant response.
- Standard dose apart from chronic renal failure (CRF) where the dose is reduced or halved, and morbid obesity where the dose is increased.
- Longer half-life, which permits once or twice daily-dosing.
- Facilitates earlier discharge and in some stable patients even home treatment.
- Lower risk of heparin-induced thrombocytopenia (HIT) or bleeding.
- Less binding to osteoblasts hence less osteopenia.

A meta-analysis of over 3,000 patients[15] who participated in DVT treatment studies showed that those receiving LMWH had lower mortality rates, less recurrence and suffered fewer complications including reduced HIT. All this was achieved at lower cost compared to UFH. A pivotal study by Levine[16] showed that enoxaparin, an LMWH administered twice daily reduced mean hospital stay from 6.5 to 1.1 days with fewer deaths and fewer bleeding complications. As a result of this and similar trials, the Food and Drug Administration (FDA) has approved enoxaparin (1 mg/kg twice a day) and tinzaparin (175 units/kg once daily) for outpatient or home treatment for

patients who present with symptomatic DVT with or without associated PE. As opposed to this data, there is as yet no data to suggest that outpatient treatment can be safely recommended in patients with PE alone. Whether LMWH or UFH is used, it serves as a bridge for five to seven days till anticoagulation with warfarin takes over.

Use of Xa Inhibitors

Fondaparinux is a factor Xa inhibitor which has been approved by the FDA for the prophylaxis of DVT and treatment of DVT and PE. The dose is 2.5–10 mg subcutaneously daily.

Oral Anticoagulation

Oral anticoagulation with warfarin is the mainstay of treatment and the dose is adjusted according to the PT. This is standardized by reporting results as the INR with a target INR of 2–3 being aimed for. In patients with recurrent PEs or underlying thrombophilic states the target INR is raised to 3–4. As mentioned earlier, current guidelines (2012)[14] recommend that warfarin is started early or the same day as heparin for treatment of both DVT/PE. Warfarin interacts with a number of commonly used drugs and even with the Vitamin K in green leafy vegetables resulting in wide fluctuations of INR. In addition, some patients (2–3% of the general population) have a genetic defect (polymorphisms in the cytochrome P450 CYP2C9), which makes them slow metabolizers and prone to major bleeding complications with even lower doses of warfarin. The current ACCP guidelines[14] on optimal duration of anticoagulation after a DVT/PE is ideally 3 months, if the patient had an underlying precipitating factor which is no longer applicable. In patients with a first episode of idiopathic DVT/PE in patients with a previous history of DVT/PE, in patients with active cancer, and in patients with high risk factors that are likely to persist, a 6–12 month initial period of anticoagulation is recommended. A study called the Prevention of Recurrent Venous Thromboembolism (PREVENT) trial[17] showed that after 6 months of warfarin, lower intensity dosing, so as to target an INR of 1.5–2 resulted in a further significant reduction in the risk of recurrences by 64%. In patients who have documented antiphospholipid antibodies or an underlying thrombophilic state, indefinite anticoagulation therapy is recommended.

Recurrent Thrombosis[18,19]

The 5-year incidence of recurrent venous thromboembolism off anticoagulants is approximately 30%. Well-documented factors for recurrent thrombosis include an initial unprovoked DVT or PE, advancing age, male sex, race (higher in blacks), presence of active cancer, obesity, an elevated serum D-dimer prior to stopping warfarin or 2 months after stopping warfarin, and ongoing immobility.

Complications of warfarin include bleeding, skin necrosis, alopecia and rashes. When patients present with very high INRs as a result of warfarin, the majority will be asymptomatic even with INR values greater than 5. Most can be managed with fresh frozen plasma, if they are bleeding or low oral doses of vitamin K. The usual injectable dose of 10 mg of vitamin K will result in patients being resistant to further anticoagulation with warfarin for at least a week and hence should be avoided.

Warfarin is contraindicated in pregnancy as it can cause embryopathy and intracranial bleed in the fetus. LMWH can be used safely in pregnancy. As far as possible, warfarin should not be used with aspirin as major bleeds can occur even when the PT is in the therapeutic range.

Newer Oral Anticoagulants[14]

The two newer oral anticoagulants are dabigatran and rivaroxaban. Dabigatran is a direct thrombin inhibitor and is FDA-approved to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation. The dose is 150 mg twice daily if the creatinine clearance is greater than 30 mL/minute and 75 mg twice daily if the creatinine clearance is less than 30 mL/minute. Rivaroxaban is a factor-Xa inhibitor. It is FDA-approved to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation. The dose is 20 mg once daily if creatinine clearance is greater than 50 mL/minute and 15 mg once daily if the creatinine clearance is less than 50 mL/minute.

Bleeding is the main complication of anticoagulant therapy. Bleeding due to warfarin and other vitamin K antagonists can be countered by vitamin K given orally or intravenously (depending on the severity of the bleed and degree of rise in INR), as also by the administration of fresh frozen plasma. Bleeding caused by UFH can be countered by IV protamine and by fresh frozen plasma. The latter is also useful in patients with a dilutional coagulopathy. However, the newer anticoagulants including the Factor-Xa a inhibitors (e.g. fondaparinux, rivaroxaban) and the direct thrombin inhibitors (e.g. bivalirudin, dabigatran, lepuridin, argatroban) do not have a true antidote. In the setting of life-threatening bleeding, recombinant factor VIIa may enhance thrombin generation and has been used for a reversal effect against these anticoagulants. Table 2 gives recommended drugs used to counter the bleeding caused by various anticoagulants.

Thrombolysis[14,20]

Thrombolysis can be a potentially lifesaving measure in patients with massive PE. In patients with PE who present with hemodynamic compromise in particular with persistent hypotension, there is little doubt that thrombolysis is indicated and can dramatically lower mortality. *A more controversial decision is whether to extend the indications of thrombolysis to include patients with submassive PE.* These are patients with PE who are hemodynamically stable on a clinical examination, but who have evidence of RV dysfunction on echocardiography putting them at higher risk of a bad inhospital course. The presence of RV dysfunction is a warning sign that escalation of therapy may be required or that death

Table 2: Recommended drugs used for reversal of major bleeding caused by anticoagulants

Anticoagulant	*Reversal agent*	*Dose/timing*	*Special considerations*
LMWH: Enoxaparin (1 mg/kg SC for DVT/PE/MI) Dalteparin— For MI: 120 IU/kg of body weight SC every 12 hours For DVT/PE: 200 IU/kg total body weight (SC) once daily	1. Protamine 2. rVIIa for severe bleeding	1. 1 mg protamine IV for every 1 mg of enoxaparin or 100 U of dalteparin 2. rVIIa 50–90 mg/kg IV	Only partially reversed by protamine and may require repeated doses
Parenteral direct thrombin inhibitors— • Lepirudin • Bivalirudin • Desirudin • Argatroban	1. Cryoprecipitate 2. Antifibrinolytics 3. Desmopressin acetate	1. >10 U cryoprecipitate 2. ε-aminocaproic acid 0.1–1.5 g/kg IV over 30 minutes then 0.5–1 g/hr infusion 3. 0.3 mg/kg IV desmopressin acetate	Desmopressin can be repeated 8 hourly. Can develop hyponatremia and seizures
Factor-Xa inhibitor— • Fondaparinux • Rivoraxaban	1. rVIIa	In severe bleeds: 90 mg/kg IV	Immediate effect Duration of effect: 2–6 hours
Oral direct thrombin inhibitor— • Dabigatran	1. Oral charcoal 2. rVIIa	1. Given within 2 hours of last dose 2. rVIIa 60–90 mg/kg IV	Hemodialysis if kidney function deranged

may occur with a conservative "hands off" approach. Even though these patients may appear stable they may develop ensuing cardiopulmonary instability over the next 48 hours. Pooled data from four studies have shown that PE patients with RV dysfunction on ECHO have a ninefold higher risk of death than those with normal RV function.[21] Other biomarkers that also attempt to predict a subset of patients with higher mortality include Troponin T and I, which are sensitive markers of myocardial cell damage, and natriuretic peptides like B-type natriuretic peptide (BNP) and N-terminal probrain natriuretic peptide (NTpro-BNP), which are sensitive indicators of ventricular dysfunction. A limitation of both sets of biomarkers is that they have low positive predictive value but high negative predictive value with regard to death or poor outcome.

Thrombolytic agents, such as tissue plasminogen activator (TPA) act on plasminogen by cleaving the peptide bond between arginine at position 560 and valine at position 561, thereby converting plasminogen to plasmin and dissolving the embolus. They help dissolve the clot at source in the pulmonary vessels and perform a medical embolectomy, preventing the downward spiral into right heart failure. They may also help in dissolution of clot at its source in the pelvic and deep veins of the leg. The only FDA-approved regimen is alteplase 100 mg as a continuous infusion over 2 hours. However, streptokinase and urokinase-based regimens are probably equally efficacious and a lot cheaper. Streptokinase is administered as a loading dose of 250,000 U IV over 30 minutes and then 100,000 U/h for 24 hours. *Thrombolytics can be administered within a 2-week time window from the onset of PE and dramatic results have been reported in patients with massive PE, even in patients in shock and circulatory arrest.* The evidence of their role in submassive PE is also emerging, initially from small case studies in the 1960s, then from eight smaller randomized Level 2 studies in the next two decades and finally from the study by Konstantinides,[22] reported in the New England Journal of Medicine in 2002. In this landmark randomized, double-blind controlled study in 49 German centers, 256 patients who met strict inclusion criteria of submassive PE (no hemodynamic instability but RV dysfunction on echocardiography) were randomized to heparin plus recombinant-tissue plasminogen activator (r-TPA) or heparin plus placebo. Although this study could not demonstrate any difference in mortality between the two groups, the clinical deterioration was significantly higher in those that did not receive alteplase. The 30-day event-free survival was also significantly higher in the alteplase group so that patients not receiving alteplase were significantly more likely to need escalation of treatment.

On the basis of this study, many experts would consider using thrombolytic therapy in patients with submassive PE though admittedly there is no unanimity on this issue. Samuel Goldhaber a leading authority in the field remarks: "I believe on the basis of this trial that we should consider expanding the indications for thrombolysis to include this group of patients." However, as yet, the current ACCP guidelines advise thrombolysis only when massive thromboembolism is characterized by hemodynamic instability, in particular hypotension.

Complications of thrombolysis include bleeding but in a pooled analysis of 896 patients[23] enrolled in every PE thrombolysis study, the overall risk of intracranial bleed was

Box 5: Contraindications to anticoagulant therapy

- Recent major surgery/ocular surgery/neurosurgery
- Persistent diastolic BP >110 mm Hg
- Central nervous system hemorrhage
- Recent trauma/head injury
- Recent hemorrhagic cerebral infarct
- Gastrointestinal bleeding or other hemorrhagic diathesis; thrombocytopenia (<50,000/mm^3)
- Concomitant hepatic/renal failure or a coagulopathy from any cause

Box 6: Management of pulmonary embolism

- Anticoagulation with unfractionated or low molecular weight heparin
- Oral anticoagulation
- Thrombolysis
- Cardiorespiratory support
- Surgical embolectomy
- Catheter embolectomy

1.2%. It is best not to use heparin and thrombolytic therapy simultaneously as this can cause uncontrollable bleeding and death.

It is important to consider patients where anticoagulants and thrombolytic therapy are contraindicated (Box 5). The contraindications include a history of a very recent bleed, very recent major surgery, trauma, platelet count less than 50,000/mm^3, disordered coagulation (coagulopathy), whatever the reason, e.g. severe hepatic failure, renal failure. It is equally important to consider a situation where thrombolytic therapy has failed in a patient with massive embolism causing hypotension and hemodynamic instability.

In a patient with PE who is hemodynamically stable but in whom anticoagulation is contraindicated, it is advisable to insert an IVC filter. Anticoagulants can be given if the bleeding risk reduces or is controlled (as for example, the use of factor VIII in a patient with hemophilia + DVT/PE). In a patient with massive PE where anticoagulation and thrombolytic therapy administered through a peripheral vein is contraindicated, the use of streptokinase or TPA in a titrated dose locally through a pulmonary artery catheter inserted into the pulmonary artery has been tried by us in selected circumstances with success. It does not obviate completely the risk of major bleed but reduces it.

CARDIORESPIRATORY SUPPORT

This is imperative in major or massive PE. Shock should be promptly treated. An intravenous infusion of isoproterenol (1–2 mg in 500 mL dextrose) is very useful as it dilates the pulmonary vasculature. If possible, the patient should have a central venous line inserted and it is advisable to keep the CVP between 12 mm Hg and 14 mm Hg in order to ensure an adequate RV stroke volume. This is best achieved by infusing 500 mL dextran or haemaccel, which besides raising right atrial pressure, also expands the pulmonary vascular bed, and thereby reduces pulmonary vascular resistance. A disadvantage of isoprenaline is that is can increase an already existing tachycardia to a significant extent. Inotropic support with dopamine is essential. Dobutamine can also be used in addition to dopamine.

The use of digoxin is disappointing, but it may be used in a dose of 0.25 mg intravenously to start with, and repeated 6-hourly till a digitalizing dose of 1 mg is given over 24 hours. Oxygen is administered at 6–8 L/minute. Ventilator support is invariably required in the presence of acute cardiorespiratory failure. Morphine or pethidine is used for the relief of pain and/or restlessness.

SURGICAL EMBOLECTOMY[24]

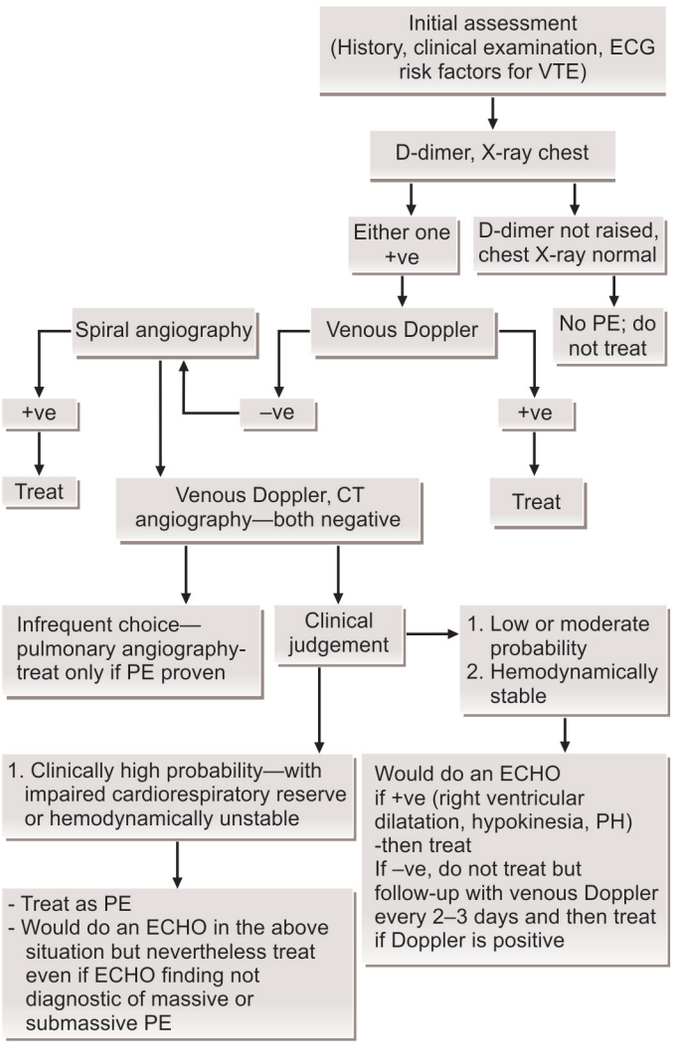
Open surgical embolectomy is the most effective procedure for emergent removal of large amounts of thrombus due to acute PE provided surgical expertise and experience are available. Surgery is especially useful in those in whom thrombolysis is contraindicated and who have not yet deteriorated to the point of cardiorespiratory arrest or shock. In this setting, when used in patients with anatomically extensive PE, and concomitant moderate to severe RV dysfunction, Goldhaber and colleagues[25] report impressive 89% survival rates. Impressive survival rates have been reported even in patients taken up in extremis after suffering cardiopulmonary arrest following massive PE.

Transvenous catheter embolectomy[26] in the catheter laboratory offers a less invasive alternative to open surgical embolectomy. A number of devices including the Greenfield embolectomy device, the Amplatz thrombectomy device, the Angiojet device and the hydrolyser thrombectomy catheter are available. The possibility that after catheter embolectomy a large fragmented clot could block the peripheral pulmonary circulation needs to be considered (Box 6).

PREVENTIVE MEASURES[27]

Prevention of venous thrombosis with the associated risk of PE is a major objective in the management of critically ill patients in the ICU. These patients often form a high-risk group as a consequence of bed rest, serious infections or trauma. Prevention of venous thrombosis in high-risk patients reduces morbidity. High-risk patients include the old and obese, those who are poorly mobile or are confined to bed, patients with myocardial infarction or a stroke, or those with atrial fibrillation and congestive heart failure. Postoperative patients are also at high risk, particularly after orthopedic surgery (particularly hip replacement or hip fracture), gynecological surgery and other major surgery. As

Flowchart 2: Algorithm for diagnostic work-up of pulmonary embolism



Initial assessment (History, clinical examination, ECG risk factors for VTE)
D-dimer, X-ray chest
Either one +ve
D-dimer not raised, chest X-ray normal
Spiral angiography
Venous Doppler
No PE; do not treat
+ve
–ve
+ve
Treat
Venous Doppler, CT angiography—both negative
Treat
Infrequent choice—pulmonary angiography-treat only if PE proven
Clinical judgement
1. Low or moderate probability
2. Hemodynamically stable
1. Clinically high probability—with impaired cardiorespiratory reserve or hemodynamically unstable
Would do an ECHO if +ve (right ventricular dilatation, hypokinesia, PH) -then treat
If –ve, do not treat but follow-up with venous Doppler every 2–3 days and then treat if Doppler is positive
- Treat as PE
- Would do an ECHO in the above situation but nevertheless treat even if ECHO finding not diagnostic of massive or submassive PE

Abbreviations: ECG, electrocardiogram; VTE, venous thromboembolism; PE, pulmonary embolism; PH, pulmonary hypertension.

Note: If venous Doppler negative, patient in shock or markedly hypotensive so that shift to the catheter lab risky, do a 2D ECHO. If positive for right ventiricular dysfunction + PH, treat as PE. If ECHO shows no RV dysfunction, search for some other cause of shock (Flowchart 1).

mentioned above, almost all patients in the ICU are at high risk for DVT. Critical illness from any cause itself constitutes a high risk. Should DVT prophylaxis with heparin be given to all critically ill patients? Each patient should be assessed individually, the risk of DVT being balanced against the risk of bleeding. Low molecular weight heparin (enoxaparin) in a dose of 40–60 mg subcutaneously daily offers good prophylaxis against DVT.

Compression stockings over lower limbs, movement of the lower limbs at the ankles and knees, pneumatic compression of the lower limbs, all help to prevent DVT. Any form of heparin is contraindicated in certain patients—as after trauma, following surgery on the brain and spinal cord, or in patients with an acute peptic ulcer or a bleeding diathesis. In this group one can only offer pneumatic compression of the lower limbs, with active and passive movements at the ankles and knees as prophylaxis.

Once venous thrombosis is detected LMWH in a dose of 40 or 60 mg of enoxaparin twice daily is given provided the above mentioned conditions are not present and there is no contraindication to the use of an anticoagulant. Warfarin is started on the same day as per the ACCP guidelines. It takes about a week of warfarin to take effect; heparin should be continued till such time as the INR is greater than 2. As mentioned earlier, a 6–12 month period of anticoagulants is advised after the first episode of DVT/PE for which there is no apparent cause, as also in patients with a previous history of DVT or PE, in patients with active cancer or in patients with high risk factors which cannot be removed. If anticoagulation is contraindicated, current guidelines advise the use of an IVC filter.

Box 7: Specific indications for insertion of an inferior vena caval filter

- Pulmonary embolism in patients in whom anticoagulants are absolutely contraindicated
- Recurrent thromboembolism in spite of adequate anticoagulation
- Hemodynamically unstable patients who have survived a massive embolism and where the possibility of recurrent embolism is strong
- Patients with septic pulmonary embolism
- Prophylaxis in high-risk patients

Transvenous Insertion of a Filter in the Inferior Vena Cava[28]

This is achieved by the placement of a filter in the IVC generally below the renal veins. The procedure is done by a vascular surgeon or an interventional radiologist through the transvenous route. The filter stops emboli from the lower limb or pelvic veins from reaching the lungs. Specific indications for vena caval interruption include the following (Box 7)—

- Pulmonary embolism in patients in whom anticoagulants are absolutely contraindicated—as in the neurosurgical patient, or in those with active bleeding.
- Recurrent thromboembolism in spite of adequate anticoagulation.
- Patients who have survived a massive embolism, but who are hemodynamically unstable, and in whom the risk of a fresh embolism is ever present.
- Patients with septic pulmonary embolism from thrombi in the lower limbs or pelvis, who have shown an unsatisfactory response after 48 hours of antibiotic plus anticoagulant therapy.
- Prophylaxis in high-risk patients, as in—
  - in extensive or progressive venous thrombosis.
  - in conjunction with catheter-based or surgical pulmonary embolectomy.
  - in patients with active cancer with extensive venous thrombosis of the pelvic or leg veins. Vena caval interruption in the last three groups should be accompanied by the use of heparin in the dosage recommended earlier.

Though IVC filters reduce the incidence of short-term embolic recurrence and reduce short-term (90 days) mortality, this benefit may be lost over a prolonged period of time. In fact, there appears to be a long-term increase in the incidence of venous thromboembolism following the use of IVC filters. For this very reason, retrievable IVC filters have been introduced. However, since these filters are endotheliazed at the point of vascular contact retrievability may be difficult after a lapse of time.

FAT EMBOLISM[29]

Fat embolism is a dramatic form of embolism, which occurs when neutral fat gains entry into the vascular system. The precipitating factor is a fracture of a long bone, the incidence increasing with multiple fractures. Fat embolism has been also noted to occur after orthopedic procedures and rarely following liposuction. It generally occurs 24–72 hours after these precipitating factors.

Pathophysiology

Fat embolism produces two effects—

1. Blockage of vessels by neutral fat.
2. The release of fatty acids due to the action of lipase on neutral fat. Liberated fatty acids cause a vasculitis with increased permeability of pulmonary, cerebral and other vascular beds.

Clinical Features

The clinical picture is characterized by the sudden onset of dyspnea, increasing hypoxemia and mental confusion. Acute lung injury or acute respiratory distress syndrome (ARDS) may occur as a result of increased permeability of pulmonary capillaries. Seizures or even focal neurological signs may be present. About 30–50% have petechiae on the skin, chiefly on the upper half of the body. There is no test, which is diagnostic of fat embolism. Fat may be present in the serum of patients with fat embolism.

Treatment

Treatment is generally supportive as no specific treatment has proved effective. Ventilatory support is invariably necessary. Use of corticosteroids in the prevention of fat embolism following an inciting factor is controversial.

AIR EMBOLISM[30]

An important form of nonthrombotic embolism is venous air embolism. The possibility of air embolism has increased with numerous invasive medical and surgical procedures in practice today. These include the use of central venous catheters, surgery on the neck, thorax, and use of positive pressure ventilation with high positive end expiratory pressure (PEEP). Two important causes are allowing a large bolus of air to enter a central vein by failing to notice that an infusion through the vein is over, and removing the central venous catheter in the sitting position.

Air bubbles enter the pulmonary vascular bed, blocking it; some bubbles go through microvascular pulmonary shunts to enter the systemic circulation.

Clinical Features

Clinical features include severe chest pain, dyspnea, hypoxia and syncope. Pulmonary edema and altered sensorium are observed if death has not already occurred. Symptoms are related to widespread blockage of the pulmonary circulation and of systemic capillaries by air and by platelet fibrin aggregates causing diffuse microthrombi.

Treatment

Treatment consists of—

- Placing the patient in the Trendelenburg position with the left side down.
- Removing air through a central venous catheter or direct needle aspiration, thereby promoting blood flow.
- Cardiorespiratory resuscitation.
- Promoting absorption of air by using 100% oxygen and when possible hyperbaric oxygen.

OTHER FORMS OF EMBOLISM

These include tumor embolism, septic thromboembolism, catheter embolism (a cut-off segment of a central venous catheter) and thrombotic complications caused by intravenous use of drugs meant to be taken orally, as is met with in some drug addicts.

CHAPTER 28

Acute Respiratory Failure in Adults

GENERAL CONSIDERATIONS

Acute respiratory failure is an important and frequently encountered problem in intensive care units (ICUs) all over the world. The usual or traditional definition of respiratory failure is the inability of the respiratory system to maintain the normal homeostasis of arterial blood gases, so that the oxygen tension in arterial blood (PaO_2) is less than 60 mm Hg, and/or the carbon dioxide tension in arterial blood ($PaCO_2$) is 50 mm Hg or greater.

Respiratory failure may be acute or chronic depending on the onset and duration of the failure. An acute exacerbation may at times prevail over a background of chronic respiratory failure (acute on chronic failure).

Respiratory failure is mainly of two types: (1) Type I or hypoxic respiratory failure is due to a failure of oxygenation with a PaO_2 less than 60 mm Hg, (2) Type II or hypercapnic respiratory failure (ventilatory failure) is due to hypoventilation and is characterized by a $PaCO_2$ greater than 50 mm Hg. Hypoxemic and hypercapnic respiratory failure may both occur in the same patient. Some intensivists also consider Type III and Type IV failure.[1]

Type III respiratory failure is that occurring perioperatively and is largely due to basal atelectasis. Cardiothoracic surgery and/or major upper abdominal surgery splint the diaphragm and induce an abnormal mechanics of the abdominal muscles. These factors cause a fall in the functional residual capacity and an increase in the closing volume of the lungs. The end result is increasing atelectasis of the dependent alveoli, small lungs with a high diaphragm, respiratory distress and hypoxemia.[1]

Type IV respiratory failure is that associated with shock—a poorly functioning circulatory system with a low cardiac output is the main cause of hypoxemic failure in this situation. Both Type III and Type IV failure merely constitute hypoxemic failure or both hypoxemic and hypercapnic failure occurring against specific background conditions.

It is important to realize that the significance of the absolute value of arterial blood gas tensions varies from patient to patient. Thus, a fall in arterial PaO_2 from 95 mm Hg to even 70 mm Hg can be of ominous significance in a young man with rapidly evolving acute respiratory failure due to acute poliomyelitis or to any acute neuromuscular disease. This is because, (1) this fall constitutes a sharp or acute drop below the predicted range; (2) ventilatory failure due to acute poliomyelitis, acute neuromuscular disease, or to severe respiratory muscle fatigue from any cause, can produce a further precipitous fall in PaO_2 that can lead to death from severe hypoxia within a matter of a few hours or even minutes. Such a fall in PaO_2 does not necessarily occur in a graded or step-wise fashion. Under the above circumstances, to await a fall in PaO_2 to less than 55–60 mm Hg before realizing the gravity of the situation, can prove dangerous. Abnormal arterial blood gas tensions in a patient should therefore be judged in perspective with the natural history of the problem producing such an abnormality. *Disaster should be anticipated, and if possible prevented; it should never be awaited.*

The above traditional definition of acute respiratory failure evolved when measurements of arterial pH and arterial blood gas tensions were first introduced into clinical medicine. This definition is useful in that (1) it focuses attention on abnormalities of gas exchange due to disturbances in lung function; (2) it stresses the importance and need for a laboratory diagnosis of respiratory failure; (3) it emphasizes the difficulty and often the impossibility of either diagnosing

acute respiratory failure, or gauging its severity on clinical grounds. Yet, this traditional definition ignores the role of the cardiovascular system in gas exchange, and above all in oxygen transport to tissues. In a critical care setting, this is of particular concern. It is vital to look upon the circulatory and respiratory systems as a single inter-related unit whose purpose is to supply oxygen to the tissues.

A broad definition of respiration would be an exchange of oxygen and carbon dioxide between man and his environment.[2] It can be divided into the following sequential steps—

- *Ventilation*—in which an exchange of oxygen and carbon dioxide occurs between the lungs and the atmosphere.
- *Gas exchange*—this occurs across the alveolar-capillary membrane within the lungs, mixed venous blood being oxygenated, and carbon dioxide being removed during its transit through the lungs.
- *Gas transport*—the transport of oxygenated arterial blood to the tissues, and of venous blood (with a high carbon dioxide content), to the lungs.
- *Gas exchange within the tissues*—release of oxygen, oxygen uptake and utilization by the tissues, and release of carbon dioxide by the cells for transport back to the lungs.

In critical care medicine, it is a great advantage to look upon acute respiratory failure as an acute impairment of any one or more of the steps described above. We shall briefly consider (1) acute ventilatory failure; (2) acute failure in gas exchange or acute hypoxemic failure; (3) a combination of (1) and (2); (4) a failure of oxygen transport and (5) a failure of tissue oxygenation.

ACUTE VENTILATORY FAILURE

Definition

Acute ventilatory failure occurs when alveolar ventilation ($\dot{V}_A$) cannot adequately remove the carbon dioxide produced by cell metabolism, via the lungs.

Relation between PaO_2 and $PaCO_2$ in Ventilatory Failure

Ventilatory failure always results in a rise in $PaCO_2$ and a fall in PaO_2, and as mentioned earlier is also termed hypercapnic respiratory failure. The relation between PaO_2 and $PaCO_2$ is defined by the alveolar gas equation

$$P_AO_2 = PIO_2 - PaCO_2 \times \frac{1}{R}$$

where P_AO_2 is the alveolar oxygen tension, PIO_2 is the inspired oxygen tension corrected for water vapor, and R is the respiratory exchange ratio (see Section Basic Cardiorespiratory Physiology in the Intevsive Care Unit). Once the P_AO_2 is calculated from the above equation, the PaO_2 can be determined if the alveolar-arterial oxygen gradient is known. In ventilatory failure due to CNS causes or due to neuromuscular disease, the alveolar-arterial gradient is normal (i.e. 10–20 mm Hg), so that the PaO_2 is 10–20 mm Hg less than the P_AO_2. The oxygen-carbon dioxide diagram (Fig. 1) gives the value of P_AO_2 and PaO_2 for any given value of $PaCO_2$. The arterial blood gas tensions of oxygen and carbon dioxide fall on this line in pure or isolated ventilatory failure.

Physiopathology of Ventilatory Failure

The carbon dioxide produced by tissue metabolism ($\dot{V}CO_2$) is removed by the lungs. Normally, the alveolar carbon dioxide tension (P_ACO_2) and the arterial carbon dioxide tension ($PaCO_2$) are maintained around 40 mm Hg by adjusting $\dot{V}_A$ to balance the $\dot{V}CO_2$. Thus, an increase in the latter is met by a proportionate increase in $\dot{V}_A$. The relationship between P_ACO_2, $\dot{V}CO_2$ and $\dot{V}_A$, can be stated as follows—

$$P_ACO_2 = PaCO_2 = \frac{\dot{V}CO_2}{\dot{V}_A} \times \text{a constant (0.86)}$$

(See Chapter Basic Cardiorespiratory Physiology in the Intensive Care Unit).

$\dot{V}_A$ or the alveolar ventilation is the difference between minute ventilation ($\dot{V}_E$) and the physiological dead space ventilation

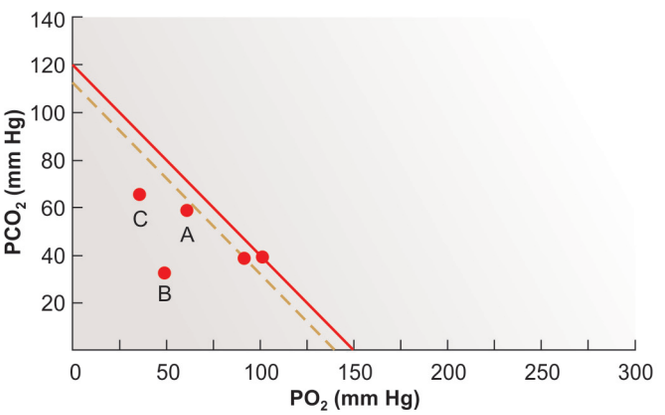

Fig. 1: O_2-CO_2 diagram. The continuous line represents the relation between alveolar PO_2 and alveolar PCO_2 with an RQ of 0.8 and when breathing air (PIO_2 = 149 mm Hg). The circle marked on this line represents the normal P_AO_2 and P_ACO_2. The broken line represents the normal relation between PaO_2 and P_ACO_2 ($PaCO_2$) when breathing air. It takes into consideration the slight venous admixture occurring in normal lungs so that the PaO_2 may be 10–15 mm less than P_AO_2. The circle marked on the broken line represents the normal PaO_2 and PCO_2. Points A, B and C illustrate blood gas readings in different types of respiratory failure: A. Ventilatory failure: $PaCO_2$ 60 mm Hg; PaO_2 65 mm Hg. The point falls on or is very close to the broken line. B. Hypoxemic failure: $PaCO_2$ 38 mm Hg; PaO_2 45 mm Hg. The point is markedly to the left of the broken line. The large alveolar-arterial gradient is chiefly due to a ventilation-perfusion imblance and/or an increase in the true venous admixture. C. Hypoxemic and ventilatory failure: $PaCO_2$ 70 mm Hg; PaO_2 30 mm Hg. Note high $PaCO_2$ indicating ventilatory failure and PaO_2 less than what can be predicted from the $PaCO_2$ reading. The point is again to the left of the broken line

Source: Udwadia FE. Diagnosis and Management of Acute Respiratory Failure, Mumbai: OUP; 1979.

($\dot{V}_D$) within the lungs—i.e. the ventilation that does not participate in gas exchange. The above equation can thus be rewritten:

$$P_ACO_2 = PaCO_2 = \frac{\dot{V}CO_2}{\dot{V}_E - \dot{V}_D}$$

Thus, a rise in $PaCO_2$ due to ventilatory or hypercapnic respiratory failure can occur under the following conditions: (1) A fall in $\dot{V}_A$ or alveolar ventilation—this could be due to (a) a fall in $\dot{V}_E$ or minute ventilation or to (b) a rise in physiological $\dot{V}_D$, without a concomitant increase in minute ventilation ($\dot{V}_E$); (2) A rise in carbon dioxide production ($\dot{V}CO_2$) without a proportionate increase in $\dot{V}_A$.

Important Causes of Acute Ventilatory or Hypercapnic Respiratory Failure in an Intensive Care Unit

- Hypoventilation in lungs which are normal to start with. This occurs in patients with a depressed ventilatory drive or in neuromuscular disease. A depressed ventilatory drive is observed in poisonings with narcotics, sedatives, antidepressants, coma from other causes, in head injuries, encephalitis, increased intracranial tension and other pathologies depressing the respiratory center. Important neuromuscular diseases causing hypoventilation include acute poliomyelitis, acute infective polyneuritis (Guillain-Barré syndrome), tetanus, myasthenia gravis, botulism and snake bite poisoning. Other causes of respiratory muscle weakness and/or decreased respiratory muscle endurance include severe myopathy, amyotrophic lateral sclerosis, polymyositis, critical illness polyneuropathy/myopathy, malnutrition, severe electrolyte disturbances, notably hypokalemia, hyperkalemia, hypomagnesemia, prolonged ventilator dependence, disorders of the phrenic nerve and respiratory muscle fatigue from any cause.
- Rarely hypoventilation can occur following large airways obstruction. In an ICU setting, this is chiefly observed in tracheal or subglottic stenosis, when an artificial airway has been in place for many weeks, or has been incorrectly managed. Upper airways obstruction with hypoventilation can also occur in children with acute epiglottitis, in obstructive sleep apnea, vocal cord paralysis, and foreign bodies including dentures, clots, secretions, soft tissue tumors or inflammation obstructing the upper airway.
- Poor expansion of the thoracic cage with ventilatory failure can occur following trauma to the thorax (as in flail chest), in patients who are severely obese, or have marked kyphoscoliosis, or in those with well-marked pleural disease (as in bilateral pleural effusion or pneumothorax).

It is important to realize that in most of the above-mentioned conditions, the lungs are normal to start with. However, if hypoventilation is not promptly recognized and correctly managed (and this is most important in hypoventilating comatose patients), secretions accumulate within the large and small airways producing areas of atelectasis. As a result of secondary changes within the lungs, gas exchange due to ventilation-perfusion imbalance is further impaired.

- Hypoventilation can also occur in lungs, which are abnormal. This is most frequently seen in severe airways obstruction—either acute severe asthma, or an acute crisis in chronic bronchitis emphysema. In these patients, hypoventilation is due to a decrease in $\dot{V}_E$, and/or an increase in physiological dead space. Extensive thromboembolic disease within the lungs can rarely produce a sufficient rise in $\dot{V}_D$, so as to cause a fall in $\dot{V}_A$. Severe late (almost terminal) stage restrictive disease can also be associated with hypoventilation and hypercapnic respiratory failure.
- Increase in carbon dioxide production, at times cannot be countered by an increase in $\dot{V}_A$. Marked increase in carbon dioxide production can occur in high fever, hypermetabolic critical illnesses, severe hyperthyroidism, frequent seizures and uncontrolled tetanus. In patients with respiratory muscle fatigue, or in those with mechanical limitations to breathing (as in severe COPD), $\dot{V}_A$ cannot keep pace with carbon dioxide production, and hypercapnic respiratory failure is observed. Hyperalimentation with increased caloric intake through carbohydrates or a high carbohydrate diet given by the enteral route also results in an increase in $\dot{V}CO_2$. An increase in $\dot{V}_A$ is imperative if this excess CO_2 is to be removed. In critically ill patients, carbon dioxide retention may occur as respiratory muscle fatigue may prevent a proportionate rise in $\dot{V}_A$ (see Section Nutritional Support in the Critically Ill Adult).

The important causes of hypercapnic respiratory failure in the ICU are listed in Box 1.

HYPOXEMIC RESPIRATORY FAILURE

Acute hypoxemic respiratory failure results from poor gas exchange of oxygen within the lungs leading to a low PaO_2. The $PaCO_2$ may be normal or even less than normal (Fig. 1).

Pathophysiology

The normal $\dot{V}_A$ is about 4–5 l and the normal perfusion (Q) is around 5 l, the $\dot{V}_A/Q$ ratio being approximately 0.8–1. Even in the normal lung, there are regional differences in ventilation and perfusion ratios, but by and large the ventilation and perfusion ratios are even and range from 0.8 to 1.2. For explanatory purposes, the lung can be compartmentalized into the following divisions—

- Alveoli with normal ventilation and perfusion—normal V/Q ratios.
- Alveoli with increase in ventilation-perfusion ratios, the V/Q ratios being greater than 1. The capillaries leaving these alveoli have a normal or slightly increased PaO_2 but a reduced $PaCO_2$.

Box 1: Important causes of hypercapnic respiratory failure in the ICU

1. Patients with normal lungs to start with (decrease in VE)—
   Depressed ventilatory drive—
   - Poisonings, e.g. narcotics, antidepressants, sedatives
   - Head injury, encephalitis, increase in intracranial tension
   - Coma from any cause

   Neuromuscular diseases—
   - Acute poliomyelitis, acute infective polyneuritis, polymyositis and critical care neuromyopathy
   - Myopathy, amyotropic lateral sclerosis
   - Tetanus, myasthenia gravis and botulism
   - Snake bite poisoning
   - Respiratory muscle weakness or fatigue from any cause

   Large airways obstruction—
   - Tracheal/subglottic stenosis, obstructive sleep apnea, vocal cord paralysis and foreign bodies

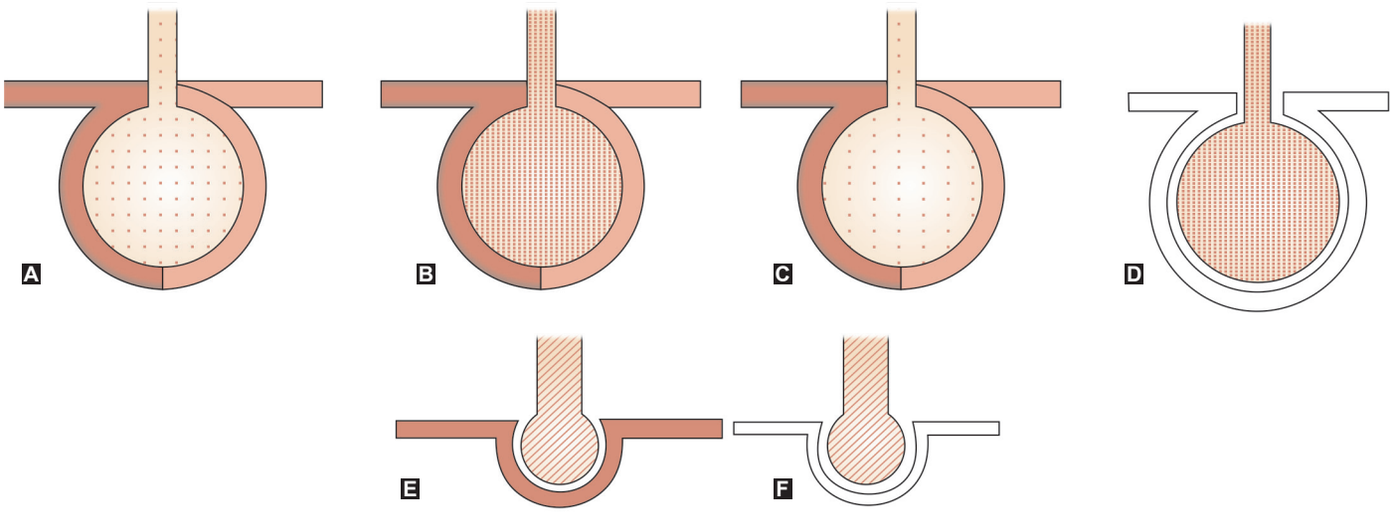
   Poor expansion of the thoracic cage (failure of the Bellows)—
   - Trauma (flail chest), severe obesity, kyphoscoliosis, extensive eschar after burns, pleural effusion and pneumothorax
2. Patients with abnormal lungs (decrease in $\dot{V}_E$ and/or increase in $\dot{V}_D$)—
   - Acute severe bronchial asthma
   - Acute crisis in chronic bronchitis, emphysema
   - Extensive thromboembolic disease
   - Severe terminal stage restrictive lung disease
3. Patients with increased production of CO_2—
   - High fever, hypermetabolic critical illnesses
   - Frequent seizures, uncontrolled tetanus
   - Hyperalimentation with increased carbohydrate intake

- Alveoli with a decrease in ventilation-perfusion ratios; blood after perfusing these alveoli has a lowered PaO_2 and an increased $PaCO_2$. The lower the V/Q ratio, the lower the PaO_2 of the blood leaving these alveoli.
- Alveoli that are ventilated, but have no perfusion. The V/Q ratio is infinity, and such alveoli contribute significantly to increased physiological dead space.
- Alveoli which are atelectatic but continue to be perfused. These alveoli contribute to a right to left shunt within the lungs. The blood leaving the alveoli has the same PaO_2 as mixed venous blood, i.e. 40 mm Hg.
- Alveoli which are neither ventilated nor perfused. These are resting alveoli, and probably come into physiological action only when ventilatory or respiratory demands increase (Figs 2A to F).

Acute hypoxemic respiratory failure occurs when: (1) there is a ventilation-perfusion mismatch characterized predominantly by low ventilation-perfusion ratios in the lungs; (2) there is a significant increase in the right to left shunt due to perfusion of atelectatic alveoli; (3) both the above factors are present; (4) there is a marked decrease in diffusion of oxygen across the alveolar capillary membrane.

Low Ventilation-Perfusion (V/Q) Ratios

Alveoli, which have a perfusion in excess of ventilation (i.e. low $\dot{V}_A/Q$ ratios), will have a reduced P_AO_2, and therefore a reduced PaO_2, as well as a reduced oxygen content of blood leaving the alveoli. When the poorly oxygenated blood mixes with the blood perfusing the alveoli that have $\dot{V}_A$ which is normal in proportion to the perfusion, or $\dot{V}_A$ even in excess of the perfusion, the resultant blood stream has a lower oxygen



Figs 2A to F: Various gas exchange units in the lung (A) Normal unit alveoli with normal V/Q ratios; (B) Hyperventilated unit-alveoli with increase in V/Q ratios (>1); (C) Hypoventilated unit-alveoli with decrease in V/Q ratios; (D) Dead space unit-alveoli are ventilated, but have no perfusion; (E) Shunt unit-alveoli are atelectatic but have good perfusion; (F) Silent unit-alveoli are neither ventilated nor perfused

Source: Modified from Udwadia FE. Diagnosis and Management of Acute Respiratory Failure. Mumbai: OUP; 1979.

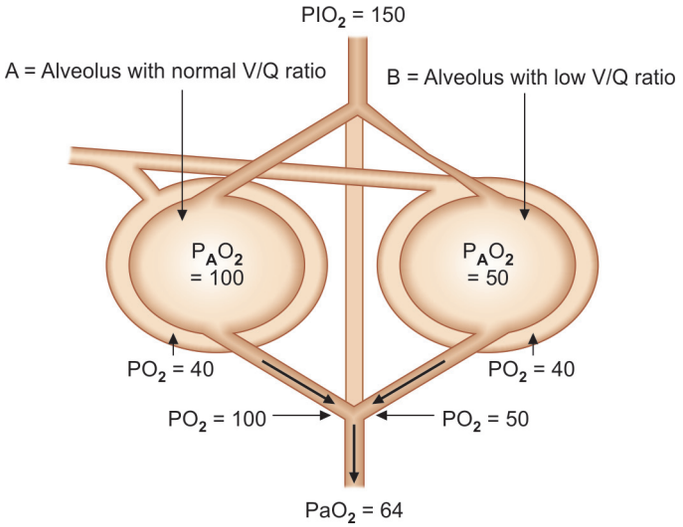


Fig. 3: The PaO_2 of blood leaving A (alveolus with normal V/Q ratio) is normal; the PaO_2 of blood leaving B (alveolus with reduced V/Q ratio) is reduced. When this poorly oxygenated blood mixes with well-oxygenated blood from alveoli with normal or high V/Q ratios, the resultant PaO_2 is still lower than normal. This shows that increased V/Q ratios in some alveoli cannot compensate for markedly lowered V/Q ratios in other alveoli

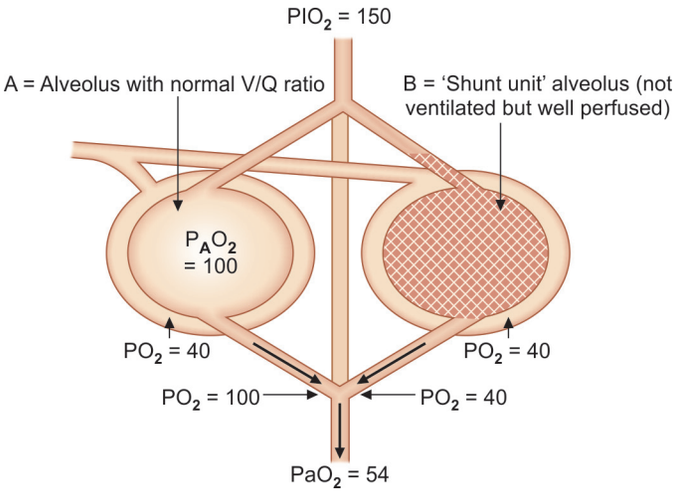


PIO_2 = 150
A = Alveolus with normal V/Q ratio
B = 'Shunt unit' alveolus (not ventilated but well perfused)
P_AO_2 = 100
PO_2 = 40
PO_2 = 40
PO_2 = 100
PO_2 = 40
PaO_2 = 54

Fig. 4: The PaO_2 of blood leaving A (alveolus with normal V/Q ratio) is normal. The mixed venous blood perfusing; B (shunt unit alveolus) is not oxygenated at all. When this blood mixes with well-oxygenated blood perfusing a normal alveolus, the resultant PaO_2 is still very low

content and a lowered PaO_2. Increased V/Q ratios in some alveoli cannot compensate for sharply lowered V/Q ratios in other alveoli. After all, the oxygen saturation of arterial blood in the presence of normal V/Q ratios is close to 100%. A further increase in the V/Q ratio may increase both the P_AO_2 and the PaO_2, but because of the plateau-shape of the upper part of the oxygen-hemoglobin dissociation curve, there will be no appreciable increase in oxygen saturation or content of blood leaving such alveoli. This is illustrated in Figure 3.

Increase in Right to Left Shunt within the Lungs

A shunt refers to the proportion or fraction of venous blood that enters the systemic arteries without coming into contact with gas exchanging areas of the lungs. The present discussion is not concerned with right to left shunts in the heart or the larger vessels due to congenital defects or anomalies. Right to left shunts within the lungs due to perfusion of atelectatic alveoli constitute the most important cause of refractory acute hypoxemic respiratory failure. It is to be remembered that there is a small right to left shunt even in normal lungs. This is because of bronchial venous blood draining directly through pulmonary veins into the left atrium, and a small amount of coronary venous blood that drains via the Thebesian veins directly into the left ventricle. The normal shunt averages not more than 5%. In patients with a right to left shunt due to perfusion of atelectatic alveoli, the shunt fraction may be as high as 30–50%. The higher the right to left shunt within the lungs, the greater the degree of hypoxemia, and lower the PaO_2.

The effect of a right to left shunt within the lungs is illustrated in Figure 4.

Combination of Low V/Q Ratios and Increased Shunt

Most lung diseases causing acute respiratory failure are characterized by a pathology in which there are areas of low V/Q ratios, high V/Q ratios and increase in the right to left shunt. Patients in whom disturbance in gas exchange is predominantly due to an increase in the shunt have the gravest prognosis.

Impairment in Diffusion of Oxygen

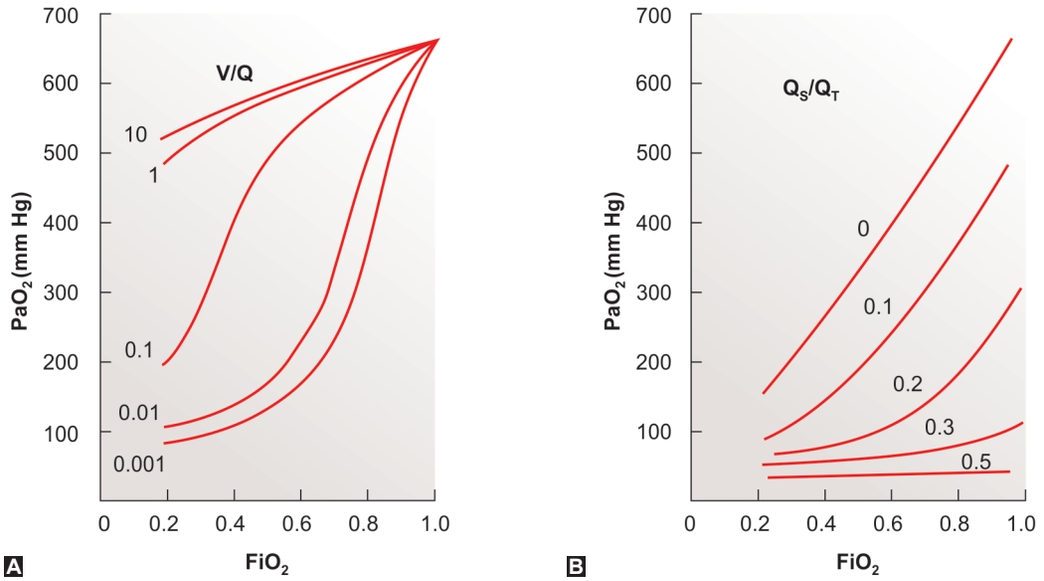
A diffusion abnormality does exist in several lung diseases, but it almost never is the chief cause of a low PaO_2 at rest. All patients with diffusion abnormalities have regional variations in compliance resulting in uneven and low ventilation-perfusion ratios.

Effect of an Increasing Inspired Oxygen Content (FiO_2) on V/Q Abnormalities

Increase in the FiO_2 rapidly produces an increase in the PaO_2 and the oxygen content of blood leaving the alveoli with low V/Q ratios. The hypoxemia of acute respiratory failure in patients with low V/Q ratios is thus easily corrected. The improvement in PaO_2 depends upon the degree of perfusion to areas with poor ventilation. Except where the V/Q ratios are extremely low, a satisfactory PaO_2 of about 60 mm Hg, with an oxygen saturation of 90% is achieved by using a FiO_2 of less than 0.6. Even in alveoli with extremely low V/Q ratios, as long as there is some ventilation present, an FiO_2 of 100% will always produce a marked increase in the PaO_2 of blood leaving such alveoli. This is illustrated in Figure 5A.

Effect of an Increased FiO_2 on the Shunt

It is obvious that the treatment of hypoxemia due to a severe right to left shunt within the lungs is difficult, because increasing the



Figs 5A and B: (A) PaO_2 improves with increasing FiO_2 in patients with a V/Q mismatch. When the FiO_2 is increased to 1 (100%), the PaO_2 reaches 600 mm Hg even if the V/Q ratio is very low. (B) Note that with increase in Q_S/Q_T beyond 0.3, increasing the FiO_2 has little or no effect on the PaO_2

Source: Albert RK. Physiology and management of failure of arterial oxygenation. In: Fallat RJ, Luce JM (Eds). Cardiopulmonary Critical Care Management (Clinics in Critical Care Medicine). Elsevier Inc.; 1988. pp. 37-59.

FiO_2 improves the oxygen content to a very slight extent. The greater the shunt, the poorer the response in PaO_2 to a rise in FiO_2 (Fig. 5B). Fortunately, acute hypoxemic respiratory failure solely due to a marked increase in the right to left shunt within the lungs is rare. Even in patients with severe acute respiratory distress syndrome (ARDS), though there are many areas of shunt, which do not respond to an increase in FiO_2, there are some areas of V/Q mismatch which respond to such an increase.

Clinical Problems Causing Acute Hypoxemic Respiratory Failure

These can be broadly divided into three groups—

1. Those characterized chiefly by airways obstruction causing uneven ventilation and V/Q inequalities—an acute crisis in chronic bronchitis emphysema, and acute severe asthma are classic examples. In some of these patients, there is an element of acute ventilatory failure in addition to hypoxemic respiratory failure. This is due to mechanical limitations, which prevent increased ventilatory demands from being adequately met, to alveolar hypoventilation consequent to a marked increase in physiological $\dot{V}_D$, or to a diminished respiratory drive. One or more of these factors may contribute to an associated ventilatory failure.
2. *Restrictive lung diseases* Examples of these include acute pulmonary edema, acute interstitial disease, acute pulmonary infections, acute lung injury (ARDS) and major atelectasis within the lungs.
3. *Acute thromboembolic lung disease* This is characterized by V/Q inequalities and increase in the dead space resulting in acute hypoxemic respiratory failure.

Box 2: Important causes of acute hypoxemic respiratory failure

- Obstructive airways disease—
  - Acute crisis in chronic bronchitis, emphysema
  - Acute severe bronchial asthma
- Restrictive lung disease—
  - Acute pulmonary edema; acute interstitial disease
  - Acute pulmonary infection
  - Acute lung injury [acute respiratory distress syndrome (ARDS)]
  - Major pulmonary atelectasis
- Trauma to the chest
- Acute thromboembolic lung disease

The important causes of acute hypoxemic respiratory failure are listed in Box 2.

A COMBINATION OF ACUTE VENTILATORY AND HYPOXEMIC RESPIRATORY FAILURE

This is seen in intensive care medicine in the following groups of patients—

1. Acute severe asthma.
2. Acute or chronic respiratory failure due to a respiratory crisis in patients with chronic airways obstruction (COPD).
3. Muscle fatigue involving muscles of respiration in patients with acute respiratory failure due to severe lung disease.
4. Advanced or late stage interstitial lung disease.
5. Severe pulmonary thromboembolism.
6. Trauma to the chest (Flail chest).

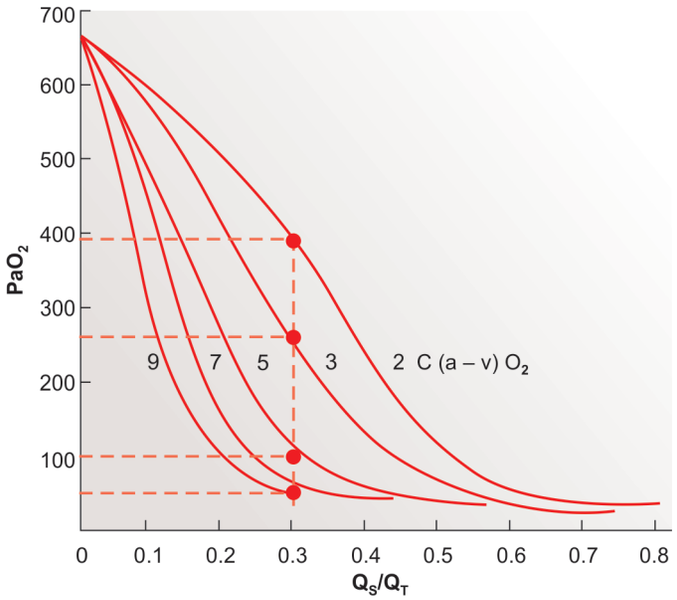


Fig. 6: Dependence of PaO_2, on the oxygen extraction C (a-v) and the shunt fraction. If the shunt fraction is 30%, the PaO_2, varies from 100 mm Hg to 400 mm Hg, as the C (a-v) O_2 narrows. The patient may have a high PaO_2, if he has a high cardiac output and a decreased C (a-v) O_2 of 3, even if his shunt fraction is as high as 0.3. However, if the patient's oxygen consumption increases without a corresponding increase in the cardiac output, the C (a-v) O_2 widens to 9, and the PaO_2, falls to 50 mm Hg

FAILURE OF OXYGEN TRANSPORT

A satisfactory gas exchange at the alveolar level must be accompanied by an adequate transport of oxygenated blood to the tissues. This requires an adequate cardiac output, a normal oxygen content of arterial blood and good tissue perfusion (see Section Basic Cardiorespiratory Physiology in the Intensive Care Unit). A low output state or shock from any cause can also indirectly lower the PaO_2 in the following ways—

- A low cardiac output results in increased oxygen extraction from the blood by the tissues. This leads to a fall in the mixed venous oxygen content (PvO_2). The lowered PvO_2 in the mixed venous blood reaching the alveoli will lead to a lowered PaO_2. This can be even more marked if the cardiac output falls in a patient who already has a right to left shunt within the lungs (Fig. 6).
- A low output state leads to a low pressure of perfused blood in the pulmonary vessels; perfusion is more in the dependent alveoli of the lungs. This results in an increase in the physiological dead space involving non-dependent alveoli, and to low V/Q ratios within the dependent alveoli of the lungs, thereby contributing to a fall in PaO_2.
- Respiratory muscle fatigue is an important factor in low output states. Hypotension and shock lead to poor perfusion of respiratory muscles and quick, easy fatigability. Respiratory muscle fatigue can cause hypoventilation, can increase ventilation-perfusion inequalities, and can thereby further reduce the PaO_2.

RESPIRATORY MUSCLE FATIGUE

The importance and role of muscle fatigue in acute respiratory failure in critically ill patients cannot be overemphasized and is best considered at this stage. As with other muscle groups in the body, excessive work performed by the muscles of respiration leads to fatigue.[1,3] Increasing fatigue results in increasingly poor function and hypoventilation; ultimately the patient literally stops breathing. Increasing respiratory fatigue explains the abrupt stoppage of breathing with resulting disaster, in patients with acute severe asthma, or in patients with a very low pulmonary compliance due to acute alveolar edema. Difficulties in weaning patients off ventilator support are also frequently related to respiratory muscle fatigue brought on by the inability to cope with the work of breathing.

The second major factor predisposing to respiratory muscle fatigue is the gravity or critical nature of an illness. The more critically ill the patient, the easier and quicker does fatigue arise in respiratory muscles. Tachypnea and an unstable circulation, hypotension with poor perfusion of the respiratory muscles, electrolyte disturbances, probably all play a role in muscle fatigue in these individuals.

The clinical recognition of respiratory muscle fatigue is difficult and may occasionally be impossible to detect till the patient very nearly has a respiratory arrest. A voiced complaint by an ill patient that he or she is tired and cannot continue to breathe for long should always be taken seriously, particularly in a patient with severe airways obstruction. Tachypnea with a rate greater than 35/minute, always predisposes to fatigue, particularly in obese individuals or very ill patients. Poor chest excursions, irregular breathing and above all apneic spells, all point to fatigued respiratory muscles. Respiratory alternans, in which intercostal muscle and diaphragmatic contractions alternate, is also observed at times. Fatigued muscles also occasionally cause a paradoxical respiratory movement, with the lower part of the chest and the upper abdomen being drawn in, instead of being pushed out during inspiration.

Objective measurements are also of use. As a rough guide, spontaneous breathing cannot be easily sustained if the effort involved in each spontaneous breath is less than one-third of the maximal respiratory effort that can be achieved.[3-5] The maximum inspiratory pressure (MIP) is a good guide to the respiratory muscle power. An MIP of less than 30 cm H_2O generally denotes muscle fatigue. Similarly, a tidal volume (VT)(measured by a Wright's spirometer) of less than 300 mL, or a vital capacity (VC) less than three times the VT, suggests respiratory muscle fatigue *under appropriate clinical conditions*. A minute ventilation greater than 10–12 L/minute is difficult to sustain indefinitely in critically ill individuals, and often ultimately leads to hypoventilation from respiratory muscle fatigue. The objective measurements stated above when judged against an appropriate clinical background can give only indirect evidence of probable respiratory muscle

Box 3: Features of respiratory muscle fatigue

- Complaint of fatigue in relation to breathing
- Respiratory rate greater than 35 breaths per minute
- Poor chest excursions, irregular breathing and apneic spells
- Respiratory alternans, paradoxical respiratory movements
- Maximum inspiratory pressure (MIP) less than 30 cm H_2O
- Tidal volume (VT) <300 mL; vital capacity (VC) <3 x TV; minute ventilation (VM) >10–12 L/min

fatigue. It has to be admitted that unequivocal direct evidence of contractile fatigue has not yet been demonstrated. The major determinants of respiratory muscle fatigue are inspiratory muscle strength, mean inspiratory pressure and the duration of inspiration, which when combined form the tension time index (TTI).[6] However, interpretation of the TTI is difficult and often misleading.[6] Recent work suggests that the magnetic stimulation of the phrenic nerve (a procedure far less painful than electrical stimulation) can detect diaphragmatic fatigue; and by measuring changes in the esophageal twitch pressure, can also detect rib-cage muscle fatigue.[7,8] Magnetic stimulation of the phrenic nerve is however a research procedure not generally performed in critical care units. It is best to act on the premise that respiratory muscles (particularly if they are weak) can, like other skeletal muscles, experience fatigue if subjected to excessive work for a prolonged period of time.

The clinical features of respiratory muscle fatigue are listed in Box 3.

Respiratory muscle fatigue causing or contributing to acute respiratory failure should be managed by resting the respiratory muscles by mechanical ventilation. During the period of rest, the acutely depleted glycogen stores of the respiratory muscles are replenished, and lactic acid and other metabolites associated with muscle fatigue are washed out.[9-11] Aminophylline is believed to preserve muscle strength and contraction of the diaphragm; however, it is doubtful if this drug has a clinical role in patients with severe respiratory muscle fatigue.

FAILURE OF OXYGEN UPTAKE

Despite good ventilation, normal exchange of blood gases at the alveolar level and good oxygen transport, oxygen uptake may be deficient at the tissue level. The main purpose of the cardiorespiratory system is then defeated. Thus, cyanide poisoning is characterized by an arrest of intracellular respiration due to the inactivation of an intracellular enzyme, cytochrome oxidase. The patient with cyanide poisoning has a normal PaO_2, SaO_2, CaO_2 and oxygen transport, but cannot utilize oxygen at the tissue level. Blood after perfusing tissues shows severe lactic acidosis and has a high PvO_2 and $S\dot{v}O_2$. The patient literally dies of strangulation or hypoxia at the tissue level.

The most important clinical problem associated with failure of oxygen uptake is septic shock, often associated with ARDS [this is discussed under Sepsis and Septic Shock and Acute Lung Injury (ARDS)]. To many physicians, it may seem inappropriate to consider failure of oxygen uptake by tissues in acute respiratory failure. Yet in critical care medicine, it is ultimately the oxygen supply to, and oxygen uptake by tissues (in particular tissues of vital organs), which are of crucial importance. In the final analysis, acute cardiorespiratory failure is a failure to adequately oxygenate the tissues.

CLINICAL FEATURES OF ACUTE RESPIRATORY FAILURE

In the presence of a background disease known to cause acute respiratory failure, the only sure way to diagnose the latter is by estimating the arterial blood gases. One should never rely only on clinical features to diagnose acute respiratory failure. Clinical features may however be present. These include the presence of disease known to cause acute respiratory failure, and the features associated with hypoxia and hypercapnia. Many, though not all patients, also show respiratory distress.

Hypoxia

Hypoxia is the basic underlying feature in every patient with acute hypoxemic respiratory failure. Increasing hypoxia depresses cell function, induces metabolic acidosis, and if marked and unrelieved leads to cellular death. It may be impossible to detect hypoxia on clinical grounds in critically ill patients. The only sure way of detecting hypoxia is by measuring the arterial PaO_2. The importance of this fact cannot be overemphasized.

The only pathognomonic manifestation of hypoxia is central cyanosis. Nevertheless, well-marked arterial hypoxemia may exist in the absence of clinical cyanosis, so that to await the development of cyanosis before diagnosing acute respiratory failure, is to court disaster. Cyanosis can only be clinically evident if the mean capillary concentration of reduced hemoglobin exceeds 5 g/dL. It is evident that a patient with severe anemia (Hb <7 g/dL), may die of severe arterial hypoxemia before cyanosis can become clinically manifest. A hypermetabolic state with a hyperdynamic circulation characterized by a quick blood flow through the peripheries also renders the clinical recognition of cyanosis difficult. The presence of anemia together with a quickened circulatory flow therefore constitute a formidable combination, which prevents the clinical appearance of cyanosis in spite of marked hypoxia.

Mental confusion, restlessness and acute anxiety are early manifestations of hypoxia. The ghastly pitfall of dubbing the anxiety and restlessness of early hypoxia in acute respiratory failure as functional, should be guarded against.

Compensatory Mechanisms Induced by Hypoxia

Hypoxia triggers compensatory mechanisms, which are easily recognized and are therefore of diagnostic value. The main compensatory mechanism is sympathetic stimulation

which causes tachycardia and hypertension. Increase in the respiratory rate is another compensatory mechanism produced by stimulation of the chemoreceptors in the carotid body and aorta. Increase in respiratory rate will not occur if the respiratory center is markedly depressed, or if there is weakness or paralysis of the respiratory muscles. However, tachycardia and hypertension are important signs of hypoxia. They should be sought for, and their significance recognized in situations that can lead to acute respiratory failure. These signs depend on the integrity of the sympathetic nervous system. In the old and feeble, in diabetics with a neuropathy involving the sympathetic nerves, or in patients who have received drugs affecting the autonomic nervous system, sympathetic response to hypoxia may be absent or feeble. With severe increasing hypoxia, the clinical hallmarks are progressive bradycardia, hypotension, lactic acid acidosis, arrhythmias, circulatory failure and death.

The myocardium has no oxygen reserve so that hypoxia depresses myocardial function, and increases ectopic irritability. Bradycardia and hypotension result from the direct depressant effect of hypoxia on the myocardium. Arrhythmias arise due to increased ectopic irritability. Atrial flutter and fibrillation are often observed; severe hypoxia ultimately results in ventricular tachycardia, fibrillation and arrest.

Hypercapnia

Hypercapnia may also be impossible to detect on clinical grounds. The $PaCO_2$ should therefore always be estimated in any disease, which can conceivably produce carbon dioxide retention.

Carbon dioxide has a local depressant effect on the cardiovascular system. It thus produces generalized vasodilatation except in the pulmonary circulation, which may be vasoconstricted. Generalized vasodilatation manifests as cutaneous flushing, warmth, sweating and a bounding pulse.

The depressant effect of carbon dioxide on the central nervous system leads to confusion, disturbance in behavior, a reversal in the sleep rhythm, and increasing drowsiness that may lead to deep coma (carbon dioxide narcosis). Carbon dioxide narcosis is an important metabolic cause of coma, and can be often missed if the $PaCO_2$ is not measured. Wing flap tremors of the outstretched hands are often observed with CO_2 retention. They are indistinguishable from those observed in hepatic failure. Wing flap tremors are not consistently present. At times, even a slight rise in the $PaCO_2$ induces wing flap tremors; at other times, a marked rise in $PaCO_2$ may not be associated with flaps. However, increasing levels of $PaCO_2$ produce increasing disturbance of consciousness. Marked confusion and drowsiness occur by the time $PaCO_2$ rises to between 80–100 mm Hg, and the patient is generally unconscious when the $PaCO_2$ is well over 100 mm Hg. Coma in CO_2 narcosis is associated with loss of the deep reflexes and urinary incontinence. The plantars are generally not elicitable or are flexor; rarely they may be extensor.

Table 1: Important clinical features of hypoxia and hypercapnia

Hypoxia	*Hypercapnia*
Cyanosis	Flushing, warmth, sweating, bounding pulse
Mental changes, restlessness, anxiety	Headache, wing flap tremors
Tachycardia, hypertension	Drowsiness, confusion, coma
Rhythm disturbances	Muscle twitching, seizures, papilledema
Metabolic acidosis	
Bradycardia, hypotension, circulatory failure, when hypoxia is marked	

High levels of $PaCO_2$ can produce headache, muscle twitchings, seizures and papilledema. The combination of drowsiness, headache and papilledema closely simulate an intracranial tumor.

An increasing $PaCO_2$ stimulates the respiratory center, producing an increase in the respiratory rate and V_T. Nevertheless, a depressed center or a center with a reduced or absent sensitivity to increasing $PaCO_2$, will not permit an increased respiratory drive to materialize.

Hypercapnia also produces a central stimulation of the sympathetic nervous system, resulting in tachycardia and hypertension. The pattern of symptoms in a patient will depend on the balance between the depressant action on the cardiovascular system, and the stimulant effects on the sympathetic nervous system.

Respiratory Distress or Dyspnea

Many patients in acute respiratory failure are uncomfortably aware of a difficulty in breathing. This unpleasant awareness of respiration and difficulty in breathing is termed dyspnea. Dyspnea is a subjective phenomenon, and its correlation with the degree of respiratory failure is difficult. In fact, breathlessness and respiratory failure are not synonymous. Many patients, who are breathless, are not in respiratory failure, and a number of patients in respiratory failure are not breathless. Nevertheless, in a patient with chronic lung disease, increasing impairment of lung function and increasing respiratory failure, are invariably associated with increasing dyspnea.

The important clinical features of hypoxia and hypercapnia are listed in Table 1.

AN ELECTIVE DIAGNOSTIC ASSESSMENT IN ACUTE RESPIRATORY FAILURE (BOX 4)

Acute respiratory failure may occur with a suddenness and severity that warrants immediate efforts toward resuscitation. Nevertheless, whenever time and the patient's condition permit, an elective diagnostic work-up is necessary. This is done with three objectives in mind—

Box 4: Elective diagnostic assessment in acute respiratory failure

1. Establish cause and estimate tempo or rate of progression of problem causing acute respiratory failure

Detailed history, for example, of poisoning, of symptoms suggestive of important diseases causing acute respiratory failure

Physical examination—

- Check for features of hypoxia, hypercapnia, patency of airways
- Meticulous examination of the cardiovascular and respiratory systems

Routine investigations—

- Arterial blood gas analysis
- Other tests, for example, complete blood count (CBC), serum biochemistry, chest X-ray

Special investigations (only if deemed necessary)—

- Monitoring of central venous pressure
- Monitoring of pulmonary artery pressures, cardiac output, and shunt fraction by use of the Swan-Ganz catheter

2. Determine nature of disturbance in respiratory physiology

Evaluate if ventilation is adequate—

- Hypoventilation if $PaCO_2$ >48–50 mm Hg
- Hyperventilation if $PaCO_2$ <35 mm Hg

Evaluate the following possible physiological abnormalities underlying a low PaO_2 —

- Hypoventilation
- Mismatched V/Q ratios
- Increased right to left shunt within lungs
- Impaired diffusion

Assess if there is increase in physiological dead space

Evaluate if work of breathing is increased

Check for evidence of respiratory muscle fatigue

Check if oxygen transport and tissue oxygenation are adequate

1. To establish the cause of acute respiratory failure.
2. To determine the nature of disturbance in respiratory physiology.
3. To estimate in so far as is possible, the tempo or the rate of progression of the disease, and the problems or complications likely to occur in the immediate or near future.

History

This is of great importance in evaluating the nature and tempo of the problem causing acute respiratory failure. Special stress should be laid on a history of poisoning, or of symptoms suggestive of important diseases known to cause acute respiratory failure—e.g. acute infective polyneuritis, airways obstruction, intracranial and other central nervous system lesions, myasthenia gravis and cardiopulmonary diseases.

Physical Examination

A thorough physical examination is mandatory. The following points are of special importance—

- An examination particularly oriented towards detection of clinical situations that lead to acute respiratory failure.
- A careful examination of the respiratory system. The importance of carefully counting the respiratory rate over a minute cannot be overemphasized. Polyphonic wheezes denote airways obstruction. The rhythm and pattern of breathing are also of importance. In ventilatory failure due to neuromuscular disease, the ability to hold the breath in inspiration and count numbers serially should be noted. Ordinarily, one can easily count up to 30. Inability to count up to 20 or more is a sure sign of marked neuromuscular weakness or of respiratory muscle fatigue. Crackles over the lungs point to pulmonary edema or to interstitial lung disease. Tight airways obstruction need not be accompanied by an auscultatory wheeze, particularly in patients with a lazy respiratory center and with carbon dioxide retention. A forced expiratory effort may bring out a wheeze in such patients, provided they are not obtunded, and can follow commands.
- The cardiopulmonary system should be regarded as a single or interrelated unit, responsible for supplying oxygen to the tissues. A careful examination of the heart and the circulatory system is therefore as important as an examination of the respiratory system. The pulse, arterial blood pressure, central venous pressure, body temperature, moisture and color of the skin, and color of the mucosal surfaces and the nails are all of importance.
- Specific features of hypoxia and hypercapnia should be looked out for; their absence however should never lull the clinician into a false sense of complacency.

Routine Investigations

Arterial blood gas analysis (pH, PaO_2, $PaCO_2$) is absolutely mandatory to confirm a clinical suspicion of acute respiratory failure, or for that matter, to establish a diagnosis even when no clinical suspicion of acute respiratory failure is entertained.

Other routine laboratory investigations include a complete blood count with a packed cell volume (PCV), urine analysis, serum electrolytes, other relevant biochemical parameters and a chest X-ray.

Special Investigational Procedures

In difficult cases, e.g. in the management of acute lung injury (ARDS), or in severe fulminant tetanus, or in patients with acute respiratory failure and shock, special procedures are of use not only in the diagnostic evaluation, but also in the management. These investigational procedures include measurements of the central venous pressure through a central line, and of the arterial blood pressure through a catheter in the radial artery. A Swan-Ganz catheter may need to be inserted to measure the pulmonary artery pressure, the pulmonary capillary wedge pressure, and the cardiac output by the thermodilution technique. The Swan-Ganz catheter is also necessary to measure the mixed venous oxygen

content, and thereby determine the shunt fraction or venous admixture within the lungs. *Invasive procedures outlined above should never be done routinely, but only in problem patients where further information is necessary not only for a complete evaluation, but also for management*. Iatrogenic problems with invasive procedures can be significantly frequent and dangerous. Every good critical care unit must be able to confidently state that the value of an invasive procedure undertaken in a given case clearly outweighs the potential iatrogenic hazards involved. Fortunately, the high cost of the Swan-Ganz catheter, prohibits its frequent use in our country.

As mentioned earlier, the basic disturbance in respiratory physiology must be determined. The following standard questions should therefore be asked, and their answers determined—

- *Is ventilation adequate?* The only certain way to determine this is to measure the $PaCO_2$; a $PaCO_2$ >48–50 mm Hg indicates hypoventilation, while a $PaCO_2$ <35 mm Hg, hyperventilation.
- *What is the physiological abnormality underlying a low PaO_2?* A lowered PaO_2 is an essential feature of acute respiratory failure, and this could be due to—
  - *A reduced FiO_2*, which could arise only at high altitudes.
  - *Hypoventilation* If so, the decreased PaO_2 is related to the increased $PaCO_2$, as determined by the O_2-CO_2 diagram, or the alveolar-oxygen equation stated earlier. The alveolar-arterial gradient remains normal (between 10 mm Hg and 20 mm Hg) in patients in whom a lowered PaO_2 is due to hypoventilation.
  - *Mismatched ventilation-perfusion ratios* Unequal V/Q ratios with an overall reduction in the ratio produce a lowered PaO_2. When plotted on the O_2-CO_2 diagram, the point lies well to the left of the line representing the O_2-CO_2 relationship. The alveolar-arterial gradient is therefore increased (>20 mm Hg).
    Hypoxia due to mismatched V/Q ratios is easily corrected by administering an increased FiO_2. Thus oxygen administered through nasal prongs or catheters, or via an orofacial mask at a rate of 4–6 L/minute suffices to produce a substantial rise in the PaO_2, and a fall in the alveolar-arterial oxygen gradient. However, if the V/Q ratios are very low, a FiO_2 of 0.6 or more is necessary to produce a significant rise in the PaO_2. 100% oxygen always abolishes hypoxia (and a low PaO_2) resulting from even the most severe ventilation-perfusion inequalities.
  - Increased right to left shunt within the lungs, i.e. an increase in the true venous admixture. A significant right to left shunt is suspected clinically when even a high FiO_2 fails to result in a significant rise in the PaO_2. The exact degree of right to left shunt can be calculated by the shunt equation as follows—

$$\frac{Q_S}{Q_T} = \frac{CcO_2 - CaO_2}{CcO_2 - CvO_2}$$

Box 5: Causes of low PaO_2 unrelated to abnormal gas exchange within the lungs

- Low PvO_2 due to decreased cardiac output, or increased oxygen extraction by peripheral tissues due to increased tissue metabolism
- Severe anemia (Hb <7 g/dL)
- Shift of oxygen dissociation curve to the left as in alkalosis, hypothermia, lowered $PaCO_2$, decreased 2, 3-diphosphoglycerate in red blood cells (RBCs)

The CvO_2 can be obtained by sampling the mixed venous blood through a Swan-Ganz catheter. The Q_S/Q_T ratio determined on 20% oxygen gives the overall physiological shunt, i.e. the true venous admixture plus the shunt effect produced by alveoli with low ventilation-perfusion ratios. The Q_S/Q_T ratio determined on 100% oxygen inspired over 20 minutes, abolishes the shunt effect produced by alveoli with low ventilation-perfusion ratios, and gives a value of the true venous admixture, or the actual right to left shunt due to perfusion of totally atelectatic alveoli.

- The degree of true venous admixture can also be roughly estimated by noting the alveolar-arterial oxygen gradient when the patient is on 100% oxygen for 20 minutes. If the alveolar-arterial gradient exceeds 100 mm Hg, it points to the presence of a right to left shunt. The greater the alveolar-arterial gradient on 100% oxygen, the greater the degree of shunt (see Chapter Basic Cardiorespiratory Physiology in the Intensive Care Unit).
- *Impaired diffusion* Though interstitial and alveolar disease might cause impaired oxygen diffusion across the alveolar capillary membrane, the contribution of this impairment to a lowered PaO_2 is not as important in clinical medicine as the effect of ventilation-perfusion inequalities. What is more, an increased FiO_2 can counter any fall in PaO_2 related to reduced oxygen diffusion.

It is extremely important to realize that a lowered PaO_2 could be due to, or influenced by factors other than an abnormal gas exchange within the lungs (Box 5). Factors unrelated to gas exchange, which can lower the arterial PaO_2 include—

- *A low PvO_2* due to a lowered cardiac output, or to increased oxygen extraction by the peripheral tissues because of increased tissue metabolism.
- *Severe anemia* This is initially compensated by an increase in cardiac output. When this does not occur, or when the hemoglobin falls below 7 g/dL, there is a significant fall in the PvO_2 and the mixed venous oxygen content, which ultimately causes a fall in the PaO_2.
- *A shift in the oxygen dissociation curve to the left* as in alkalosis, hypothermia, lowered $PaCO_2$, or a decrease in the 2,3-diphosphoglycerate in the red blood cells. A leftward shift of the oxygen dissociation curve leads to a fall in the PaO_2 for an equivalent degree of oxygen saturation,

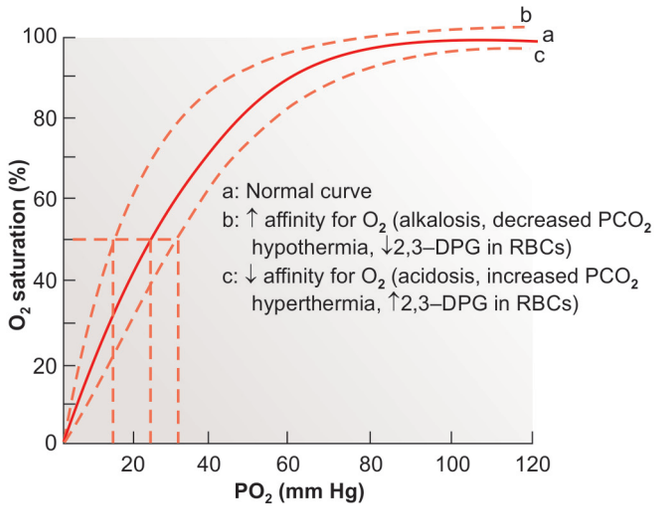

Fig. 7: Normal oxygen-dissociation curve (a), and curve shifted to left (b), and right (c). Curve (b) indicates increased affinity for oxygen, while curve (c) denotes decreased affinity for oxygen. Note that for an equivalent degree of O_2 saturation, the PO_2, level fails with a leftward shift in the oxygen dissociation curve

as compared to a normal oxygen dissociation curve. This is even more marked when there is a sudden shift of this curve from right to left (Fig. 7).

A clear evaluation of extrapulmonary factors is of great importance in critically ill patients, as it improves patient management and care.

- *Is there an increase in the physiological dead space?* An increase in the physiological dead space immediately points to uneven ventilation-perfusion ratios and to regional hyperinflation. An indirect method of assessing dead space is by determining the minute ventilation required to maintain a normal $PaCO_2$. The volume of ventilation exceeding the predicted value, is a measure of increased ventilatory requirements, and is generally due to an increase in the physiological dead space, provided that an increase in the $\dot{V}CO_2$ (i.e. CO_2 produced by tissue metabolism) can be excluded.

If the PCO_2 of mixed expired gas can be determined, then the dead space volume ($\dot{V}_D$), in relation to the V_T is given by the following equation—

$$\frac{\dot{V}_D}{V_T} = \frac{PaCO_2 - PECO_2}{PaCO_2}$$

where $PECO_2$ is the PCO_2 of mixed expired gas.

In patients on ventilator support, Levesque and Rosenberg[12] have devised a rapid and easy method of calculating dead space in relation to V_T. Assuming a normal $\dot{V}_D/V_T$ of 0.3 and a normal $PaCO_2$ of 40 mm Hg,

$$\frac{\dot{V}_D}{V_T} = \frac{V_M \times PaCO_2}{\dot{V}_E} \times \frac{0.3}{40}$$

where V_M is the measured minute ventilation, and $\dot{V}_E$ is the expected minute ventilation from a Radford nomogram.

- *Is the work of breathing increased?* Increased airways obstruction and/or a decrease in the compliance of the lungs or the thoracic wall, or both, result in an increased work of breathing. Though both can be gauged clinically, an exact estimation of airways resistance, and/or of pulmonary compliance in a critically ill patient with acute respiratory failure, is convenient only when the patient is on ventilator support. However, peak flow readings in patients with obvious airways obstruction, particularly when serial readings are measured, are of considerable value in estimating the degree and progress of airways obstruction (see Chapter Acute Severe Asthma).
- *Is there evidence of respiratory muscle fatigue?* Muscle fatigue is determined by the strength of the respiratory muscles and the load of breathing on respiration. Weak muscles and an increased load or work of breathing predispose to muscle fatigue. A clinical evaluation of muscle fatigue and simple bedside objective measurements to assess the possible presence and degree of respiratory muscle fatigue has already been discussed earlier.
- *Is oxygen transport satisfactory?* An adequate cardiac output is necessary for oxygenated arterial blood to reach the tissues. Cardiac output can be clinically gauged by noting the pulse, arterial blood pressure, skin temperature, urine output per hour, the presence or absence of lactic acid acidosis and the presence or absence of dysfunction of major organ systems. In difficult problems, the cardiac output needs to be measured by the thermodilution technique. When the cardiac output is low, oxygen transport can be enhanced by measures to increase the cardiac output. This chiefly is through manipulation of factors that determine cardiac output, namely the preload, cardiac contractility, the afterload, and the rate and rhythm of the heart (see Section Basic Cardiorespiratory Physiology in the Intensive Care Unit).

A normal hemoglobin is also necessary for an adequate oxygen content; a hemoglobin of 9–10 g/dL is generally aimed at in critically ill patients with acute respiratory failure.

- *Is tissue oxygenation adequate?* Good tissue oxygenation is the ultimate aim of restored cardiopulmonary function. There is a great deal more that we need to know about assessment of tissue oxygenation. An increase in lactate levels in the blood is a sure sign of poor tissue oxygenation. In septic shock and in ARDS, utilization of oxygen by the tissues may be inadequate even in the presence of a normal oxygen transport and supply.

MANAGEMENT OF ACUTE RESPIRATORY FAILURE (BOX 6)

There are a number of diseases producing acute respiratory failure for which there is no specific cure. The patient then needs respiratory care and support till such time as the

Box 6: Management of acute respiratory failure

- Maintenance of clear airway—
  - Clear secretions—
    - Liquefy secretions
    - Promote cough—good physiotherapy
    - Suctioning of secretions
    - Use of an airway—oropharyngeal airway, other airways, endotracheal intubation/tracheostomy
- Maintenance of adequate ventilation—
  - Artificial ventilation with an AMBU bag in an emergency till mechanical ventilator support is organized
  - Use of respiratory stimulants (in rare situations)
- Use of oxygen
- Treat cause of acute respiratory failure whenever possible
- Use mechanical ventilator support if cause cannot be treated, or if patient hypoxic or hypercapnic despite above measures

disease resolves. There are other diseases producing acute respiratory failure for which specific therapy is available. Prompt diagnosis and specific treatment in such instances can quickly reverse respiratory failure. The general principles involved in the management of acute respiratory failure include: (1) maintenance of a clear airway; (2) maintenance of adequate ventilation; (3) use of oxygen; (4) treating the cause of acute respiratory failure, in so far as this is possible and (5) the use of mechanical ventilation when indicated—if the cause of acute respiratory failure cannot be treated, or if the patient is hypoxic or hypercapnic despite above measures.

Maintenance of a Clear Airway

Obstruction of the airways due to retained secretions, mucus plugs or foreign matter (invariably food particles), worsen respiratory failure. Secretions obstructing airways can lead to hypoventilation with a further fall in the PaO_2. Mucus plugs within airways contribute to uneven and poor distribution of inspired gas to the alveoli within the lungs, and also produce areas of atelectasis. Uneven ventilation accentuates V/Q inequalities, whilst increasing areas of atelectasis worsen or produce a right to left shunt within the lungs. The net effect is increasing hypoxia and worsening respiratory failure. Undrained secretions or mucus plugs also form a nidus for infection, which may ultimately lead to pneumonia or bronchopneumonia. Maintaining a clear airway is, therefore, vital. This is often lost sight of in a comatose patient who may have normal lungs to start with, but who develops a quickly worsening respiratory failure due to undrained secretions plugging the airways.

Methods to Clear Secretions

- *Liquefy secretions* Undrained secretions can dry and form crusts, which obstruct the airways. Such crusted secretions can be removed only with great difficulty; therefore drying of secretions should be prevented, and their liquefaction promoted by—
  - Proper hydration of the patient, if necessary with intravenous fluids. A severely ill, distressed and breathless patient generally does not drink enough water on his own.
  - *Humidification of inspired gas* This is of utmost importance when the nasal and upper respiratory passages are bypassed, and the patient is breathing through an endotracheal or tracheostomy tube. Lack of humidification in such patients besides causing drying and crusting of secretions in the trachea, the large and the small airways, can also result in inspissated secretions that block the endotracheal or tracheostomy tube with disastrous consequences.
  - *Use of N Saline* 2–3 mL of N saline can be instilled through the endotracheal or tracheostomy tube to liquefy thick secretions which can then be aspirated. Acetylcysteine is also a good liquefactant of inspissated mucus, but is a strong irritant. It can produce severe bronchospasm even in a dose as small as 0.5 mL. The drug can also markedly increase the volume of secretions in the tracheobronchial tree, necessitating very frequent suction. We use this drug very rarely in our unit.
- *Promotion of cough* Cough, in a patient with acute respiratory failure should always be assisted and promoted and never suppressed. When pain prevents cough (as after thoracic, open heart or upper abdominal surgery, or in crush injuries), analgesics need to be given, taking care to use a dose that does not produce respiratory depression. Physiotherapy is vital to enable secretions to be brought up and coughed out. The patient may need to be postured to drain his secretions. In critically ill patients who retain secretions within the respiratory tract, good physiotherapy often spells the difference between survival and death.
- *Removal of secretions by suction* When secretions gather in the mouth and the upper respiratory passages, and the patient is too ill to spit or cough them out, frequent suction should be done to keep the upper airways patent, and to prevent the possibility of aspiration of the secretions into the lungs. Secretions around the larynx can be sucked with the aid of indirect laryngoscopy. Suction stimulates cough in an obtunded patient, and this is of added help. It is important never to roughly touch or hit the tip of the catheter to the pharynx or larynx during suctioning, as this can traumatize the pharyngeal or laryngeal mucosa, induce bleeding and sloughing, and further worsen the problem of maintaining a clear airway. The tip of the suction catheter should lie on the posterior portion of the tongue, preferably not touching the pharynx during suctioning. The floor and sides of the mouth should be suctioned; the nasal cavity and the pharynx can also be conveniently suctioned through a catheter inserted through the nares.
- *Endotracheal intubation* (also see Chapter Airway Management). If the upper airway cannot be kept clear

and open by the methods indicated above, or by the use of a simple oropharyngeal or nasopharyngeal airway, the patient should be intubated. Endotracheal intubation is an invaluable aid to maintain a clear airway as it allows easy access to secretions in the trachea and the large airways. The indications for endotracheal intubation and a tracheostomy as also the management of these artificial airways have been discussed in the Chapter Airway Management.

The main indication for endotracheal intubation is upper airways obstruction and the inability of the patient to handle upper respiratory secretions. The latter feature is frequently observed in unconscious patients, and is invariably so in comatose patients. It also occurs when the cough reflex is poor or the patient is just too ill or feeble to cough. Paralysis of the palate and pharynx will also prevent the patient from handling his upper respiratory secretions because of difficulty in swallowing. This could lead to aspiration of accumulated secretions, as also to aspiration of regurgitated stomach contents. The four common conditions in critical care medicine wherein an endotracheal tube serves to maintain an open airway are poisonings by respiratory depressants, cerebrovascular accidents, coma from any cause and following major surgery. Endotracheal intubation is also indicated when the patient is to be put on mechanical ventilator support.

Maintenance of Adequate Ventilation

Artificial Ventilation

When respiration is feeble, or the patient is apneic, immediate resuscitation is aimed at ensuring adequate ventilation. Initially, mouth-to-mouth respiration may be necessary, followed within seconds by a mask fitted to an AMBU or anesthetic bag, fed with 100% oxygen. This should be quickly followed by endotracheal intubation, mechanical ventilation being carried out either through an AMBU bag or by a mechanical ventilator.

Use of Respiratory Stimulants in Acute Respiratory Failure

The role of respiratory stimulants in acute respiratory failure in ICUs is very limited and to many non-existent. No respiratory stimulant acts specifically and solely on the respiratory center; all such drugs in addition to stimulating the respiratory center, also act as analeptics, in that they awaken the patient, and thereby enable him to ventilate and cough better. In fact, almost certainly the analeptic effect is clinically more important than the specific stimulating effect on the respiratory center. Good physiotherapy should always be given during an analeptic phase, so that secretions within the lungs are mobilized, and either coughed up or removed through suction. Unfortunately, all respiratory stimulants and analeptics frequently produce vomiting as a side effect, and if the dose is large, or the drug is administered rapidly, localized twitchings or generalized seizures can result. If alveolar hypoventilation due to a depressed respiratory center is sufficiently severe to produce well-marked hypoxia and hypercapnia, it is far better to use noninvasive ventilation or to intubate and ventilate the patient, rather than waste time in administering respiratory stimulants. We have stopped using respiratory stimulants in our unit.

Perhaps the only valid use of respiratory stimulants is (1) to tide over a critical period in a patient with acute respiratory failure, while he awaits transfer to an ICU; (2) in patients with hopelessly crippling chronic obstructive pulmonary disease (COPD) who on balance, are not given ventilator support. Respiratory stimulants could then be tried along with the other far more important conservative measures.

The respiratory stimulant with probably the least side effects is doxapram. It is given intravenously at a rate of 1–3 mg/minute, and can be continued till a maximum dose of 600 mg is reached.[13] The risk of seizures is low with doxapram. The infusion can however cause hypertension and cardiac arrhythmias as the drug can stimulate the release of epinephrine from the adrenals. It should therefore be avoided in hypertensive patients, and in those with ischemic heart disease.

Use of Oxygen

The prompt administration of oxygen is crucial in the management of acute respiratory failure. This is considered in a separate section.

Treatment of the Cause of Acute Respiratory Failure Whenever Possible

Treatment is individualized depending upon the etiological factor operating in a patient. The following examples are illustrative and worthy of mention—

- *Treatment of infection* This is the commonest cause that precipitates acute respiratory failure in patients with chronic lung disease. Infection can also occur later as a complication in the natural history of acute respiratory failure due to other causes.
- Removal of air in a tension pneumothorax, and tapping of a massive unilateral pleural effusion or moderate sized bilateral effusions.
- Removal of a foreign body obstructing the larynx, trachea, or a large bronchus.
- Expanding an atelectatic lobe or lung with physiotherapy or bronchoscopic suction.
- Use of prostigmine in myasthenia gravis and of antivenin in snake bite poisoning.
- Use of naloxone in narcotic poisonings.
- Use of nebulized beta-2 agonists, intravenous aminophylline, and oral or intravenous corticosteroids in acute severe asthma.

There are many situations where the cause of acute respiratory failure cannot be promptly treated. This particularly holds true for the numerous conditions, which produce

ARDS, severe tetanus, severe head injuries and other CNS problems and poisonings due to sedatives and tranquillizers. The doctor in charge of the ICU has then to rely on the general principles of management outlined above, till such time as the illness causing acute respiratory failure resolves over a period of time.

Mechanical Ventilation

When well-marked and in particular life-threatening hypoxia and/or hypercapnia are uncorrected by the general principles stated above, the patient needs mechanical ventilator support to aid in more effective gas exchange within the lungs. This is dealt with in a separate chapter.

CHAPTER 29

Oxygen Therapy

INTRODUCTION

Oxygen is used as therapy in most critically ill patients under intensive care. It can be lifesaving in acute respiratory failure, yet can be lethal if incorrectly used. Oxygen administration aims at increasing the P_AO_2 and thereby the PaO_2 and the oxygen saturation of arterial blood (SaO_2). Except in some instances, it is enough to aim at a saturation of 90%; oxygen saturation less than 90% generally corresponds to a PaO_2 less than 60 mm Hg, and denotes the presence of moderate hypoxia. A moderate degree of hypoxia disturbs normal cell metabolism and function; marked hypoxia results in cellular death. A PaO_2 less than 20 mm Hg for a significant length of time generally produces brain death; yet a PaO_2 a little above 30 mm Hg probably maintains adequate cell function if the blood flow is adequate.

We have no means of accurately assessing cell function, and there is no doubt that the sensitivity of certain tissues (such as the brain and the heart) to oxygen lack is far greater as compared to other tissues (e.g. skin and muscle). It is possible that even minor degrees of hypoxia which are easily tolerated in a young healthy individual, might pose problems in critically ill individuals, or in those with a poor coronary circulation, or with impaired cerebral blood flow due to diffuse cerebrovascular disease. It is important to relieve hypoxia of even mild intensity in all such critically ill patients, and preferably aim at oxygen saturation well over 90%.

INDICATIONS FOR OXYGEN THERAPY

Hypoxia is the prime indication for oxygen administration. Dramatic relief with oxygen therapy is chiefly observed when arterial hypoxemia (i.e. a low PaO_2) is due to a low P_AO_2 or ventilation-perfusion mismatch within the lungs. Relief of hypoxia in such patients often brings in its wake three other effects—

1. Decrease in the work of breathing. Hypoxia often causes increased ventilatory work and relief of hypoxia is often followed by a decrease in the work of breathing.
2. Decrease in myocardial work. The heart and circulatory systems are frequently involved in compensatory responses to hypoxia; once the hypoxia is reversed, these compensatory responses abate and the work of the myocardium is reduced.
3. Improvement in cell function involving various organ systems of the body is a welcome aspect of adequate oxygenation to the tissues.

Indications for oxygen therapy are given in Box 1.

Hypoxemia[1]

In an acute setting, hypoxemia (low SaO_2 with a low PaO_2) is the most important and most frequent indication for administering oxygen. These patients (particularly when hypoxemia is due to a respiratory problem) benefit the most with oxygen therapy. The following situations are included in this group—

- Cardiopulmonary or respiratory arrest. Administration of oxygen is of vital importance, but is of no avail unless the patient is simultaneously ventilated and cardiac resuscitation (in a cardiac arrest) is successfully performed.
- Anesthetic error or accident.
- Hypoventilation from any cause.
- Respiratory diseases characterized by ventilation-perfusion mismatch, with or without impaired diffusion across the alveolar capillary membrane. These include severe chronic obstructive pulmonary disease (COPD), acute severe

Box 1: Indications for oxygen therapy

- Hypoxemia—
  - Cardiopulmonary or respiratory arrest
  - Anesthetic error or accident
  - Hypoventilation from any cause
  - Respiratory diseases characterized by ventilation-perfusion mismatch, with or without impaired diffusion across the alveolar capillary membrane
- Respiratory distress with a respiratory rate >24/min
- Pneumothorax
- Myocardial infarction and unstable angina
- Decreased oxygen content of arterial blood—
  - Severe anemia
  - Carbon monoxide poisoning
  - Methemoglobinemia, sulfhemoglobinemia
- Decreased transport of oxygen with impaired perfusion of tissues—
  - Shock from any cause
  - Left ventricular failure
  - Cardiac arrhythmias causing hemodynamic instability
  - Cardiac arrest
- Poor uptake or utilization of oxygen in tissues
- Postoperative states

asthma, as also interstitial lung disease. The commonest cause of hypoxemia in clinical medicine is a ventilation-perfusion mismatch. Patients who have this underlying abnormality benefit the most with oxygen therapy. In fact, if in a hypoxemic patient administration of oxygen leads to a sharp rise in the PaO_2 and SaO_2, the underlying cause of hypoxemia can be confidently attributed to a ventilation-perfusion mismatch or to hypoventilation.

- Respiratory diseases associated with an increase in the right to left shunt within the lungs as in acute respiratory distress syndrome (ARDS), atelectasis, and pneumonia. When there is a true right to left shunt in the lungs (desaturated blood pumped by the right ventricle perfusing totally atelectatic alveoli), there can be no relief of hypoxemia following use of oxygen. However, even in well-marked ARDS there also exists some degree of ventilation-perfusion abnormality with ventilation/perfusion (V/Q) ratios less than 1. Some degree of relief may therefore be expected. The larger the right to left shunt the lesser the relief. Patients with shunts greater than 30% may show little relief from administered oxygen.
- Respiratory distress with a respiratory rate greater than 24/minute is an indication for oxygen therapy as per American College of Chest Physicians (ACCP), National Heart, Lung and Blood Institute (NHLBI) Conference on Oxygen therapy.[2]

Pneumothorax

High concentration of pure oxygen [fraction of inspired oxygen (FiO_2) 60%] has been shown to quicken resolution of a pneumothorax. This is related to an increase of pressure in the gases within the pleural space following use of pure oxygen at a high FiO_2, so that the increased pressure gradient between the air in the pleural space and the surrounding tissues accelerates the absorption of nitrogen from the pleural space.

Myocardial Infarction and Unstable Angina[3]

The American Heart Association (AHA) guidelines for Advanced Cardiac Life Support (ACLS) recommend the use of supplemental oxygen in all patients with the acute coronary syndrome regardless of the presence or absence of hypoxemia. Though undoubtedly useful in hypoxemia (which may be present in the acute stage of a myocardial infarct), the administration of oxygen in patients who are normoxic is not based on convincing data.

Decreased Oxygen Content of Arterial Blood (Other Than That Caused by a Decrease in PaO_2)

- Severe anemia.
- Carbon monoxide (CO) poisoning.
- Methemoglobinemia, sulfhemoglobinemia.

The use of high concentration of oxygen is useful but limited in scope as the PaO_2 is generally normal in this group; it is the oxygen content which is low.

Chronic anemia is generally well tolerated. In acute severe anemia, use of high-flow oxygen through a non-rebreathing mask is of help, in addition to blood transfusions.

In carbon monoxide poisoning, CO combines avidly with hemoglobin (Hb) to form a stable compound carboxyhemoglobin (COHb), thereby sharply reducing the oxygen-carrying capacity of the blood. Management consists of administering oxygen at 10 L/minute through a tight-fitting reservoir mask. The use of close to 100% oxygen provides one-third of the body requirement of oxygen through the extra oxygen dissolved in plasma. It also reduces the half-life of COHb from 10 hours to 4 hours. Hyperbaric oxygen can further reduce the half-life to 20 minutes and can provide enough oxygen in solution to fully take care of the oxygen requirements of the body.

In acute severe methemoglobinemia, inhalation of a high concentration of oxygen is a useful temporary measure (for reasons stated above) till the methemoglobenemia is reversed.

Decreased Transport of Oxygen with Impaired Perfusion of Tissues

- Shock from any cause.
- Left ventricular failure.
- Cardiac arrhythmias causing hemodynamic instability.
- Cardiac arrest.

A fall in systolic blood pressure to less than 100 mm Hg, a low cardiac output with metabolic acidosis (bicarbonate less than 18 mmoL/L), severe shock from any cause are indications for oxygen therapy.

A marked fall in the partial pressure of oxygen in venous blood (PvO_2) due to a fall in the cardiac output leads to a significant fall in the PaO_2. Also, many of these conditions

produce an increase in the physiological dead space and/or a ventilation-perfusion mismatch. It is important to maximize both the PaO_2 (and the oxygen content), as also increase oxygen transport through an increase in the cardiac output in these patients.

Acute left ventricular failure, tachyrhythms or bradyrhythms causing hemodymamic instability, and cardiac arrest are important indications for the administration of oxygen.

Poor Uptake or Utilization of Oxygen in Tissues

Poor uptake and/or utilization of oxygen in tissues is seen in septic shock, ARDS; here again the PaO_2, oxygen content and oxygen transport or delivery to the tissue cells must be adequate if cellular and organ functions are to be well maintained.

Oxygen is not utilized by tissues in cyanide poisoning as cyanide inactivates the enzyme cytochrome oxidase within the cells. A high FiO_2 is only of marginal help; reversal of cyanide toxicity by suitable antidotes is of prime importance.

Postoperative States

General anesthesia usually induces a decrease in the functional residual capacity, an increase in venous admixture and a slight to moderate ventilation-perfusion mismatch. This is particularly observed following thoracic surgery, coronary artery bypass graft surgery, open heart surgery, upper abdominal surgery and any protracted surgical procedure. A mild to moderate hypoxemia results, easily relieved by administering oxygen for an appropriate period of time.

It is important to remember that even though oxygen helps in the relief of hypoxia, it does not eradicate the root cause of hypoxia. It is therefore no substitute for adequate alveolar ventilation, neither does it solve the problem of V/Q abnormalities, nor does it abolish a right to left shunt within the lungs. Again, the oxygen content of blood is not only dependent on the PaO_2 but also on the hemoglobin concentration of the blood. The importance of an adequate cardiac output to ensure good oxygen transport cannot be overstressed. Finally, the proper uptake and utilization of oxygen by the tissue or cells is necessary if tissue hypoxia is to be countered or prevented.

Important Considerations in Oxygen Administration

When uncontrolled oxygen (at high flow rates) is given to relieve hypoxia in patients with severe COPD or in patients who suffer an acute exacerbation of COPD, relief of hypoxemia may be accompanied by a sharp rise in the arterial carbon dioxide tension ($PaCO_2$). Marked hypercapnia is undesirable and can cause a sharp fall in the pH of the arterial blood increasing both morbidity and mortality in these patients. The hypercapnia that results in the above circumstances is largely related to alveolar hypoventilation rather than to the inability of the respiratory center to respond to an increasing $PaCO_2$. This has been dealt with in the Chapter Acute Exacerbation of Chronic Obstructive Pulmonary Disease.

Therefore an important consideration is to use controlled oxygen therapy to relieve hypoxemia in patients with an acute exacerbation of COPD. This is achieved by administering oxygen through a Venturi mask (24.5% or 28%) or using low-flow oxygen at 2 L/minute via nasal prongs. Arterial blood gas analysis should be done before starting oxygen therapy. The incidence of sharply increasing hypercapnia with controlled oxygen therapy is observed only in a small percentage (13% in a recent study) of patients. If the PaO_2 during controlled oxygen therapy rises close to 60 mm Hg and the arterial pH is not lower than 7.25, controlled oxygen therapy should be continued. If however even with controlled oxygen therapy the $PaCO_2$ continues to rise so that the arterial pH falls below 7.25, or it is impossible to relieve hypoxemia (PaO_2 <55 mm Hg) without increasing hypercapnia and a falling arterial pH, other measures such as ventilator support become necessary. The ventilator support may be noninvasive or invasive depending upon prevailing circumstances (see Chapter Acute Exacerbation of Chronic Obstructive Pulmonary Disease).

One other consideration to be remembered is that in patients who hypoventilate due to neurogenic diseases, respiratory muscle weakness, poisonings (and in other conditions where to start with the lungs are essentially normal), administering oxygen will relieve hypoxemia but will have no effects on the hypercapnia observed in these patients. Finally, it should be remembered that oxygen is a dry gas and should always be humidified before administration, particularly so when the upper airway is bypassed by the use of an endotracheal tube or a tracheostomy. Ventilation of the lungs with dry gases produces heat loss, and moisture loss from the respiratory passages, and also alters pulmonary function. Heat loss causes a fall in body temperature and increases oxygen consumption. Moisture loss leads to drying or dehydration of the respiratory mucosa. The most important effect consequent to this drying is a reduced activity of the mucociliary escalator with sputum retention. Blocked airways from inspissated respiratory secretions result in ventilation-perfusion inequalities, and may lead to or accentuate hypoxia. Thus the importance of humidifying oxygen in inspired gas cannot be overemphasized.

METHODS OF OXYGEN ADMINISTRATION[4]

Routine Oxygen Therapy Using Low-Flow Oxygen

Administration Devices

A moderate rise of oxygen concentration in the alveoli suffices to relieve moderate hypoxia. An oxygen concentration of approximately 40% may be achieved by using nasal catheters, nasal prongs, or simple orofacial masks, if the flow rate is maintained between 6 L/minute and 8 L/minute. Patients cannot ordinarily tolerate flow rates higher than 6–8 L/minute through the above mentioned devices.

Nasal catheters and nasal prongs These are the simplest and most commonly used techniques of oxygen administration.

Fig. 1: Nasal prongs

Fig. 2: Simple face mask

If a nasal catheter is used, its tip should be advanced to the fold of the soft palate, and then pulled back very slightly. If it is introduced too far, it can produce gaseous distension of the stomach, as oxygen finds its way into the stomach rather than into the lungs. Irritation of the nasal mucosa can be minimized by lubricating the catheter with xylocaine jelly. The catheter can be changed from one nostril to the other every 6–8 hours.

Most units prefer nasal prongs to nasal catheters. Nasal prongs (two short plastic prongs that fit into the external nares) (Fig. 1) offer the advantage of simplicity and comfort. An added advantage over an orofacial mask is that the administered oxygen does not have to be discontinued during eating, speaking or coughing.

When oxygen is administered through nasal prongs or a nasal catheter, at a flow rate of 1–2 L/minute, the oxygen concentration is approximately 24%. At flow rates of 6–8 L/minute, the oxygen concentration approximates 40%. Further increase in flow rates are poorly tolerated and produce very little additional increase in oxygen concentration.

The effect of a given flow of oxygen through a nasal catheter or prongs is dependent not only on the flow rate, but the tidal volume and minute ventilation of the patient. If the tidal volume and minute ventilation decrease, i.e. the patient hypoventilates, then the inspired oxygen concentration will rise. Precise regulation or control over inspired oxygen concentration is thus not possible with nasal prongs or catheter. Recently developed methods of administering supplemental oxygen include the use of *reservoir cannulae, transtracheal oxygen delivery and pulsed oxygen delivery*. Transtracheal oxygen delivery is affected via a small catheter inserted into the trachea at the base of the neck. It is totally unnecessary for intensive care unit (ICU) use though it has some benefits for patients on domiciliary oxygen therapy. Pulsed oxygen devices deliver oxygen only during inspiration. This conserves oxygen, yet provides a PaO_2 equivalent to that obtained with a continuous flow system through prongs or a face mask. Pulse type devices deliver fixed oxygen volume and flow each time a pulse is triggered. Demand devices vary the volume of oxygen delivered from breath to breath depending on the depth of inspiration.

Face mask A simple oronasal plastic mask (Fig. 2) fed with oxygen at a flow rate of 6–10 L/minute, is a frequently used method for administering oxygen. The oxygen fed directly into the mask (after humidification), displaces air and creates a small oxygen reservoir. During inspiration, oxygen in the mask is inhaled; room air is also entrained through the ports and through the space between the face and the mask. The oxygen concentration of inspired gas is thus much less than 100%. The extent to which inspired oxygen concentration can increase depends on the size of the mask (and therefore of the oxygen reservoir), and the flow rate of oxygen. Higher flow rates are generally better tolerated through the use of a mask as compared to nasal prongs or catheters. At a flow rate of 6–10 L/minute, an oxygen concentration of approximately 35–55% can be achieved. The face mask is less easy and less comfortable to wear than nasal prongs. The major disadvantage is that it has to be removed when the patient speaks, eats, drinks, coughs, or expectorates.

Face mask with reservoir bag The addition of a reservoir bag to the face mask (Fig. 3) increases the potential reservoir of oxygen, and allows a further increase in the concentration of inspired oxygen. Inspired oxygen consists of oxygen from the reservoir bag of the face mask, together with some air entrained through the side ports and the small space

Fig. 3: Face mask with reservoir bag

between the mask and the skin of the face. During expiration, most of the exhaled gas passes out through the side ports, but some expired gas may return to the reservoir bag. This could lead to a fall in the partial pressure of oxygen (PO_2) and a rise in the partial pressure of carbon dioxide (PCO_2) in the reservoir bag, and should be avoided by a sufficiently high rate of oxygen flow to keep the bag washed out. Oxygen flow rates of 8–12 L/minute are commonly used with this device, and can provide an inspired oxygen concentration between 50% and 80%. The flow rate of oxygen must be so adjusted that the reservoir bag is not emptied by more than half during inspiration.

Face mask with reservoir bag and directional valves The entrainment of room air during inspiration can be almost completely prevented by covering the side ports with directional valves (Fig. 4). Except for some air passing between the mask and the face, the entire volume of inspired gas consists of oxygen from the reservoir bag and the face mask. During exhalation, the side port directional valves open and air passes out from the mask into the atmosphere. The passage of expired air back into the reservoir bag can be prevented by a directional valve.

It is important that the flow rate of oxygen fed into the mask and reservoir bag with directional valves is in the range of 10–15 L/minute. The inspired oxygen concentrations can thereby be raised in such instances to as high as 90–95%. It is also extremely important to ensure that there is no failure in oxygen supply nor a sharp fall in the flow rate, as breathing is dependent on oxygen fed into the mask-reservoir device. If the reservoir bag is inadvertently empty, asphyxia results. Table 1 compares the oxygen flow (L/minute) and oxygen concentrations (%) obtained by using low-flow oxygen administration devices.

Fig. 4: A patient breathing through a face mask with reservoir bag and directional valves

Table 1: Correlation between oxygen flow (L/min) and oxygen concentrations using low-flow oxygen administration devices

Device	*Approximate O_2 flow (L/min)*	*Approximate O_2 concentration (%)*
Nasal cannula	6	40–50
Facial mask	8	35–55
Mask with reservoir	10	50–80
Mask with reservoir plus directional valves	12	90–95

Controlled Oxygen Therapy

Principles

The purpose of controlled oxygen therapy is to relieve dangerous hypoxia by producing an adequate increase in the P_AO_2 and the PaO_2, and yet control and limit the associated rise of $PaCO_2$. This would also limit the fall in arterial pH due to respiratory acidosis.

Technique

The concentration of inspired oxygen is controlled by using high air flows with known oxygen enrichment. The principle underlying this technique is entrainment of air with constant pressure jet mixing. High air flows allow the immediate space or environment around the patient's face to be so thoroughly flushed, that there is no rebreathing and no contamination with room air. In this manner, the concentration of inspired oxygen can be controlled to within 2%.

Ventimask

The ventimask works on the Venturi principle and allows perfectly controlled oxygen administration. Oxygen is delivered to the mask through a nozzle, and the aperture of the nozzle is of set size so that as the oxygen is released through the aperture, it entrains a fixed portion of air through the side holes of the mask. Thus, if an oxygen concentration of 24% is desired, the aperture of the delivery nozzle is such that 1 L of oxygen/minute will entrain 20 L of air, and 2 L of oxygen/minute will entrain 40 L of air. The entrainment ratio is 1:20, and is independent of the flow rate; the oxygen concentration of the inspired gas is thus independent of the flow rate.

Different ventimasks have different aperture size nozzles, and provide different but fixed oxygen concentrations. For example, a mask that is designed to provide an oxygen concentration of 28% will have a nozzle aperture that allows 1 L of oxygen delivered through the nozzle to entrain 10 L of air through the side holes, i.e. a 1:10 entrainment ratio, which is again independent of the flow rate of oxygen.

As mentioned at the outset, the ventimask works on the Venturi principle, and the Venturi is fairly accurate at the recommended total flow of 40 L/minute (i.e. 2 L of oxygen/minute for a 24% mask, and 4 L of oxygen/minute for a 28% mask). The gas flow around the patient's nose and mouth flushes the mask continuously, washing out the expired carbon dioxide, and ensuring that the patient only breathes the oxygen-air mixture provided to him.

The greatest advantage of the ventimask is that the oxygen concentration it provides is independent of the flow rate, and also independent of the patient's tidal volume and minute ventilation. It can be easily used by all nurses, and requires no special adjustment. Also, the concentration of oxygen delivered is not at the mercy of faulty flow meters or reducing valves. The disadvantage as with all oronasal masks is that it has to be removed during coughing, eating, speaking, or drinking. In a seriously ill patient, removing the mask during feeds can cause a dangerous deterioration due to a sharp fall in the PaO_2 and worsening hypoxia. In severely hypoxic patients, the administration of oxygen should be continued, even when the patient is being fed, via nasal prongs at a flow rate of 1–2 L/minute; this prevents the temporary but dangerous hypoxia.

Currently, other commercially available high airflow systems have been designed to deliver oxygen concentrations varying from 24% to 50%, using the same principle as the Venturi mask. A jet of oxygen from a wall or tank source is passed through a precisely designed (exact size) orifice, and this results in the entrainment of room air through the ports in the surrounding cylinder.

Nasal Prongs

Many ICUs in Mumbai and other large cities (leave aside smaller towns all over the country), do not use ventimasks or other high airflow oxygen-enriched delivery systems to provide controlled oxygen therapy. It is recommended that in the absence of these devices, nasal catheters or nasal prongs be used in an attempt to give controlled oxygen therapy. Oxygen at a flow rate of 1–2 L/minute through nasal prongs or catheters is generally effective in providing controlled oxygen concentrations of 24–28% in inspired gas. The flow rate should be initially kept at 1 L/minute; if this is well tolerated, it is increased to 2 L/minute. Measurements of the PaO_2 and the $PaCO_2$ are of help, and the patient is kept under a close watch, especially as regards his ventilation. If the patient has marked hypoventilation, administration of oxygen even at 1–2 L/minute can lead to an uncontrolled or higher than desired concentration of oxygen. In such patients, the flow rate should be reduced to less than 1 L/minute. Oxygen delivered through nasal prongs or catheters at low flow rates as stated above, is generally effective in relieving hypoxia without producing a dangerous rise in the PCO_2.

Hyperbaric Oxygen

Hyperbaric oxygen is not administered in the ICU. Yet some critically ill patients under intensive care have to be transported to hyperbaric oxygen chambers in the same or distant hospitals to avail of this therapy. The administration of oxygen at higher than atmospheric pressure has certain advantages. When breathing air at atmospheric pressure, the oxygen in solution in plasma is 0.3 mL/dL; when breathing oxygen at a pressure of 2 atm, it is 4.5 mL/dL. This is just a little less than the amount of oxygen taken up by tissues in unit time, and goes a long way in aiding jeopardized tissue perfusion, and relieving tissue hypoxia. The main use of hyperbaric oxygen is in the treatment of carbon monoxide poisoning. The dissolved oxygen relieves hypoxia, and the markedly increased oxygen tension helps the quick dissociation of carbon monoxide from COHb. Hyperbaric oxygen therapy is also useful in the management of sepsis secondary to wounds contaminated by anaerobic gas-forming organisms, and in the treatment of wounds with a poor blood supply. Hyperbaric oxygen is also used in the treatment of an ischemic limb where definitive surgical or non-surgical techniques are either not indicated or have failed.

Humidification of Oxygen and Inspired Gas[5]

Oxygen is dry and should always be humidified before administration. Ventilation of the lungs with dry gases produces heat loss, and moisture loss from the respiratory passages, and also alters pulmonary function. Heat loss causes a fall in body temperature and increases oxygen consumption. Moisture loss leads to drying or dehydration of the respiratory mucosa. The most important effect consequent to this drying is a reduced activity of the mucociliary escalator with sputum retention. Blocked airways from inspissated respiratory secretions result in ventilation-perfusion inequalities, and may lead to or accentuate hypoxia. Thus, the importance of humidifying oxygen in inspired gas cannot be overemphasized.

When oxygen is administered by nasal prongs, nasal catheters, or a facial mask, the upper respiratory passages, particularly the nose, will normally humidify the inspired gas. Even so, oxygen should preferably be humidified before administration. When upper respiratory passages are bypassed by an endotracheal or tracheostomy tube, humidification becomes absolutely mandatory.

It should be noted that even if room air or administered oxygen is saturated to 100% with water vapor at room temperature, this saturation drops considerably when it comes into contact with respiratory passages whose normal temperature is 37°C. The fall in saturation is even greater if the body temperature is higher, as in patients running fever. Therefore to prevent drying of the respiratory mucosa either the air or oxygen inspired by the patient should be saturated

Fig. 5: A bubble humidifier

Fig. 6: A heated vaporizer

with water vapor at 37°C; or the inspired air or oxygen should be supersaturated by suspending water droplets in it at room temperature. When this supersaturated oxygen or air is warmed during its passage through the trachea, the suspended droplets vaporize and provide a humidity of well-nigh 100%.

There are a number of techniques for humidification. All modern ventilators are provided with humidifiers with temperature control of the humidified gas delivered to the patient, as also with nebulizers, which allow nebulization of inspired gas or nebulization of drugs into the respiratory tract.

Devices for the humidification of inspired gas or oxygen can be broadly divided into those that add water to gases, and those that retain water from expired gases (heat and moisture exchangers).[6]

Devices Adding Water to Gases

Vaporizers (unheated)[7]. A bubble humidifier is an example of an unheated vaporizer (Fig. 5). When oxygen is moistened by bubbling it through a large surface of water, because of the heat loss by vaporization, the temperature of oxygen falls below the ambient temperature, at flow rates greater than 6 L/minute. The cooled gas has sufficient moisture, but when it comes into contact with the warm respiratory mucosa, the water vapor saturation falls to 20–25%. With nasal prongs or a face mask, this method suffices as warmth and humidification are supplied by the nose, mouth and pharynx. A bubble humidifier is however quite inadequate for humidification of oxygen or inspired gas in patients with an endotracheal tube or tracheostomy.

Heated vaporizers (Fig. 6)[8-10] The Blower Humidifier devised by Spalding,[11] is a good example of this type. Air or oxygen from a blower or a mechanical ventilator is passed over a surface of water thermostatically maintained at a temperature of 45–55°C. The inspired gas is 100% saturated at this temperature, and the thermostat is set so that the air or oxygen is delivered to the patient at about 37°C. At this temperature, the inspired gas or oxygen is saturated to about 70–90%. The blower humidifier tends to get overheated, and the temperature of inspired gas should therefore be frequently checked to prevent thermal injury to the respiratory passages. There is also a risk of bacterial colonization of the water in the reservoir, or in the delivery tubing.

Fig. 7: Ultrasonic nebulizer

Nebulizers Various nebulizers can be used to suspend water particles in inspired gas. The water droplets should be 1–10 µm in diameter. Larger droplets are of no use as they get deposited within the delivery tubes. Smaller droplets are stable and are not deposited in the respiratory tract. Nebulizers can be gas driven (Fig. 7) mechanically actuated (e.g. spin disc nebulizer), or ultrasonic.[12]

The main disadvantage of gas driven and mechanically actuated nebulizers is the risk of microbiological contamination of the reservoir. This can be dangerous as microbes suspended in the aerosol can reach deep into the lungs, right up to the alveoli. Ultrasonic nebulizers are costly and can cause overhydration, as most devices can produce water well in excess of 250 g/m^3, and some, over 1000 g/m^3.[12] Bacterial contamination of the aerosol can also occur.

A saline drip through the tracheostomy tube In a patient with a tracheostomy, when the above described methods are not available because of financial or other constraints, an easy and effective method of humidification of inspired gas, is to drip normal saline slowly into the tracheostomy tube through a thin sterile plastic catheter, at the rate of 10–12 drops/minute or 16 mL/hour. With a minute ventilation of 8 L/minute, this gives a theoretical humidity of 31 mg/L to the inspired gas.[13]

Devices Retaining Water from Expired Gases

Heat and moisture exchangers (HME)[7,14] An HME is a device which when connected to an artificial airway will extract heat and moisture from the expired gas, and will return this heat and moisture to the inspired gas during inspiration. Ideally an HME should retain at least 70% of expired moisture. HME devices include Condenser Humidifiers, Hygroscopic Condenser Humidifiers and Hydrophobic Condenser Humidifiers. Filtration of inspired and expired gases can be provided by the associated use of heat and moisture exchanging filters.

HME devices have important advantages—

- Humidification is satisfactory with artificial airways (endotracheal or tracheostomy tubes).
- The breathing circuit remains dry.
- They are comparatively inexpensive, disposable, and do not require an external power source.

They cannot however provide very high levels of humidification, and ventilation can be obstructed if sputum is expectorated on the exchanger membrane. Some HME devices have a significant internal volume, and therefore increase the dead space. This is a disadvantage in a spontaneously breathing patient with a reduced tidal volume. These devices also produce a slight increase in the resistance to breathing, and when saturated with water vapor, result in a significant obstruction to airflow.

In conclusion, humidification of inspired gases is necessary for all critically ill patients receiving ventilatory support, for those breathing through a tracheostomy or endotracheal tube, and for those who have been breathing spontaneously, but have recently been extubated. The humidifier used should produce adequate saturation of the inspired gas or oxygen with water vapor. Heat and moisture exchangers have greater advantages as compared to hot water bath humidifiers. Bacterial colonization is a major risk and can result in nosocomial pneumonia. The use of filters that prevent bacterial or viral contamination of humidified inspired gas helps to decrease the incidence of this complication.

COMPLICATIONS OF OXYGEN THERAPY

Progressive Hypercapnia[15]

The danger of progressive hypercapnia, particularly after uncontrolled oxygen therapy in a number of patients with hypoxia due to COPD, has already been discussed (also see Chapter Acute Exacerbation of Chronic Obstructive Pulmonary Disease).

Circulatory Depression

This is very rare, but has been occasionally observed in patients who have been acutely, severely hypoxic, and whose circulation is maintained by excessive sympathetic activity and excessive catecholamine discharge, induced by the severe hypoxia. Sudden relief of hypoxia abolishes this sympathetic overactivity, causing temporary hypotension, and occasionally circulatory collapse. We have observed this phenomenon following sudden relief of acute severe hypoxia in glottic or subglottic obstruction, after establishing an open airway (through a tracheotomy) and administering a high concentration of oxygen. Circulatory depression is temporary, and can be corrected by a volume load, or by an infusion containing a sympathomimetic agent.

Drying and Crusting of Secretions in the Respiratory Tract

Oxygen should always be humidified prior to administration. This is particularly imperative in patients with artificial airways. Unhumidified oxygen causes drying of secretions, and this can result in blockage of the bronchi by inspissated mucus. Partial or complete blockage of artificial airways (endotracheal or tracheostomy tube) by crusted secretions can have disastrous consequences.

Danger of Oxygen Withdrawal

Moderate or severe hypoxia warrants continuous oxygen therapy till such time as the hypoxia is relieved. Some hypoxic COPD patients may become drowsy or disoriented even on controlled oxygen therapy. To discontinue oxygen in such a situation is dangerous and wrong. If oxygen administration is stopped with the $PaCO_2$ markedly elevated, the P_AO_2 (and consequently the PaO_2) falls to an even lower level than that prior to starting oxygen therapy. This is because the P_ACO_2 has risen to a higher level than that prevailing at the start of oxygen therapy. Such patients therefore have a worsening of their already severe hypoxic state. Intermittent oxygen therapy can be dangerous in a hypoxic patient, and is wrong on principle. It only serves to give periods of relief from hypoxia, followed by periods of worsening and often extreme hypoxia. Oxygen, if indicated, needs to be given continuously till hypoxia is relieved.

Oxygen Toxicity

Lung Toxicity

High concentrations of oxygen over a prolonged period of time can produce changes in the lungs characterized by atelectasis, damage to the surfactant, interalveolar edema, and interstitial thickening and fibrosis. It is generally accepted that oxygen concentrations up to 50% are safe for long periods. We have used 60% oxygen for weeks, and have observed that the patients have recovered without residual effects. We have also been forced to use 100% oxygen in two patients (who would otherwise have died of hypoxia) for as long as 24 hours, followed by 80–90% oxygen for the next 4–7 days, and then 60–70% oxygen for another week. Both patients survived without any significant residual damage to the lungs. This does not mean that very high oxygen concentrations should be used with abandon. It does however signify that in our experience, the use of 100% oxygen is not as lethal as is often made out to be.

The practical applications to be derived from experimental and clinical studies on oxygen toxicity are summarized below—

- For patients with chronic hypoxemia (as in severe chronic airways obstruction), it is sufficient to use a concentration of oxygen that will correct dangerously low PaO_2 levels. A PaO_2 between 55 mm Hg and 60 mm Hg (O_2 saturation—90%) is generally adequate in these patients.
- Positive end-expiratory pressure (PEEP) should be used during mechanical ventilation if an inspired oxygen concentration greater than 50% fails to relieve dangerous hypoxia in patients with acute pulmonary disease.

In acute pulmonary problems with severe hypoxia, the oxygen concentration must be sufficient to allow an oxygen saturation of about 90%. If in spite of the use of PEEP, very high oxygen concentration (>80%) is needed over a prolonged period of time to maintain an oxygen saturation of 90%, it may be permissible to allow mild to moderate hypoxemia (O_2 saturation around 85%) so as to enable a reduction in the FiO_2. The degree of hypoxia one allows will depend on the patient's tolerance to hypoxia, the age of the patient, and the ability or otherwise to increase oxygen transport to the tissues.

Life-threatening hypoxia must always be relieved, even if this requires the use of 100% oxygen for prolonged periods of time. The fear and danger of possible oxygen toxicity is never an argument to allow a patient to irreversibly deteriorate and die of hypoxia.

It is difficult, if not impossible, to detect signs of lung toxicity due to high oxygen concentrations in critically ill individuals with serious pulmonary problems. A fall in the compliance and the PaO_2 can occur due to very high oxygen concentrations, but it may be impossible to ascertain in clinical practice, whether this is related to the disease, or is iatrogenic due to oxygen toxicity.

Retrolental Fibroplasia

This complication occurs in the neonatal period, and is related to high PaO_2 levels. If the inspired oxygen concentration is high enough to raise the PaO_2 to about 160 mm Hg even for a few hours, retrolental fibroplasia can occur. Therefore in neonates, PaO_2 levels should never equal or exceed 100 mm Hg.

Cerebral Oxygen Toxicity

This is occasionally observed when oxygen is breathed at hyperbaric pressures above one atmosphere. The syndrome is chiefly characterized by epileptic fits and is termed the Paul Bert effect, after the individual who first described it.

CHAPTER 30

Airway Management

ESTABLISHING THE AIRWAY

Nothing is more critical in emergency respiratory care than ensuring a patent airway and then maintaining it. An obstructed airway can lead to death within a few minutes. In patients with cardiac arrest, inability to secure a patent airway generally renders all efforts at cardiopulmonary resuscitation ineffective.

UPPER AIRWAYS OBSTRUCTION

Upper airways obstruction may result from soft tissue obstruction or from laryngeal obstruction. Soft tissue obstruction is probably the most common airway emergency. It results from the encroachment on the patency of the upper airway by soft tissues of the pharynx or by tissue in close relation to the pharynx. Upper airways obstruction is thus seen in comatose patients when the pharynx loses its tone or in patients with lower cranial nerve palsies when the pharynx is paralyzed. It also occurs in angioneurotic edema, inflammation, retropharyngeal abscess, and can be caused by bleeding and soft tissue tumors within that area. Foreign bodies, dentures, vomitus, blood clots, thick oropharyngeal secretions can also block the upper airway. The common factor underlying all these causes of upper airways obstruction is the absent or the markedly diminished patency between the base of the tongue and the pharyngeal wall. Obstruction at the larynx can be caused by laryngeal spasm as in tetanus, by a bilateral vocal cord abductor palsy, by inflammatory or neoplastic lesions above or within the larynx or by laryngeal edema. A foreign body or food (such as a piece of meat) may also obstruct the larynx and cause severe asphyxia and death. Partial upper airways obstruction is characterized by noisy breathing, akin to snoring. Partial upper airways obstruction can be easily missed, particularly in comatose patients who in addition often hypoventilate due to a depressed respiratory center. Laryngeal or tracheal obstruction gives rise to a high-pitched inspiratory sound termed stridor. Complete or almost complete airways obstruction results in marked inspiratory efforts with little or no movement of air into the lungs. There is severe retraction of the intercostal spaces, the sternum and epigastrium, together with strong contraction of the accessory muscles of respiration during inspiratory efforts. The patient, to start with, is extremely distressed, restless and anxious; and becomes increasingly cyanosed. Tachycardia or a bradyarrhythmia is related to hypoxia. Death ensues if hypoxia is unrelieved.

MANAGEMENT

The treatment obviously is to relieve soft tissue obstruction by simple basic maneuvers.

Neck Extension with Forward and Upward Chin Thrust

This should be the first maneuver to be attempted as it can promptly relieve mild to moderate obstruction by increasing the patency between the back of the tongue and the pharynx. Careful suction of secretions, blood and vomitus from the pharynx may be necessary, as also the removal of dentures or a foreign body that may be obstructing the airway.

Bag-Mask Ventilation

Once the above basic maneuvers have been accomplished, it is important to ventilate the patient so as to prevent and combat hypoxia. The immediate and simplest way to attempt this is through Bag-mask ventilation. Next only to cardiac compressions, bag-mask ventilation is of crucial importance

in a patient with cardiac or cardiopulmonary arrest. It is also the initial step in a patient with a semi-obstructed airway or in a patient acutely hypoxic from any cause. Bag-mask ventilation is often preparatory to the possible need to intubate the patient so as to secure the airway. As far as possible, endotracheal intubation should be performed by an individual with the requisite experience and expertise. Attempts to abandon bag-mask ventilation and intubate the patient by inexperienced personnel have often proved harmful. Unsuccessful attempts to intubate with damage to the airway make a subsequent attempt at intubation by even an experienced individual difficult.

Technique

The mask should cover the bridge of the patient's nose at the upper end and should cover the mouth at the lower end; so that the nose and mouth are enclosed by the mask. The doctor stands at the patient's head, presses the mask down with the left hand. The thumb fixes the nasal portion of the mask and the index finger is over the oral portion, the rest of the fingers of the left hand are spread over the left side of the patient's mandible so as to push it forward. The bag attached to the mask is alternatively squeezed and relaxed with the operator's right hand at 15–18 times per minute so that air (or 100% oxygen if the bag is connected to an oxygen supply) is pushed via the mask into the airway and into the lungs with each squeeze of the bag. The success of bag-mask ventilation is judged by the rhythmic rise and fall of the patient's chest with each squeeze and relaxation of the bag, by satisfactory auscultatory breath sounds and generally by improvement of the patient's oxygen saturation. The lung chest compliance can be roughly assessed by the amount of pressure or force required to squeeze the bag. The minimum pressure or squeeze should be used to satisfactorily expand the chest so as to decrease the risk of insufflating the stomach with gas as this could increase the risk of aspiration.

Management of Aspiration during Bag-Mask Ventilation

Danger of aspiration is significant in high-risk patients—those with a full stomach, patients with a hiatus hernia or gastroesophageal reflux, obese individuals and in pregnancy. Aspiration should be countered by maintaining pressure over the cricoid cartilage (thereby closing the esophageal lumen), putting the patient promptly in the Trendelenburg position and suctioning the gastric contents. If possible, intubation should be performed with the help of direct laryngoscopy. The airway should be secured and the cuff of the endotracheal tube inflated before resuming positive-pressure ventilation.

Airway Adjuncts

If positioning of the head and neck with clearing of secretions (or foreign material) from the mouth fails to establish a clear airway, several airway adjuncts are available if an individual with necessary expertise for intubating the patients is not available. The oropharyngeal and nasopharyngeal airways are simple airway adjuncts that can be of use to keep the upper airway patent if head positioning has not sufficed. These are briefly described below.

Oropharyngeal Airway

This device is a conduit inserted along the top of the tongue until the teeth or gums limit its insertion. It is positioned between the base of the tongue and the pharynx (separating the two) thereby maintaining a patent airway. The airway should be inserted with its curve up initially and rotated into position when the end reaches the base of the tongue. It is designed to permit a suction catheter to pass through it, and allow suction of secretions in the pharynx and upper larynx. An oropharyngeal airway is chiefly suited for comatose patients and that too for limited periods of time. As it rests at the base of the tongue, it stimulates the gag reflex, and can induce excessive salivation, vomiting and even laryngospasm in the conscious patient.

Nasopharyngeal Airway

The nasopharyngeal airway is a pliable plastic tube inserted (after lubrication) through the nares to follow the posterior wall curvature of the nasopharynx and oropharynx so that its tip rests on the base of the tongue, separating it from the pharyngeal wall. This airway is better tolerated than the oropharyngeal airway by the semiconscious and fully awake patient. It can prevent or relieve soft tissue upper airways obstruction and allows suctioning of the pharynx through a suction catheter passed through the airway. The nasopharyngeal airway can cause bleeding and airway trauma through pressure necrosis. Some advocate daily changing of the airway from one nare to the other to minimize trauma to the nasal passages. We very rarely use the nasopharyngeal airway in our unit (Fig. 1).

ARTIFICIAL AIRWAYS

An artificial airway is a conduit or tube inserted into the trachea bypassing the pharynx and larynx, which no longer form part of the total airway. In essence, this means endotracheal intubation or tracheostomy.

Indications

1. Hypoxia and/or hypercapnia (due to acute respiratory failure) severe enough to necessitate invasive ventilator support through an endotracheal tube or a tracheostomy is the prime indication for the insertion of an artificial airway. In certain circumstances, noninvasive ventilator support is preferred to invasive ventilator support at least to start with. When noninvasive ventilator support fails or is contraindicated, invasive ventilator support is mandatory. Noninvasive ventilator support, its indications and contraindications have been discussed later in another chapter.

Fig. 1: Maintaining a clear airway by triple airway maneuver: (1) Tilt head backward; (2) Lift mandible forward and (3) Open the mouth and try to remove any foreign body

2. To maintain an open airway in the presence of obstruction to the pharynx or larynx. Obstruction to the upper airway could be caused by trauma to the mandible or larynx, or the inhalation of smoke or noxious chemicals. Obstruction could also result from acute epiglottitis (particularly in children), a large retropharyngeal abscess or hematoma or a subglottic stricture. Laryngeal edema and/or laryngeal spasm are important causes of upper airway obstruction. Finally, tumors involving the upper airway may lead to obstruction necessitating endotracheal intubation. If the obstruction is such that it is technically impossible to do an endotracheal intubation one has no option other than to perform a tracheostomy.
3. To protect the airway in a patient whose protective reflexes are poor. The pharynx, vocal cords and the epiglottis play an important role in protecting the airway from aspiration of secretions, foreign matter, food or regurgitating gastric contents. The reflexes that normally protect the airways are: (1) the pharyngeal reflex, which normally includes the gag and swallowing reflexes; (2) the laryngeal reflex, which is a vagal reflex, and is responsible for the apposition of the vocal cords, and closure of the epiglottis on stimulation of the larynx by secretions or by foreign matter; (3) the tracheal reflex, which is a vagal reflex causing cough when the trachea is stimulated by some irritant or foreign matter and (4) the carinal reflex, which is a vagal reflex causing cough and irritation of the carina. The protective reflexes are generally obtunded from above downward, irrespective of whether the cause of obtundation is due to drugs, disease or a deepening state of unconsciousness. When these reflexes return in a recovering patient, they recover from "below-up". The preservation of the pharyngeal reflex (gag reflex) therefore suggests preservation of the laryngeal and tracheal reflexes. However, the gag reflex is believed to be diminished or inelicitable in 10% of the normal population. Therefore, absence of this reflex does not always indicate absence of other protective reflexes. Clinically, the inability to handle secretions in the upper airway and to swallow in a coordinated manner denotes a loss of protective airway reflexes and necessitates the establishment of an artificial airway. In such patients, the artificial airway also seals the respiratory from the alimentary tract, thereby preventing aspiration of gastric contents into the tracheobronchial tree (Box 1).
4. To facilitate suction of secretions (from within the tracheobronchial tree), which the patient is incapable of coughing up and expectorating. This could be because the secretions are copious, the cough reflex is poor, or the patient is just too feeble to cough and expectorate. Although it is possible to insert a suction catheter through the vocal cords for suctioning tracheal secretions, it is not advisable to do so except on rare occasions. Laryngeal edema and obstruction, and precipitation of fatal arrhythmias in critically ill patients can occur following such attempts. The establishment of an artificial airway allows easy, safe and direct suctioning of the tracheobronchial tree.

Box 1: Indications for artificial airway

- Acute respiratory failure necessitating invasive ventilator support
- To maintain an open airway in the presence of obstruction to the pharynx or larynx
- To protect the airway when protective reflexes are lost
- To facilitate suction of secretions within the tracheobronchial tree which the patient is unable to cough up and expectorate

Disadvantages of Artificial Airways

The establishment and maintenance of an artificial airway (endotracheal intubation or tracheostomy) has its hazards and complications depending on the expertise with which it is established, the quality of after care, and the nature and degree of the critical illness in the patient. These complications are dealt with later. However, there are some inherent universal drawbacks of artificial airways, which need to be considered.

1. An artificial airway bypasses the normal defence mechanisms, which counter bacterial contamination of the airways. The airways and lungs are more prone to nosocomial infection.
2. An endotracheal tube removes the effectiveness of cough because the vocal cords are nonfunctional; a tracheostomy bypasses the cords.
3. An artificial airway prevents the patient from communicating vocally. This can be frustrating and frightening, and it is important, in a conscious patient, to provide a pad and a pen to help the patient communicate in writing.

4. In a conscious patient, there is often a feeling of a loss of dignity and a loss of control over one's self due to tubes which prevent the patient from speaking or breathing normally.

ESTABLISHING AN EMERGENCY AIRWAY

An emergency airway is one that must be established immediately, with utmost urgency, as it involves a matter of life and death. The chief indications for an immediate airway are—

- Severe life-threatening upper airways obstruction.
- Cardiac or respiratory arrest—or impending cardiorespiratory arrest.
- Fulminant pulmonary edema.

The emergency airway of choice is an oral endotracheal intubation, with the aid of direct laryngoscopy. In an intensive care unit (ICU) or in any setting where the expertise and the necessary equipment is promptly available, oral endotracheal intubation can be performed in a matter of minutes. However, emergency endotracheal intubation may prove difficult even in experienced hands, and at times, may fail. In such circumstances, an alternative airway needs to be established urgently.

OTHER EMERGENCY AIRWAYS

Laryngeal Mask Airway

The laryngeal mask airway (LMA) can secure the airway in an emergency, in a situation where endotracheal intubation fails, or in a situation where experienced personnel to intubate are unavailable. A properly placed LMA not only secures the airway, but allows ventilatory support and reduces the risk of gastric aspiration. A standard adult LMA consists of a 12-mm internal diameter tube fused at a 30° angle to an elliptical spoon-shaped cuff with an inflatable rim. The cuff is soft and when inflated adapts to the shape of the larynx forming an airtight seal over it. The tube opens into the concavity of the cuff ellipse through a fenestrated aperture. The LMA should be placed with the patient placed in sniffing position—neck flexed and head extended. The cuff is deflated and lubricated prior to insertion. The patient's mouth is opened and with the distal aperture of the cuff positioned anteriorly, the tip of the cuff is applied against the hard palate and advanced by the index finger of the right hand over the back of the tongue till it meets resistance when it abuts on the upper esophageal sphincter. The cuff is inflated with 10–30 mL air, so that the cuff centers on the laryngeal inlet. Studies show that the procedure is easily learnt by nurses and that adequate ventilation could be provided in 87% of cases.[1] Studies in mannequins suggest that the LMA decreased gastric distension compared to the artificial manual breathing unit (AMBU) and could be more easily placed than the combitube (Fig. 2).[2]

Intubating Laryngeal Mask Airway

The standard LMA can allow intubation with the aid of a fiberoptic bronchoscope. However, the size of the endotracheal tube that can be inserted through the LMA is necessarily small. The intubating LMA (I-LMA) consists of an anatomically curved rigid tube with a metal-guided handle and a distal silicone laryngeal cuff. The floor of the cuff aperture has an epiglottis elevating bar and guiding ramp, which permits an especially designed endotracheal tube (8 mm in diameter) to be directed toward the glottis and inserted blindly into the trachea. The I-LMA can be placed without moving the patient's head or neck. This is of definite advantage to patients who have sustained an injury to the cervical spine or to those who have an unstable cervical spine—situations where spinal flexion is best avoided.

Fig. 2: Laryngeal mask airway

The major concerns in the use of the LMA are: (1) the risk of gastric aspiration, (2) the possibility of ineffective ventilation because of suboptimal positioning over the larynx, (3) the inability to generate high inflation pressures in patients with increased airway resistance or low lung compliance.

Cricothyroidotomy (see Chapter Procedures in the Intensive Care Unit)

A cricothyroidotomy with insertion of a tube or a conduit into the trachea may serve as a life-saving temporary emergency procedure. A cricothyroidotomy should be replaced by an appropriate airway as soon as possible.

Emergency Tracheostomy

An emergency tracheostomy can be performed by an experienced surgeon in 15 minutes.

Percutaneous Tracheostomy (see Chapter Procedures in the Intensive Care Unit)

A percutaneous tracheostomy can be carried out by an experienced intensivist or surgeon in perhaps even lesser time. Till such time as an emergency airway is ultimately secured, it is vital to continue to ventilate the patient with a bag-mask using 100% oxygen and to ensure that at least the upper airway (above the vocal cords) is patent.

Endotracheal Intubation (also see Chapter Procedures in the Intensive Care Unit)

Endotracheal intubation is often performed electively and in less emergent situations. It can be performed—

- *With the patient awake* This is very unpleasant for the patient but has the great advantage that it allows the patient to ventilate and oxygenate himself or herself. It is preferred particularly in patients with difficult airways. The approach may be a blind nasotracheal intubation or endotracheal intubation using topical anesthesia and direct laryngoscopy to visualize the larynx, or endotracheal intubation through the use of a fiberoptic bronchoscope.
- *With the patient sedated* Sedative agents such as midazolam or propofol are administered as a bolus. The patient although sedated, maintains spontaneous ventilation. Endotracheal intubation is then done with the aid of direct laryngoscopy, or if needs be with the help of a laryngoscope or a bronchoscope. If an LMA has been introduced earlier, intubation can be done via a fiberoptic bronchoscope passed through the larynx.
- *After inducing neuromuscular paralysis* This is the method most frequently used when performing endotracheal intubation with the aid of direct laryngoscopy. Muscle paralysis with relaxation of the masseters and paralysis of the pharynx generally allows a good view of the larynx with the aid of a laryngoscope and allows quick intubation. However, respiratory muscle paralysis abolishes spontaneous ventilation and the physician must therefore obtain immediate airway control, or failing this, ensure effective bag-mask ventilation till spontaneous ventilation returns. Also, in a difficult intubation, the larynx if situated anteriorly may not be visualized even after neuromuscular paralysis, so an alternative plan to secure the airway and maintain ventilation should be promptly available. A standard rapid sequence method is followed when using neuroparalytic agents prior to endotracheal intubation in patients at risk for aspiration of gastric contents.
  - The patient is oxygenated with 100% oxygen for some minutes through a bag and full-face mask.
  - A sedative (midazolam) is administered as a bolus followed immediately by the administration of the neuroparalytic agent.
  - At the same time, an assistant exerts pressure on the cricoids using the Sellick's maneuver, which occludes the esophagus and reduces the risk of aspiration.
  - Endotracheal intubation is quickly performed, the pressure on the cricoid being relieved only after the airway has been secured.

The major disadvantage of neuromuscular paralysis is that effective spontaneous respiration may not return for several minutes so that a failed intubation can turn into a disaster (Table 1).

The procedure for endotracheal intubation has been described in the Chapter Procedures in the Intensive Care Unit. The position of the head and neck for endotracheal intubation is illustrated in Figure 3. Figure 4 shows the endotracheal tube in place.

Complications of Endotracheal Intubation

Complications during Intubation

1. Damage to the lips, teeth, pharynx and larynx can occur when performed in a hurry or when performed clumsily. The vocal cords can be badly bruised and injured and a dislocation of the arytenoid cartilage could occur. A broken tooth can be aspirated and lodged within a bronchus. Perforation of the pharynx and damage to or even perforation of the trachea has been reported. Aspiration of stomach contents is to be guarded against, particularly in a patient with a full stomach.
2. The endotracheal tube instead of being positioned above the carina may be pushed into the right main bronchus. The left lung is then unaerated and becomes atelectatic.

Cardiovascular complications A number of cardiovascular complications can occur during intubation. Ventricular arrhythmias occur in 5–10% of patients. Ventricular tachycardias and rarely ventricular fibrillation may be observed. Patients with myocardial ischemia or patients with a fresh myocardial infarction are particularly susceptible to ventricular arrhythmias and even to cardiac arrest. Lignocaine prophylaxis (75 mg IV) or amiodarone prophylaxis (150 mg IV) can be used, particularly in patients with ischemic heart disease who have ventricular extrasystoles. Delay in intubating a patient with cardiac arrest may potentiate dangerous hypoxia with all its complications. Bradyrhythms during intubation have also been reported. They generally respond to IV atropine. Both hypotension and hypertension can occur during intubation and may necessitate urgent treatment.

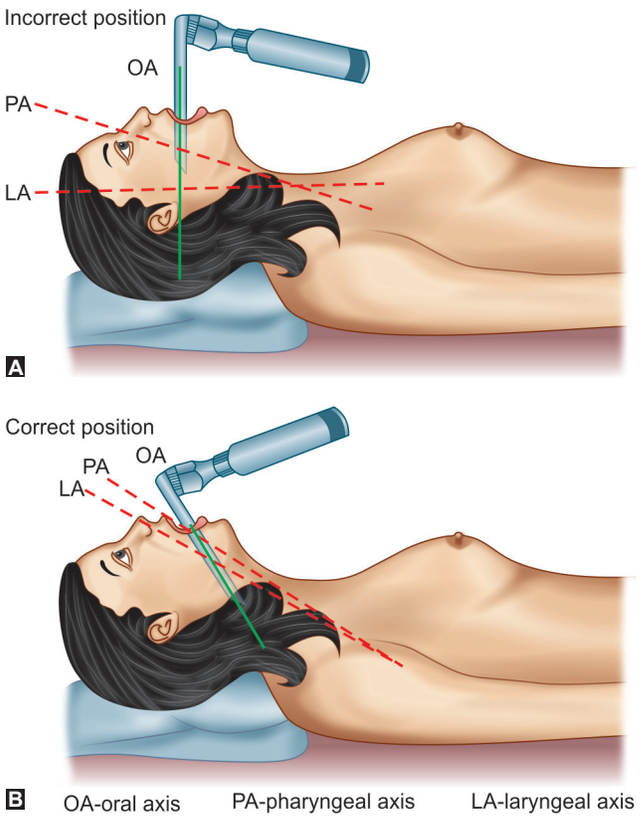
Complications When the Tube Is in Place

The greatest danger is blockage of the tube causing hypoxia and death if not promptly recognized and corrected. Kinking of the tube can also occur. The tube sometimes is inadvertently advanced or slips into a bronchus (generally the right main bronchi). The tube can erode the trachea anteriorly and can cause severe bleeding through erosion of vascular structures in the mediastinum. A sudden spurt of bleeding should suggest this diagnosis. The tube could also erode posteriorly into the esophagus causing a tracheoesophageal fistula. Both the above situations warrant an urgent bronchoscopy with a careful look at the mucosa underlying the cuff. Other complications include tracheomalacia, damage to the vocal cords and subglottic stenosis, the later being evident on extubation. A cuff leak in a patient on ventilator support can lead to hypoventilation. It can be countered by appropriately increasing the tidal volume. The tube may however need to be changed. Finally, nosocomial pulmonary infection is a dreaded complication, the most important and common being a ventilator associated pneumonia (Box 2).

Table 1: Drugs used during endotracheal intubation

Drug	*Action*	*IV (mg/kg)*	*Onset of action*	*Side-effects*
Thiopental	Induction	2.5–4.5	20–50 seconds	Hypotension
Propofol	Induction	1.0–2.5	<1 minute	Hypotension
Midazolam	Induction	0.02–2.0	30–60 seconds	Hypotension
Ketamine	Induction	0.5–2.0	30–60 seconds	Increased secretions and raised ICT
Rocuronium	Relaxant	0.6–1.0	60–90 seconds	–
Succinylcholine	Relaxant	1–2	45–60 seconds	Increased intragastric and intracranial pressure; hyperkalemia

Abbreviation: ICT, intracranial tension.



Figs 3A and B: The position of the head and neck for endotracheal intubation

Fig. 4: Endotracheal intubation, with the tube in place

Box 2: Complications of endotracheal intubation

- Complications during intubation—
  - Damage to lips, teeth, pharynx, larynx, trachea (including perforation and laceration)
  - Dislocation of arytenoid cartilage
  - Aspiration of gastric contents
  - Insertion of tube in right main bronchus
  - Hypoxia due to delayed intubation
  - Cardiovascular complications—
    - Ventricular extrasystoles
    - Ventricular tachycardia
    - Bradyrhythms
    - Hypotension, hypertension
- Complications with the tube in place—
  - Blockage of tube
  - Kinking of tube
  - Cuff leak
  - Advancement of tube into the right main bronchus
  - Displacement of tube above larynx
  - Damage to vocal cords
  - Nosocomial pulmonary infection: tracheitis, tracheobronchitis, nosocomial pneumonia
- Complications after extubation—
  - Laryngeal spasm, laryngeal edema
  - Postglottic stenosis
  - Laryngitis, laryngeal ulcerations, laryngeal granuloma
  - Vocal cord paralysis
  - Vocal cord synechiae

DIFFICULT AIRWAY

A difficult airway is a clinical situation in which an anesthesiologist or an intensivist experiences difficulty with bag mask ventilation, or difficulty with tracheal intubation or both. Difficult bag-mask ventilation implies an inability to maintain an O_2 saturation more than 90% using 100% oxygen and positive-pressure bag-mask ventilation. Difficult intubations are those requiring three or more attempts using conventional laryngoscopy. In an ICU setting, a difficult-to-intubate airway may be apparent on a preintubation evaluation or becomes manifest only on attempted intubation. A markedly receding jaw, prominent incisors, macroglossia, soft tissue lesions obstructing the oropharynx or the entrance to the larynx, a rigid spine as in ankylosing

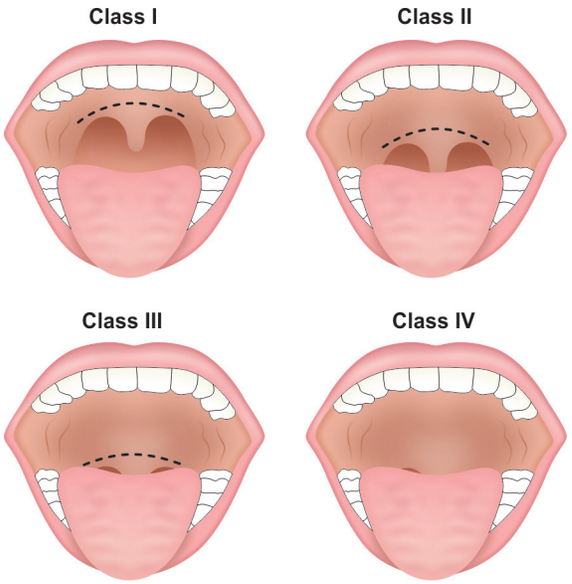


Fig. 5: Mallampati classification
Class I: Clearly visible fauces, uvula, with a wide oropharynx
Class II: Less clearly visible fauces and uvula, with a smaller opening of the oropharynx
Class III: Poorly visible fauces, uvula with a small oropharynx
Class IV (added by Samson and Young): Inability to see the fauces, uvula and the oropharyngeal opening

spondylitis or a very anteriorly placed glottis can make intubation difficult or impossible.

Mallampati assessed the ability to perform a direct laryngoscopic endotracheal intubation by noting the degree of visibility of the faucial pillars and the uvula, with the patient seated, mouth wide open and the tongue fully protruded. Patients were classified into four classes according to the difficulty experienced in intubation (Fig. 5).

1. Class I—Clearly visible fauces, uvula, with a wide oropharynx—easy intubation.
2. Class II—Less clearly visible fauces and uvula, with a smaller opening of the oropharynx—intubation not as easy as in Class I.
3. Class III—Poorly visible fauces and uvula, with a small oropharynx encroached upon by the above structures—intubation could prove difficult. This preintubation evaluation correlated with the laryngoscopic visualization of the larynx—in Class I the larynx being well-visualized and in Class III, the larynx being poorly visualized. Samson and Young added a Class IV to Mallampati's classification.
4. Class IV—It is characterized by the inability to see the fauces, uvula and the oropharyngeal opening (patient seated, tongue protruded, mouth wide open). The vocal cords are not visualized on direct laryngoscopy, and intubation in these patients is generally unsuccessful.

In an emergency setting in the ICU, there is no time for elaborate preintubation evaluation. Patients requiring intubation are often hypoxic, restless, uncooperative and hemodynamically unstable. The simplest predictor of a likely successful intubation at the bedside in an emergency is the "Rule of Three". If the intensivist can place three finger breadths (6–7 cm) between the upper and lower teeth, between the mandible and the hyoid bone and between the thyroid cartilage and the sternal notch, intubation is usually successful.

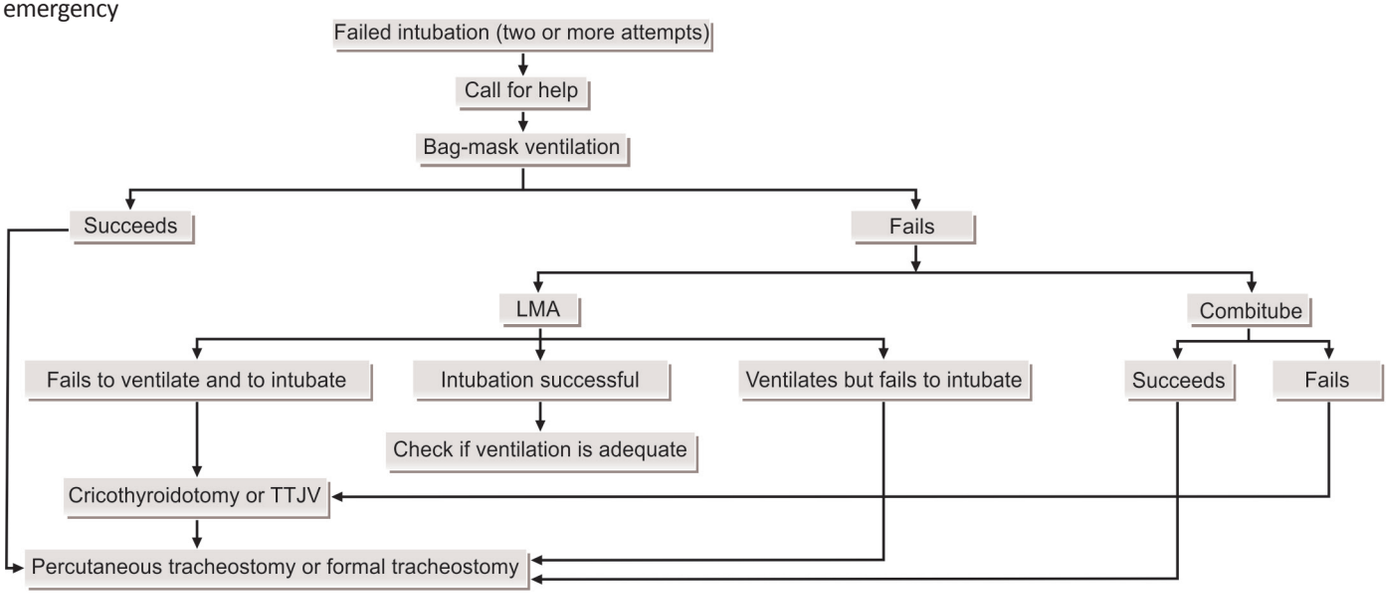
Difficult Intubation in the Critical Care Unit[3]

It is important not to make several attempts at intubation as this traumatizes the pharynx, larynx and makes a subsequent successful intubation doubly difficult. More than two attempts are associated with increased morbidity and an increased risk of cardiac arrest. Patients who are hypoxic are rendered even more hypoxic with all the attendant risks. Patients who to start with are hypotensive, hemodynamically unstable, or are in shock from any cause, or who are on vasopressors to maintain perfusion are at grave risk from preintubation death following repeated failed attempts at intubation. Sudden fluctuations in blood pressure and heart rate consequent to repeated attempts at intubation are dangerous in patients with aneurysms or in patients with unstable angina or myocardial infarction.

The management of failed endotracheal intubation attempts in a critical care setting should be considered under two heads—

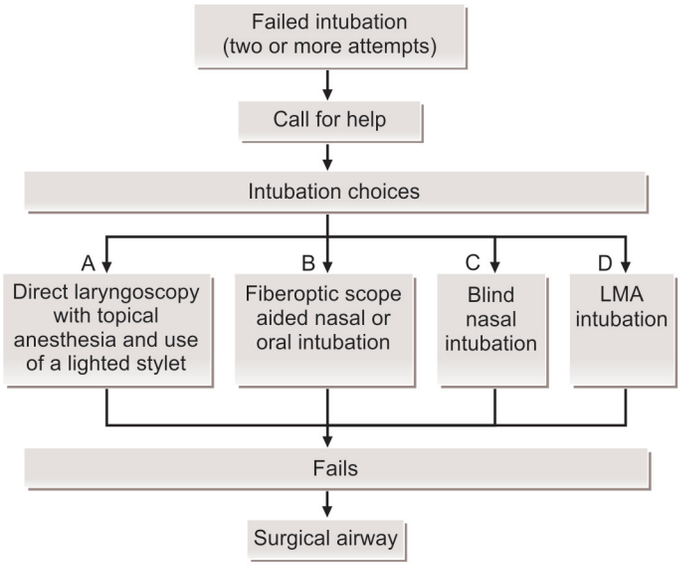
1. Failed intubation attempts in patients in whom securing an airway and establishing effective ventilation is a matter of extreme urgency, a matter of life and death, e.g. cardiac arrest, respiratory arrest, extreme obstruction to the airway (Flowchart 1).
   The following emergency measures need to be followed—
   - Call for help.
   - Continue bag-mask ventilation with 100% oxygen. Two individuals can perform this more effectively than one. One individual ensures that the mask fits tightly over the nose and mouth, preventing any air leak; the other squeezes the AMBU bag fed with 100% oxygen. The intensivist or physician should note whether the bag-mask ventilation is effective, as judged by good breath sounds over both lungs and by an oxygen saturation more than or equal to 90%. Difficulties in bag-mask ventilation are likely if any two of the following are present—age more than 55 years, edentulous patient, obesity (body mass index >26 kg/m^2), beard, history of snoring.
   - If a bag-mask ventilation fails or is ineffective, the situation is indeed very critical (cannot intubate-cannot ventilate scenario). Insert an LMA or even better (if available), an I-LMA and ventilate the patient via this airway. If the I-LMA is in place, attempt to intubate blindly using the specially designed endotracheal tube that goes with the I-LMA. Intubation (with a small-sized endotracheal tube) can also be attempted through a plain LMA with the aid of a fiberoptic bronchoscope. If effective ventilation through an LMA fails, and intubation via the LMA or via the I-LMA is unsuccessful, the quickest way of securing ventilation and preventing death from

Flowchart 1: Algorithm for the management of difficult airway and ventilation [in the intensive care unit (ICU)] in a life and death emergency



Abbreviations: TTJV, transtracheal jet ventilation; LMA, laryngeal mask airway.

Flowchart 2: Algorithm for the management of difficult airway and ventilation [in the intensive care unit (ICU)] in failed laryngoscopic attempts in less emergent situations



Abbreviation: LMA, laryngeal mask airway.

hypoxia, is by performing a cricothyroidotomy. A cricothyroidotomy should be promptly followed by an emergency percutaneous tracheostomy or by an emergency formal tracheostomy.

- Even if either bag-mask ventilation or ventilation through an LMA is successful, a more permanent and secure artificial airway is mandatory if spontaneous effective breathing has not returned. This is achieved either by a percutaneous tracheostomy or a formal tracheostomy. In expert hands, this can be performed within 10–15 minutes.
- If a preintubation clinical evaluation suggests that bag-mask ventilation or LMA ventilation cannot possibly be successful (as in extreme obstruction to the oropharynx, facial, neck injuries), proceed straight to a cricothyroidotomy, or a percutaneous tracheostomy, or a formal tracheostomy depending on the degree of the urgency of the situation.
- Transtracheal jet ventilation (TTJV) is an alternative to a surgical airway in a "cannot intubate-cannot ventilate" situation. After stabilizing the larynx, a 12–16-gauge catheter-over-needle (attached to a syringe partially filled with saline) is directed caudally through the cricothyroid membrane into the trachea. Tracheal entry is confirmed by aspiration of air bubbles. The catheter is now advanced (up to the hub), over the needle into the trachea with the aid of a small skin incision. The placement is confirmed by aspiration of air. The hub of the catheter is connected to a jet ventilation system. Care should be taken to stabilize the catheter and prevent any air leak at the incision site. We are not familiar with TTJV but it has been performed in all age groups and is the preferred surgical airway in children below 12 years. Airway obstruction below the larynx or complete upper airway obstruction can render expiration impossible and is a contraindication to TTJV. Complications with TTJV include subcutaneous emphysema, esophageal puncture, bleeding and barotraumas. TTJV is an emergency measure and is continued only till such time as a definitive airway has been secured.

2. Failed intubation attempts in situations which are emergent but which still allow some time to the intensivist for establishing an airway (Flowchart 2) . In the above

circumstance, the intensivist should use one or more of the other intubation techniques—

- Direct laryngoscopy with topical or local anesthesia (if topical anesthesia has not been already used).
- Use of a stylet, preferably a lighted one, to help guide the endotracheal tube into the trachea.
- A flexible fiberoptic scope to aid nasal or oral intubation.
- Blind nasal intubation.
- Intubation through an LMA.
- Retrograde intubation (in very rare circumstances).

Retrograde intubation is attempted by first puncturing the cricothyroid membrane with an 18-gauge introducer needle with catheter. A guidewire is threaded through the needle cephalad into the oropharynx and is then pulled out under vision using Magill's forceps. The guidewire is then placed directly in the lumen of the endotracheal tube. The latter is then guided along the guidewire through the glottis into the trachea. The guidewire is now pulled out through the proximal end of the endotracheal tube and the endotracheal tube fixed in proper position. This procedure requires practice and is more difficult than it appears; we have as yet never attempted retrotracheal intubation in our units.

TRACHEOSTOMY

A tracheostomy is in our opinion the most satisfactory artificial airway, particularly when the airway needs to be maintained for over 7–10 days. It completely bypasses the upper airway and the glottis, thus preventing any potential complications in that area. It causes less resistance to airflow (vis-à-vis the endotracheal tube), reduces dead space, allows easy and efficient suction of the tracheobronchial tree, and is easy to fix and stabilize. The conscious patient can eat freely, is not bothered by oropharyngeal secretions commonly observed with endotracheal tubes and tolerates the tracheostomy without undue discomfort. When performed by a skilled, experienced surgeon, the overall mortality (procedural with the tube in situ, or after removal) is around 1.5% (range 0–5%). This holds even when the procedure is done in critically ill patients.

Endotracheal Tube versus Tracheostomy

There is still a controversy as to when to continue with an endotracheal tube and when to opt for a tracheostomy. The decision to do a tracheostomy or persist with the endotracheal tube rests on the intensivist's perception of optimal patient care, available nursing care and the unit's experience and record of complications with each of the two artificial airways.

We prefer to do an elective tracheostomy after first intubating the patient, whenever we are convinced that the disease will necessitate the use of an artificial airway for more than 7 days. If it is difficult to gauge the time duration required for the artificial airway, we persist with the endotracheal tube for about 7–10 days, and then change over to a tracheostomy.

Probably each unit has its own preferences. We base our preferences on the fact that our unit has had few complications with tracheostomies, and that tracheobronchial toilet with suction of secretions is far easier through a tracheostomy than through an endotracheal tube. We have also noticed a significant incidence of subglottic edema and stenosis whenever an endotracheal tube has been in place for more than 10 days, prompting us to switch to a tracheostomy if we feel that an artificial airway is required beyond that period of time. However, there are many units in the West who persist with an endotracheal tube for as long as 3 weeks without encountering significant complications.

Complications of Tracheostomy[4]

It is to be noted that the three major emergencies associated with both tracheostomies and endotracheal tubes are—

1. Obstruction to the artificial airway.
2. Inadvertent extubation.
3. A major cuff leak.

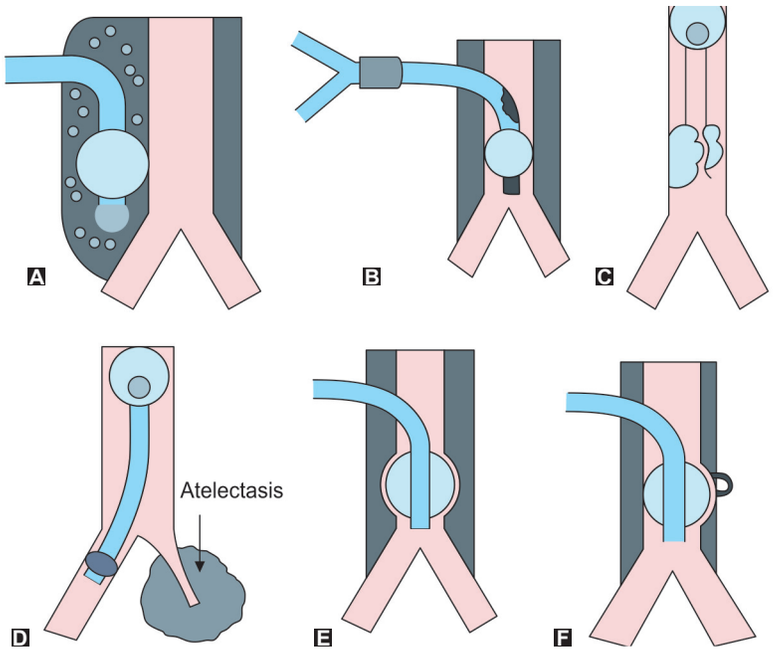
Obstruction Partial or complete obstruction of the tube by crusted inspissated secretions is perhaps the commonest and most important complication. A blocked tube can be disastrous if undetected or detected too late. Prevention of blockage by proper care of the artificial airway is vital.

Obstruction at times is observed below the lower end of the artificial airway. This is generally due to an overdistended cuff herniating over the lower end and blocking it. Prompt deflation of the cuff rapidly relieves the obstruction. Obstruction also occurs when the trachea below the cuff is partially clogged by inspissated mucus—a problem invariably due to inadequate humidification of inspired gas.

An endotracheal tube may sometimes be obstructed by a kink; slight manipulation of the head and neck should then restore patency. The bevel of the artificial airway may occasionally abut against the tracheal wall, carina or even bronchus, producing partial obstruction. This is relieved by gentle manipulation of the tube.

When faced with a possible obstruction to an artificial airway: (1) attempt to pass a suction catheter through the tube and note its passage—whether easy or obstructed; (2) deflate the cuff; (3) gently manipulate the tube. If none of these measures are effective, then the tube is promptly removed. Also, whenever there is a doubt about the exact cause of respiratory distress, as an ample measure of safety, the tube should be promptly changed. It is worth bearing in mind that an important cause of severe respiratory distress which resembles a blocked tube is a tension pneumothorax. A cardinal rule in the ICU is that a patient with an artificial airway must always have a duplicate artificial airway as also intubation and ventilation equipment at his bedside.

Inadvertent extubation This could prove disastrous if not urgently rectified in a patient on ventilator support who is paralyzed or heavily sedated. It abruptly cuts off ventilation, can produce serious surgical emphysema of the head, neck and chest as also mediastinal emphysema. If the endotracheal or tracheostomy tube lies above the vocal cords serious gastric distension can occur.



Figs 6A to F: Complications of tracheostomy. (A) Tube in pretracheal fascia-resulting in surgical emphysema of face and neck and sometimes of the mediastinum; (B) Blocked tube; (C) Overinflated cuff slipping over the end and blocking it; (D) Tube slipping into right main bronchus, preventing ventilation to the left lung; (E) Damage to trachea, either due to a very tight-fitting tube with an overinflated cuff, or injury to the posterior wall-end result, dilatation (as in the figure) or stricture and (F) Erosion of the posterior wall of the trachea, and rarely erosion of the innominate artery

Source: Udwadia FE. Diagnosis and Management of Acute Respiratory Failure. Mumbai: OUP; 1979.

Cuff leaks Cuff leaks are the least dangerous of the three artificial airway emergencies. A cuff leak can generally be compensated for by merely increasing the tidal volume in a patient on ventilator support. If this does not provide adequate ventilation, the airway will need to be changed.

OTHER COMPLICATIONS OF TRACHEOSTOMY (FIG. 6)

- *Ulceration with pressure necrosis of the trachea* Pressure of an inflated cuff or the tip of the tracheostomy tube may result in ulceration with pressure necrosis. The incidence of this is increased by the presence of an associated infection or the use of corticosteroids. In rare instances, the trachea may be perforated, and there is serious danger of erosion of a large vein or even the innominate artery, with severe bleeding and death resulting from aspiration of blood into the lungs.
- *Tracheal bleeding* Bleeding often occurs into and around the trachea, and within the wound in patients who have a bleeding tendency, particularly in the presence of hypoxia and hypercapnia. It takes the form of a capillary ooze, the main danger being of aspiration pneumonia and infection. Tracheal bleeding also occurs from pressure of the tube, especially when the tracheal mucosa has been rendered friable by repeated suction or infection. Exsanguinating bleeds are invariably due to perforation of a large vessel within the mediastinum.
- *Respiratory nosocomial infection* Infection is a serious and common complication. Prevention is by scrupulous asepsis during the performance of tracheostomy, and meticulous after-care of the tracheostomy. Every single tracheal aspiration should be considered as an aseptic surgical procedure, and should be performed with meticulous attention to detail. The mere growth of bacteria in tracheal aspirates is no evidence of active infection. Gram-negative organisms invariably grow from tracheal aspirates within a few days of a tracheostomy. The presence of fever, purulent secretions, leukocytosis and changing X-ray shadows determine the diagnosis of nosocomial infection (see Chapter Nosocomial Infections).
- *Mediastinal emphysema* This is invariably associated with surgical emphysema of the neck, and at times of the face and chest.
- *Tracheal stenosis* Tracheal stenosis is an important and dreaded complication of tracheostomy (Fig. 7). It can

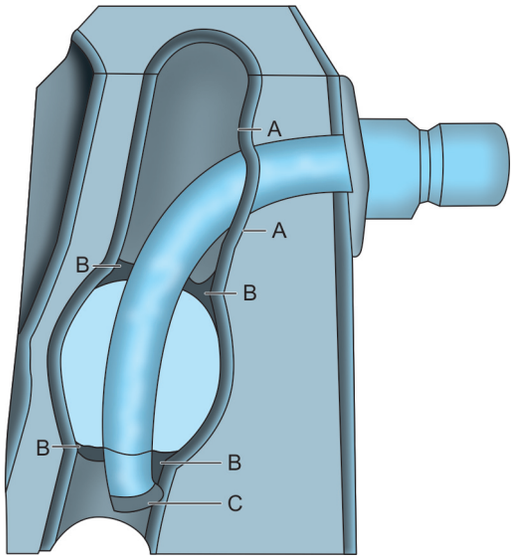


Fig. 7: Sites for occurrence of postextubation tracheal stenosis: (A) site of tracheostomy, (B) cuff site (the most common), (C) where tip irritates tracheal wall

occur anytime between 1 week and 2 years following tracheostomy. Post-extubation tracheal stenosis occurs at any one of the following three sites: (1) at the tracheostomy site, the incidence of this depends on the surgical technique; (2) at the cuff site: this is the commonest site for stenosis; (3) at the point where the tube tip irritates or damages the tracheal wall.

Conditions predisposing to tracheal stenosis include a high cuff pressure, prolonged ventilatory support over weeks or months, and hemodynamic instability with periods of poor perfusion which contribute to devitalization of the tracheal mucosa. Infection of the trachea, undue movement of the tracheostomy tube, or a tube tilted to one side so that its end irritates and produces pressure necrosis of a localized area of tracheal mucosa, are all contributory factors. Some workers have incriminated toxicity from chemical irritation produced by the tube material as an aggravating factor, particularly following ethylene chloride sterilization.

In over 1,200 tracheostomies performed, we have had only five patients with significant tracheal stenosis.

- *Tracheal dilatation* This occurs over the area of pressure exerted by the cuff, and can be prevented by proper cuff care.
- *Tracheomalacia* A softening of the trachea may occur following tracheostomy. This leads to inspiratory collapse of the trachea with obstruction of the airway following extubation.
- *Cardiorespiratory collapse* The association of cardiorespiratory collapse has been observed by us immediately following tracheostomy performed to relieve severe upper airways obstruction. It is generally seen when the tracheostomy is done on a patient who is in extremis. It does not occur if the airway has been first secured by an endotracheal tube, and the patient ventilated and oxygenated before doing a tracheostomy. Bendixen and his colleagues[5] believe that in patients with sudden severe airways obstruction, the hypoxia and hypercapnia produce a marked sympathetic stimulation with catecholamine liberation. If the sympathetic stimulus is suddenly removed, as after an emergency tracheostomy, then cardiovascular collapse may occur. In a similar fashion, if the respiratory drive produced by acute hypoxia and hypercapnia ceases, respiratory arrest can occur.

MAINTAINING THE ARTIFICIAL AIRWAY

It is not enough to establish and secure the airway. It is equally important to maintain, manage and care for the artificial airway if the hazards and complications involving the use of artificial airways are to be minimized.

Tracheostomy Care[6]

A high tracheostomy is always preferable as it enables the tip of the tube to lie well above the carina. It is best to use the largest tube that can be comfortably accommodated by the trachea. Small tubes should be avoided as they tend to get blocked, and they offer resistance to airflow. This is particularly unwelcome in those patients with acute respiratory failure who have well-marked airways obstruction, or who have a low compliance due to stiff lungs. The tube should have an even inflated cuff. High residual volume (low-pressure) cuffs should be always used; high-pressure cuffs have no place in modern respiratory care. Even when using high volume, low-pressure cuffed tubes, the cuff pressure should be checked daily and kept within acceptable limits. Excessive cuff pressures can induce tracheal injury and subsequent stenosis, particularly if the tracheostomy has been in use over several days or weeks. Salient points in tracheostomy care are given in Box 3.

SPECIAL CONSIDERATIONS IN AIRWAY MANAGEMENT[7]

Cervical Spine Injury[8]

A patient with polytrauma, who requires intubation should be presumed to have a cervical spine injury. In the absence of severe maxillofacial trauma or cerebrospinal rhinorrhea, a nasal intubation can be attempted. However, if urgent intubation is required as in the apneic or hypoxic patient, oral intubation should be done. During oral endotracheal intubation, a colleague or assistant should hold the neck in position, ensuring axial stability and preventing any flexion or anterior movement of the neck for fear of damaging the spinal cord.

Increased Intracranial Tension

Intubating patients with head injury who have a rise in intracranial pressure may be difficult for several reasons—change

Box 3: Salient points in tracheostomy care

Use sterile gloves for handling tracheostomy tube

- Care of cuff—
  - Use minimal occluding volume for inflating cuff—minimal leak techniques
  - Measure cuff pressure daily, and keep this within acceptable limits (14–24 cm H_2O)
  - Deflate cuff periodically, except when this is contraindicated for specific reasons
- Care over suction of secretions—
  - Use "no-touch" sterile technique
  - Preoxygenate (with high FiO_2) in a hemodynamically unstable patient before suction
  - Do not suck for more than 10 seconds
  - Do not use a very large bore catheter for suction
  - If possible, suck through an adaptor so that ventilator support on high-flow O_2 is not interrupted
  - Stop suction if bradycardia or hypotension occur; increase FiO_2 to 100% for a short time
  - Liquefy viscid secretions; use physiotherapy
  - Humidify inspired gas
- Care of tracheostomy tube—
  - Ensure that tube is central in position and does not tilt or slip into one bronchus
  - Ensure that tube does not get blocked
  - Change tube every 4–7 days
- Care of tracheostomy wound:
  - Use sterile dressing and antibiotic ointment
  - Be alert to possible complications of tracheostomy

in mental state, difficulty in opening the mouth, associated facial trauma. Further rise in intracranial pressure should be avoided as far as possible during intubation. Also, cervical spine trauma should always be suspected in a patient with head injury. The anesthetic agent used for intubating these patients should ideally preserve cerebral perfusion, and lower cerebral blood volume while maintaining hemodynamic stability. Thiopental offers neuroprotection but cerebral hypoperfusion may result from its depressant effect on the myocardium and because of peripheral vasodilatation. Etomidate is preferred in hemodynamically unstable patients. If a neuroparalytic agent needs to be used for intubation, vecuronium (0.25 mg/kg) or rocuronium (1.2 mg/kg) is to be preferred.

In patients with polytrauma including head injury with raised intracranial pressure, it may at times be impossible to perform a laryngoscopic endotracheal intubation. The airway may need to be secured by alternative means.

CHAPTER 31

Acute Exacerbation of Chronic Obstructive Pulmonary Disease

INTRODUCTION

Acute exacerbations of chronic obstructive pulmonary disease (COPD) are in-built features in the natural history of the disease, punctuating its course from time-to-time. They significantly increase both morbidity and mortality, the in-hospital mortality of COPD exacerbations being as high as 10%. In the UK, COPD exacerbations are the most common cause of medical hospital admissions, amounting to 15.9% of the hospital admissions at a huge cost to the national exchequer. In large metropolitan cities in India, COPD exacerbations are an important and frequent cause of admission to critical care units. Approximately, 1 in 15 patients reporting to the emergency department in a busy Mumbai hospital comes with worsening of symptoms of COPD.

Acute exacerbations are more frequent and often more severe in patients with increasing severity of COPD. The annual frequency of exacerbations in different patients having the same severity of COPD varies for unknown reasons. Predisposition to acute exacerbations may well be related to increasing severity of the disease, greater inflammation of the small airways, greater exposure to and perhaps greater susceptibility to infection and to the presence of lower airways bacterial colonization.

Definitions

An acute exacerbation of COPD is an acute worsening of symptoms associated with worsening lung functions that could in some patients precipitate acute respiratory failure (ARF) or the acute worsening of chronic respiratory failure. Respiratory failure (acute or acute on chronic) is often the culminating feature of an acute severe exacerbation of COPD. It is important to stress this fact as it entails an awareness for diagnosing this event and necessitates expert critical care in management.

The guidelines of the Global Initiative for Chronic Obstructive Lung Disease (GOLD) define an exacerbation as an event in the natural course of the disease characterized by a change in the patient's dyspnea, cough and/or sputum that is beyond day to day normal variations, is acute in onset and may warrant a change in medication in a patient with underlying COPD.[1]

PATHOPHYSIOLOGY[2,3]

Acute exacerbations are associated with increased inflammation within the peripheral airways and the lungs. Clinically, this is manifested by worsening dyspnea and sputum production.

Pathological features include an even more intense inflammatory exudate and edema of the mucosa of the peripheral airways, an increase in tone of the bronchial muscle and increased mucous production. The acute increase in obstruction to the airways and the further increase in airflow limitation, if sufficiently severe, produce dynamic hyperinflation. Dynamic hyperinflammation is the mechanism responsible for progressive air-trapping within the alveoli leading to a progressive increase in the intra-alveolar pressure and the functional residual capacity (FRC). It can occur with frightening rapidity during an acute exacerbation of COPD. The underlying cause is airways obstruction and airflow limitation. A dynamic compression and collapse of the peripheral airways during expiration leads to a reduced rate of lung emptying. In these circumstances, an inspiratory effort starts before the prolonged expiration is complete. Air is

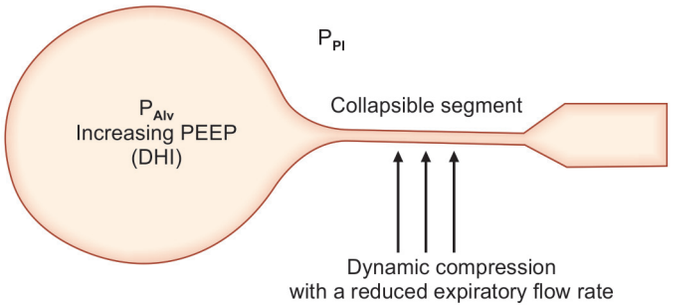

Fig. 1: Dynamic compression of the airways during expiration resulting in dynamic hyperinflation (DHI)
Abbressions: P_{Alv}; intra-alveolar pressure, P_{pl}; intra-pleural pressure.

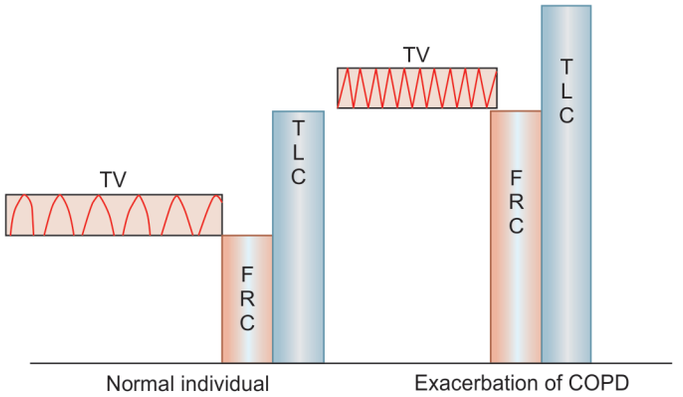

Fig. 2: Increased functional residual capacity (FRC) with the patient breathing at higher lung volumes in severe chronic obstructive pulmonary disease (COPD)

thus trapped in the alveoli causing a rise in the intra-alveolar pressure. The end-expiratory alveolar pressure continues to rise every time a prolonged expiration is prematurely cut short or interrupted by an inspiration. This progressive rise in end-expiratory alveolar pressure is termed intrinsic PEEP or auto-PEEP; it results in an increase in the FRC and in overinflated lungs (Figs 1 and 2).

Dynamic hyperinflation exerts a deleterious effort on the respiratory and circulatory systems—

- Breathing at higher lung volumes is greatly uncomfortable and causes increasing distress. The work of breathing is significantly increased because of an overinflated chest. An overinflated chest has ribs which are more horizontally placed; also the length-tension relationship of the intercostals muscles is far from optimal so that the chest bellows work at a mechanical disadvantage. The low diaphragm and the decreased area of apposition between the diaphragm and the chest wall are further mechanical disadvantages adding to the work of breathing.
- Though it would appear that the expiratory muscles need to work hard because of expiratory obstruction to the airways and expiratory airflow limitation, it is in fact the inspiratory muscles that endure a great workload. This is because with each inspiration the inspiratory muscles need to contract strongly and generate a sufficiently negative intrapleural pressure so that the collapsed peripheral airways are pulled open and the pressure in the central airways and alveoli is rendered subatmospheric, to enable inspiratory air flow to occur. This increased work of inspiratory muscles is required when they are for reasons stated above working at a mechanical disadvantage. Therefore, when dynamic hyperinflation is marked (as in an acute exacerbation of COPD), inspiratory muscle fatigue occurs, and may lead to a respiratory arrest (Fig. 3).
- Increasing dynamic hyperinflation is often associated with hypoxia and hypercapnia because of ventilation-perfusion inequality and alveolar hypoventilation (Flowchart 1).
- The markedly hyperinflated lungs associated with severe dynamic hyperinflation squeeze the capillaries in the functioning and perfused alveoli, resulting in an increased pulmonary vascular resistance and precipitating pulmonary hypertension and right heart failure in patients with moderate to severe COPD. Hypoxia and hypercapnia also cause pulmonary vasoconstriction and contribute further to pulmonary hypertension.

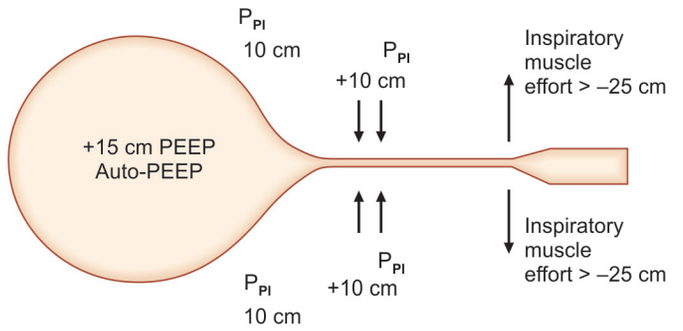

Fig. 3: An increased inspiratory effort is necessary to open collapsed airways and produce a sufficient negative intrapleural pressure to overcome the positive intra-alveolar pressure so as to allow inspiratory air flow. During expiration, the intrapleural pressure of +10 cm H_2O prematurely closes the airways. Total intra-alveolar pressure is 25 cm H_2O. During inspiration, the inspiratory muscles must create a negative intrapleural pressure of well over –25 cm H_2O to allow inspiratory airflow

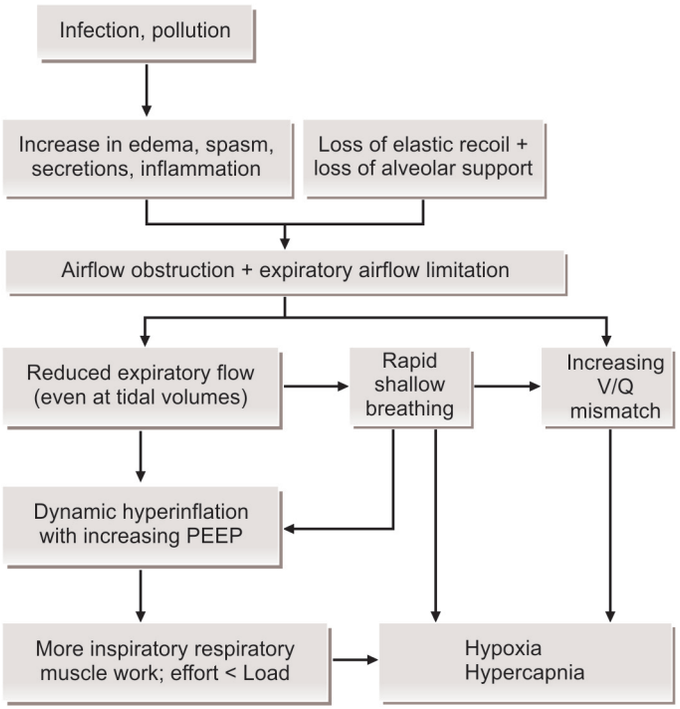
Severe dynamic hyperinflation is associated with well marked rise in the positive end-expiratory pressure (auto-PEEP). This hinders venous return and causes hypotension. When the auto-PEEP is very marked, it exerts an effect similar to that seen in cardiac tamponade (caused by a large pericardial effusion). Severe dynamic hyperinflation with very high auto-PEEP can cause cardiac arrest. Hyperinflated lungs with increase in auto-PEEP can cause barotrauma. Spontaneous pneumothorax is the commonest result of barotrauma. Mediastinal emphysema and interstitial emphysema are two other complications resulting from barotrauma.

Marked hyperdynamic inflation is classically seen in patients with severe exacerbations of COPD, or in patients in a crisis who are incorrectly ventilated. End-stage COPD is also often associated with progressive dynamic hyperinflation.

Flowchart 1: Pathophysiology of acute respiratory failure (ARF) in exacerbation of chronic obstructive pulmonary disease (COPD)



Infection, pollution
Increase in edema, spasm, secretions, inflammation
Loss of elastic recoil + loss of alveolar support
Airflow obstruction + expiratory airflow limitation
Reduced expiratory flow (even at tidal volumes)
Rapid shallow breathing
Increasing V/Q mismatch
Dynamic hyperinflation with increasing PEEP
More inspiratory respiratory muscle work; effort < Load
Hypoxia
Hypercapnia

As has been already explained, dynamic hyperinflation in acute severe exacerbations can occur with frightening rapidity, the patient becoming increasingly uncomfortable and dyspneic, because he has to breathe at progressively high lung volumes. The work of breathing is substantially increased, well beyond what it was prior to the exacerbation, and there is further impairment of respiratory muscle function. The effort expended by the chest bellows and the respiratory muscles is not commensurate with the extra load of breathing. This results in alveolar hypoventilation and hypercapnic respiratory failure. Hypoxia is also worsened in severe exacerbations because of increasing ventilation-perfusion inequality.

Not all acute exacerbations are severe, the degree of exacerbation being probably dependent on the degree of small airways inflammation present in the stable state.

Moderate and severe COPD (Grade III, Grade IV) is associated with a greater degree of inflammation of the small airways, when compared to Grade I and Grade II COPD. This may well be the reason why acute exacerbations are generally more severe in patients with Grade III, Grade IV COPD.

ETIOLOGY[2]

The commonest cause of an acute exacerbation in COPD is infection. The common bacteria causing infective exacerbations are *Streptococcus pneumoniae*, *H. influenzae*; in older patients, *Klebsiella pneumoniae* and *Pseudomonas aeruginosa* are often the infecting agents. There is growing incidence of *Moraxella catarrhalis* as a causative infective agent, both in the West and the developing world. Molecular biology using polymerase chain reaction (PCR) techniques has provided evidence for an increasing role of viruses in the etiology of acute exacerbations. The commonest responsible virus is the rhinovirus. Other viruses include the respiratory syncytial virus, coronavirus, influenza virus and the adenovirus. The role of atypical organisms, in particular mycoplasma and chlamydia is unclear.

Acute exacerbations have also been noted to occur following an acute increase in indoor pollution, exposure to increased outdoor pollution, and due to sudden increase in exposure to an occupational risk factor. One reason for increased incidence of exacerbations during winter is excessive outdoor pollution which blankets large cities in India at almost ground level. Exposure to pollution from exhausts of cars in traffic jams can lead to acute exacerbations, and is another reason for the emergency visits to hospitals. A sudden and marked spurt in the number of cigarettes smoked has been known to cause an acute exacerbation of COPD. The common organisms and pollutants responsible for acute exacerbation of COPD are listed in Box 1.

Clinical Features (Box 2)

An acute exacerbation of COPD is characterized by a clear worsening of respiratory symptoms, well beyond what the patient is used to experiencing. These symptoms chiefly include increased dyspnea, increased cough with an increase in sputum volume, purulent sputum and an increase in wheeze.

Physical findings include all the features observed with airways obstruction and airflow limitation. Tachycardia, tachypnea, excessive use of accessory muscles of respiration,

Box 1: The common organisms and pollutants responsible for acute exacerbation of COPD

- Bacteria—
  - *Streptococcus pneumoniae*
  - *Haemophilus influenzae*
  - *Moraxella catarrhalis*
  - *Pseudomonas aeruginosa*
- Viruses—
  - Rhinovirus
  - Influenza
  - Parainfluenza
  - Coronavirus
  - Adenovirus
  - RSV
- Atypical bacteria—
  - *Chlamydia pneumoniae*
  - *Mycoplasma pneumoniae*
- Common pollutants—
  - Nitrogen dioxide
  - Particulates
  - Sulfur dioxide
  - Ozone

Abbreviations: COPD, chronic obstructive pulmonary disease; RSV, respiratory syncytial virus.

Box 2: Clinical features of acute severe exacerbation of COPD

- Increase in dyspnea, cough, sputum
- All the clinical features of severe airflow limitation
- Features of hypoxia and hypercapnia
- Features of right heart failure may be present

Abbreviation: COPD, chronic obstructive pulmonary disease.

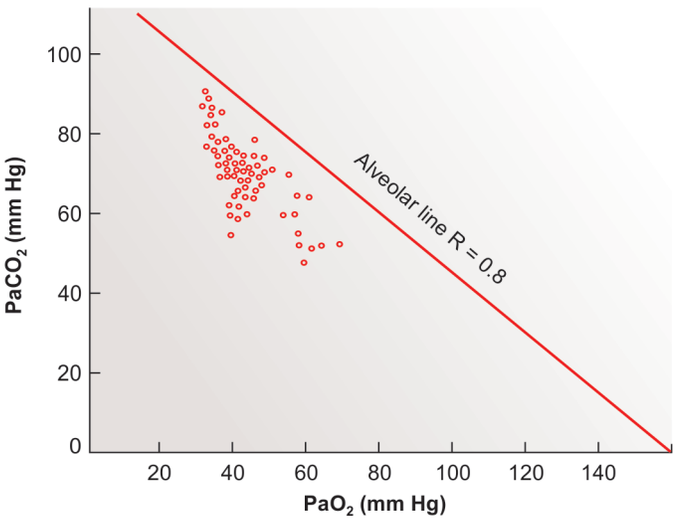


Fig. 4: Arterial blood gas (ABG) in 64 patients with Grade III–Grade IV chronic obstructive pulmonary disease (COPD) who developed an acute exacerbation of COPD. Note severity of hypoxemia and hypercapnia present in most patients with Grade III–IV COPD in an acute severe exacerbation

in-drawing of intercostal spaces during inspiration with paradoxical breathing are all seen in severe exacerbations. Expiration is clearly prolonged and there is an audible wheeze. Rapidly increasing dynamic hyperinflation will cause an actual measurable increase in the circumference of the chest, increasing tachycardia, hypotension, marked distress and difficulty in breathing, the breath sounds ultimately being reduced to short gasps. Auscultation in the presence of rapidly progressive dynamic hyperinflation may reveal faint or absent breath sounds, the expiratory wheeze often being inaudible. Periods of apnea may interrupt the breathing which is often irregular. Central cyanosis may be evident because of increasing hypoxia. Hypercapnia may progressively worsen, leading often, though not always to flapping tremors and confusion. Rhythm disturbances may occur in the form of multiple atrial or ventricular extrasystoles, supraventricular tachycardia, chaotic atrial tachycardia, atrial fibrillation and even ventricular tachycardia.

Severe acute exacerbations can precipitate right heart failure, particularly in patients with Grade III and Grade IV COPD (Fig. 4). This is related to pulmonary vasoconstriction and pulmonary hypertension caused by acute hypoxia and hypercapnia in an individual who often has a baseline increase in pulmonary vascular resistance due to inflammatory changes in the small airways, periphery of the lungs and the pulmonary vessels. The most important and early sign of right heart failure in COPD patients is edema of the feet for which there is no other obvious cause. The edema can worsen and can be so marked as to be generalized. In severe exacerbations in Grade III and Grade IV COPD, electrocardiography (ECG) shows a P pulmonale often associated with clockwise rotation. There may be evidence of right ventricular enlargement and/or a right bundle branch block pattern. These ECG findings are acute, for they generally regress after recovery and often return to a stable state. Echocardiography may corroborate right ventricular systolic dysfunction, some degree of functional tricuspid incompetence and pulmonary hypertension.

Acute exacerbations of COPD are not necessarily severe; some are indeed mild, easily manageable at home. Apart from a worsening of symptoms more than what is usual for the patient, physical signs are limited to those caused by a modest increase in airways obstruction and airflow limitation. The duration of acute exacerbations varies. Milder exacerbations often treated at home may be relieved within 4–7 days with adequate treatment, though full recovery with return to baseline symptoms may take as long as 3–4 weeks in some of these patients. Recurrence rate varies in different individuals for unclear reasons. In a cohort of patients with moderate to severe COPD followed up after acute exacerbation, 22% suffered a recurrence within 50 days of the first (index) exacerbation. Perhaps an initial exacerbation may well increase susceptibility to a subsequent one.

Box 3: Causes of hypoxemia

- V/Q mismatch causing an increased alveolar arterial O_2 gradient
- Alveolar hypoventilation
- Small shunts amounting to 4–10% of the cardiac output
- Low PvO_2 (observed in some patients with cor pulmonale and severe heart failure)

Abbreviation: V/Q, ventilation/perfusion.

Box 4: Causes of hypercapnia

- Alveolar hypoventilation due to increased load and the inability of the respiratory muscles (inspiratory in the main) to meet this load. Inspiratory work of breathing is doubled in acute respiratory failure (ARF); increase in auto or intrinsic PEEP accounts for more than half of this increase in the work of breathing
- V/Q mismatch
- Change in the pattern of breathing—smaller tidal volume with an increase in respiratory rate. This may be an adaptive mechanism to avoid increasing ventilation and respiratory muscles activation to the point where muscle fatigue ensues

Abbreviation: V/Q, ventilation/perfusion.

The causes of hypoxemia and hypercapnia in an acute exacerbation of COPD are listed in the Box 3 and Box 4 respectively.

Investigations

Investigations are done with three objectives in mind—

1. To determine the severity of the exacerbation.
2. If infection is the cause, to determine if possible the infective agent responsible for the exacerbation.
3. To exclude other complications which can cause an acute respiratory crisis in COPD; a crisis that may be clinically indistinguishable from that caused by an acute exacerbation of COPD.

Investigations include a routine complete blood count (CBC), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP). The latter is believed to be an important marker for the presence and degree of the underlying inflammation in the peripheral airways. X-ray chest and ECG are always done routinely. O_2 saturation, arterial blood gases (ABGs), and pH are vital tests. The O_2 saturation will serve as a guide to the degree of hypoxia, but it is often impossible to diagnose the presence and degree of CO_2 retention without actually determining the partial pressure of carbon dioxide in the blood. In severe exacerbations causing ARF or acute on chronic respiratory failure, arterial pH is of vital importance. An arterial pH less than 7.25 is perhaps the most important single factor associated with high mortality.

In severe exacerbations, it is important to determine the baseline function of organ systems. Serum creatinine, blood urea nitrogen (BUN) levels and serum electrolytes need to be done. Sputum microscopy and culture may help (though not necessarily so) in arriving at the organism responsible for an acute infective exacerbation. It is of particular help if *P. aeruginosa* or *K. pneumoniae* are grown on culture, as this will dictate the correct choice of antibiotics.

Spirometry is not useful in severe exacerbations as the patient is too ill to allow reliable results. Also, baseline spirometric readings of a patient admitted in an emergency are not generally available.

PROBLEMS IN DIAGNOSIS

Problems in diagnosis are not infrequent in patients who on clinical examination appear to have an acute exacerbation of COPD. The major difficulty encountered is to distinguish left ventricular dysfunction and failure in a patient with COPD from an acute severe exacerbation of COPD. This difficulty is compounded when acute left ventricular (LV) failure is the sole manifestation of ischemic heart disease (IHD), without a preceding history of anginal pain and without clear evidence of ischemia on the ECG. Both COPD and IHD often manifest in similar age groups. Interestingly, patients with COPD who develop acute LV failure often present with tachypnea and marked wheezing rather than the usual crackles of pulmonary edema. An X-ray chest may be unhelpful and in fact misleading, because occasionally predominantly unilateral pulmonary edema may be seen in COPD patients who develop acute LV failure. The unilateral pulmonary edema is often misdiagnosed as pneumonia. Investigations are often noncontributory. We have found echocardiography notoriously unreliable and even misleading in the diagnosis of diastolic dysfunction in acute LV failure.

A case history illustrates this well. Mr S, a heavy cigarette smoker with Grade III–Grade IV COPD was admitted with classic features of an acute exacerbation of COPD due to an acute pulmonary infection. He went into ARF with severe hypoxia, hypercapnia and respiratory-cum-metabolic acidosis. Medical management including noninvasive ventilator support failed to help. He was intubated and put on mechanical ventilator support. He could not be weaned off support for over 10 days. Every night there was a crisis characterized by sudden tachypnea so that he would clash with the machine. There was marked bronchospasm during tachypneic spells, no change in the X-ray chest, with the central venous pressure (CVP) remaining within the normal range. A tracheostomy was done and ventilator support continued. One night he had an exceptionally severe bout of tachypnea with marked wheezing and increased desaturation, requiring a significant step-up in the fraction of inspired oxygen (FiO_2). On this occasion, the tracheal aspirate was frothy and copious, pointing to pulmonary edema. LV failure due to IHD was diagnosed. A coronary angiography showed a tight stenosis in the proximal left anterior descending artery. An angioplasty with stenting was performed. The patient

Box 5: Problems in diagnosis

- Complication of pulmonary embolism in a patient with COPD
- Complication of a pneumothorax in a patient with COPD
- Pneumonia, atelectasis, presenting with acute respiratory failure (ARF)
- Acute severe asthma
- Non-respiratory causes triggering ARF in COPD

Abbreviations: LV, left ventricular; COPD, chronic obstructive pulmonary disease.

could be weaned off the ventilator support within the next 2 days. It is now 5 years since the episode. He is on continuous oxygen therapy and has a reasonable quality of life.

Pulmonary embolism complicating COPD can also mimic an acute exacerbation. Here again when pulmonary embolism occurs in a patient with COPD, breathlessness is invariably associated with severe wheezing. A negative D-dimmer test is a strong point against pulmonary embolism. When in doubt, a pulmonary angiography should be done.

Acute pneumonia, lobar atelectasis due to mucus plugging, are other pulmonary pathologies that can precipitate severe acute respiratory failure. The clinical diagnosis may be missed as an acute exacerbation of COPD causing ARF.

Even a shallow pneumothorax in a patient with moderate to severe COPD can induce ARF. This is because an overinflated lung (as occurs in COPD) does not easily collapse even with a good-sized pneumothorax. The pressure within the pneumothorax may be high but it appears quite shallow on the X-ray. This is one reason why any patient with a diagnosis of acute exacerbation of COPD admitted to the hospital, or reporting to the emergency department, should always have an X-ray chest done. It is almost impossible to clinically detect a shallow pneumothorax in a patient with COPD. The only reliable sign is diminished breath sounds over the area of the pneumothorax, but unequal breath sounds over both lungs are not uncommon in COPD, even without pneumothorax.

It is obvious that each of the three complicating conditions listed above can worsen lung function in patients with COPD. This is because each of these conditions will cause tachypnea. Tachypnea in moderate to severe COPD is often characterized by an expiration which is incomplete, being interrupted by the next inspiration. This will lead to progressive air-trapping, hyperinflated lungs with all the consequent deleterious effects on the work of breathing.

Acute severe asthma may in the absence of a good history be difficult to distinguish from an acute severe exacerbation of COPD when the patient is seen for the first time in an emergency. In fact some severe asthmatics have very poor reversibility in airways obstruction and airflow limitation, exactly resembling patients with COPD. Fortunately, the management remains exactly the same.

Box 6: Conditions other than acute exacerbation of COPD which are known to precipitate an acute respiratory crisis in COPD patients

- Respiratory conditions—
  - Pneumonia
  - Pulmonary atelectasis
  - Pneumothorax
  - Pleural effusion
  - Pulmonary thromboembolism
  - Sputum retention from any cause
- Non-respiratory conditions—
  - Acute left ventricular failure
  - Use of respiratory depressants, drugs, tranquilizers
  - Postoperative conditions
  - Trauma (fracture ribs, fracture femur)
  - Systemic infections
  - Severe blood loss

Abbreviations: COPD, chronic obstructive pulmonary disease.

A number of other complications occurring outside the respiratory system may produce an acute respiratory crisis with respiratory failure in patients with well-marked Grades III and IV COPD. For example, narcotic drugs, anesthetics, sedatives, tranquilizers even in small doses can depress the ventilatory drive sufficiently to lead to increasing hypercapnic respiratory failure and a mistaken diagnosis of acute exacerbation of COPD. Trauma causing rib fractures or fractures of the femur, acute systemic infections and sputum retention from any cause are other complications that cause an acute respiratory crisis in COPD patients.

It is therefore, a cardinal principle in medicine that if a patient with well-marked COPD develops ARF or acute on already existing chronic respiratory failure, a careful search for all possible causes must be made. An acute exacerbation of COPD is an important and common cause for the above scenario, but it certainly is not the only cause (see Boxes 5 and 6).

MANAGEMENT[4]

The principles in the management of an acute exacerbation of COPD are—

- Relief of airways obstruction and airflow limitation through a more intensive use of inhaled bronchodilators.
- Use of corticosteroids to reduce the increased inflammation within peripheral airways and lung parenchyma.
- Use of antibiotics in the presence of bacterial infection.
- Use of oxygen to relieve dyspnea and most importantly to relieve hypoxia.
- Use of ventilatory support in patients who are in acute respiratory failure or in acute on chronic respiratory failure in spite of conservative treatment mentioned above.
- Treatment of right heart failure.

We consider the role of the physiotherapist invaluable in patients who have a great deal of sputum but are unable to expectorate it.

Treatment is tailored to the degree of severity of the acute exacerbation. Mild exacerbations may just need intensified bronchodilator therapy. If the sputum is purulent, antibiotics need to be given after collecting sputum for culture or sensitivity but without waiting for the results. If the exacerbation seems more than mild, corticosteroids need to be administered. Controlled oxygen is given for the relief of both hypoxia and dyspnea. It is the first important therapeutic measure in hypoxic patients, and should be started promptly in a patient admitted with ARF. Persistence or increasing respiratory failure in spite of conservative management necessitates the use of ventilator support. Noninvasive ventilator support is preferable, but invasive ventilator support should not be delayed if indications so exist.

Inhaled Bronchodilator Therapy[5]

Mild exacerbations of COPD are often controlled merely by increasing the frequency of inhaled bronchodilators. Both short acting β2-agonists and an anticholinergic-ipratropium bromide can be used, preferably through a spacer device, though there is no evidence that the use of both is more effective than the use of either one or the other. Severe exacerbations necessitate the administration of levosalbutamol (1.25 mg 8-hourly) and an anticholinergic agent like ipratropium (500 mcg 8-hourly) through a nebulizer, even though again there is no evidence that this is superior to the use of a metered dose inhaler with a spacer device. Patients in our part of the world who come in with an acute severe exacerbation may have never used a metered dose inhaler and find it impossible to do so effectively at this juncture. Women in particular find it difficult to use the metered dose inhaler even when the COPD is stable. Patients with severe exacerbations are extremely dyspneic, have a poor inspiratory effort and very small tidal volumes. Very little of the drug reaches the airways in spite of using a volume spacer with the metered dose inhaler. The relief in dyspnea due to reduced airways obstruction following a switchover from a metered dose inhaler with a spacer device to the nebulized administration of the drugs, is at times too obvious to be disbelieved.

The frequency of nebulization of salbutamol is generally three times a day, perhaps repeated once in the middle of the night if necessary.

Theophylline

Oral theophylline should be given or continued (if the patient is already on the drug) for its bronchodilator effect in the milder forms of acute exacerbation of COPD. In the more severe forms of acute exacerbation, intravenous (IV) aminophylline 0.25 g to at the most 0.75 g intravenously over 24 hours through an infusion pump may be given, particularly when there is marked bronchospasm. Great care must be taken particularly in patients who have received oral theophylline during the stable phase of COPD. Theophylline levels in the blood should be carefully monitored and should not exceed 15 mg/dL.

Use of Corticosteroids[6]

Systemic corticosteroids are indicated in all except the very mild exacerbations that respond well to inhaled bronchodilator therapy alone. A number of randomized trials indicate that the use of steroids relieves airways obstruction producing a rapid improvement in forced expiratory volume in one second (FEV_1). Other outcome effects such as hospitalization, length of hospital stay, and oxygenation are variable. Their effect on mortality has not been determined. Corticosteroids act through their anti-inflammatory effect. The generally accepted dose is 40 mg prednisolone orally for 10–14 days. Critically ill patients or those in whom absorption of the drug is suspect because of vomiting should be given methyl prednisolone 40 mg 8-hourly intravenously till improvement occurs, following which oral prednisolone is used. Nebulized budesonide (0.5 to 1 mg nebulized twice daily) also acts through its direct anti-inflammatory effect on the airways. It is however difficult to ascertain to what extent the drug reaches the peripheral airways, where inflammation is most marked. In severe exacerbations, budesonide should not substitute the use of systemic corticosteroids.

Antibiotics[7,8]

Antibiotics should be used whenever the sputum is purulent—colored yellow or green. These patients should be given antibiotics promptly without awaiting culture sensitivity reports. The choice of antibiotics depends on the organism generally prevailing in patients with acute exacerbation of COPD in a particular locale. The antibiotics used should cover the common organisms generally responsible for acute exacerbations—*S. pneumoniae*, *H. influenzae* and *M. catarrhalis*. In elderly individuals, Gram-negative infections are not uncommon, particularly those due to *P. aeruginosa* and *K. pneumoniae*. An appropriate cover for Gram-negative infections is then necessary. Viral infections (the rhinovirus in particular) are being increasingly recognized as a cause of acute exacerbations of COPD. Antibiotics are of no use when this is so.

The question often arises—does one use empiric antibiotic therapy in patients with severe acute exacerbation, particularly in those with ARF, when there is no evidence of bacterial infection? Rightly or wrongly, we do so, as some patients who have infection may have no sputum and the danger of not treating a possible infection in such critically ill patients, particularly when they are old and feeble is great. When such patients need intubation and ventilatory support, suction through the endotracheal tube has often revealed dirty yellow or green tracheobronchial secretions. Interestingly, a meta-analysis of six sufficiently well-designed randomized trials by Saint and colleagues[7]

confirmed a statistically significant benefit that favored the use of antibiotics. Duration of antibiotic therapy is generally not more than 4–7 days.

Controlled Oxygen Therapy[2,5,9,10]

Oxygen through nasal prongs or a Venturi mask is used to relieve dyspnea, but most importantly to relieve hypoxia. Patients with Grade III, IV COPD who develop a severe acute exacerbation are invariably hypoxic and often hypercapnic. The PaO_2 very often is less than 55–60 mm Hg. These patients always need oxygen and are at risk of death from worsening hypoxia. *It should be a cardinal rule to administer oxygen immediately, and as the very first measure in any acutely ill patient with COPD*. Oxygen should be administered in a controlled manner and should be carefully supervised. Uncontrolled oxygen therapy can be lethal in these patients. Intensive care is crucial for survival. The objective is to increase PaO_2 to a safe level of 60 mm Hg or ensure an oxygen saturation of 90%, without the arterial pH falling below 7.25. Controlled oxygen therapy can be given through a Venturi mask, which allows an FiO_2 of 24%; this can be increased through Venturi masks that allow an FiO_2 of 26% or even 28–30%, or more, if dangerous hypoxia is unrelieved. Oxygen given through nasal prongs at a flow rate of 1–2 L/minute is a cheap, convenient and effective alternative, as this generally equates to an FiO_2 of 24%.

The response to controlled oxygen therapy (starting with an inspired oxygen content of 24%, and increasing to 26% or even 28–30% if dangerous hypoxia is unrelieved), falls into the following three patterns—

1. Relief of hypoxemia, with a fall in the $PaCO_2$ and an overall clinical improvement.
2. Relief of hypoxemia, but an initial increase in the $PaCO_2$ with a further fall in arterial pH to not less than 7.25. The $PaCO_2$ then steadies at a higher level, or returns to pretreatment levels. After a couple of days, the $PaCO_2$ generally falls below pretreatment levels. The initial rise in $PaCO_2$ with a fall in arterial pH, is usually observed during the first night after starting oxygen therapy, and is associated with increasing drowsiness, dullness, confusion and apathy. Thereafter, there is a gradual fall in the $PaCO_2$ to pretreatment or even lower levels and a return of pH toward normal, occurring pari passu with clinical improvement.
3. Relief of hypoxemia, but a rapid, progressive, marked increase in the $PaCO_2$ with an increasing respiratory acidosis (pH <7.25). This response is to be expected if oxygen is administered in an uncontrolled manner, using high oxygen concentrations. It can however also occur with carefully controlled and supervised oxygen therapy (O_2 concentration between 24% and 28%). The severe respiratory acidosis and the marked rise in the $PaCO_2$ can prove lethal in these patients.

Unfortunately, it is generally the severely hypoxic patient with a fairly high $PaCO_2$ to start with, who is more prone to developing a progressively increasing, dangerously high $PaCO_2$ with a dangerously low arterial pH (<7.2).

Box 7: Blood gas patterns observed in acute exacerbation of COPD

- Hypoxia + hypercapnia during crisis; hypercapnia persists after recovery from acute exacerbation
- Hypoxia + hypercapnia during crisis; normocapnia after recovery
- Hypoxia but no hypercapnia during crisis

It is important to understand why uncontrolled oxygen therapy (and in some patients even controlled oxygen therapy) can lead to a sharp rise in $PaCO_2$. It used to be believed that the essential drive to breathe in these patients was due to the prevailing hypoxia, because the respiratory center was considered to be relatively insensitive (compared to normal subjects) to the rise in $PaCO_2$. Giving a high FiO_2 (uncontrolled oxygen) would remove the hypoxic stimulus to breathe, so that the patient would have a further rise in $PaCO_2$. This is not true; the ventilatory drive in these patients is even more than normal. Uncontrolled O_2 therapy produces vasodilatation in the pulmonary capillaries due to relief of hypoxia. This leads to a further ventilation/perfusion (V/Q) mismatch with low ventilation-perfusion ratios. It is the increasing alveolar hypoventilation due to the above cause that leads to a sharp rise in $PaCO_2$. The blood gas patterns observed in acute exacerbation of COPD are listed in Box 7.

Patients who on conservative management (outlined earlier), and on controlled oxygen therapy show poor relief in hypoxia or show a progressive rise in the $PaCO_2$ with a fall in the arterial pH less than 7.25, require mechanical ventilator support. Ventilator support could be of two types: (1) noninvasive and (2) invasive. It should be noted that many patients with severe Grade IV COPD have a persistent hypercapnia between 50 mm Hg and 60 mm Hg even in a stable state. It is unwise to attempt to reduce a very high $PaCO_2$ seen during an acute exacerbation to normal levels. These patients tolerate a $PaCO_2$ between 50 mm Hg and 60 mm Hg fairly well.

Noninvasive Mechanical Ventilation[2,11,12]

Noninvasive positive pressure ventilation (NIPPV) has been proven to be useful in several studies of acute respiratory failure caused by an acute exacerbation of COPD. Studies show that the use of NIPPV is associated with a lesser risk of nosocomial infections, less antibiotic use, and a lower mortality when compared to patients who are equally ill but did not receive NIPPV.

NIPPV has the ability to increase alveolar ventilation, rest muscles of respiration, reduce work of breathing and prevent respiratory muscle fatigue. Potential benefits include an increase in tidal volume, a fall in respiratory rate, improved oxygenation, a fall in $PaCO_2$ and greater patient comfort.

Box 8: Indications and contraindications for NIPPV

- Indications for NIPPV—
  - Respiratory rate >30/min
  - Respiratory distress due to moderate or severe dyspnea
  - pH ≤7.30 and or a $PaCO_2$ >60 mm Hg, provided these values fail to improve or worsen after a trial of 6–12 hours of conservative treatment
- Contraindications to NIPPV—
  - Obtunded patient
  - Breathes very poorly, irregularly
  - Unable to protect the airway
  - Copious respiratory secretions
  - Risk of gastric aspiration
  - Hypotension; CVS instability
  - pH ≤7.20 with an acute rise of $PaCO_2$ >70 mm Hg

Abbreviations: NIPPV, noninvasive positive pressure ventilation; $PaCO_2$, arterial carbon dioxide tension; CVS, cardiovascular system.

When these benefits occur, they do so within a few hours of initiating NIPPV. Perhaps the most important advantage of NIPPV in an acute crisis of COPD is that it obviates the need for endotracheal intubation and invasive mechanical ventilation, which is far more inconvenient to the patient, and has more risks—particularly the risk of nosocomial infection.

Having said this, it is our considered opinion that many patients admitted to intensive care units in this country for an acute exacerbation of COPD are offered NIPPV when ventilatory support is not required, i.e. these patients would have recovered on conservative measures outlined above. Also, many such patients are offered NIPPV when they in fact needed prompt intubation and invasive ventilator support.

The indications for initiating NIPPV in an acute crisis of COPD are—

- Respiratory rate greater than 30/minute.
- Respiratory distress due to moderate or severe dyspnea.
- pH less than or equal to 7.30 and/or a $PaCO_2$ greater than 60 mm Hg, provided these values fail to improve or worsen after a trial of 6–8 hours (or even earlier) of conservative measures.

Noninvasive mechanical ventilation should not be used as the mode of ventilatory support if the patient is hemodynamically unstable, breathes poorly or irregularly, is unable to protect the airway, has copious respiratory secretions, and has a risk of aspirating gastric contents. It is preferable to intubate and ventilate those whose PaO_2 is less than 45 mm Hg and who are admitted with a pH less than 7.20. Patients who show an acute rise of $PaCO_2$ greater than 70 mm Hg are often obtunded, and in our opinion, are more effectively managed by endotracheal intubation and invasive ventilator support. Endotracheal intubation and ventilation should obviously be also resorted to when NIPPV fails to prove of benefit within 6–10 hours of its initiation, or even earlier, if the patient worsens on this mode of support. Indications and contraindications for NIPPV are listed in the Box 8.

Box 9: Indications for endotracheal intubation and ventilator support

- Respiratory rate >40/min
- Respiratory muscle fatigue
- Mental obtundation
- A silent chest—respiratory arrest
- Hypotension
- Falling pH <7.25
- PaO_2 <50 mm Hg
- Rising $PaCO_2$ >70 mm Hg, often ≥100 mm Hg

Implementation of NIPPV

Noninvasive positive pressure ventilation can be offered through either a light-fitting face mask or a nasal mask. Each has its own advantages. We prefer the face mask in patients with severe respiratory failure. A wide variety of ventilatory modes can be used in NIPPV. The biphasic positive airway pressure (BiPAP) mode allows for good gas exchange and effectively reduces both the work of breathing and patient distress. Pressure support ventilation (PSV) is perhaps an equally useful mode and is generally better tolerated than the assist-control mode. In a BiPAP mode, to start with, the inspiratory pressure (IP) is kept at 8–10 cm above the end-expiratory pressure (EP), so that if the EP is 5–7 cm H_2O, the IP is 12–15 cm H_2O. The pressure can then be adjusted to allow for effective alveolar ventilation and good gas exchange.

If the PSV mode is used for NIPPV, the IP support to start with is kept on 15–20 cm H_2O. A small PEEP of 4–5 cm H_2O may be of help in patients who have a large auto-PEEP, as it helps reduce inspiratory effort to generate inspiratory airflow in these patients.

Weaning from NIPPV is accomplished by progressively decreasing the level of IP support if the PSV mode is used, or by allowing the patient to be intermittently off NIPPV for increasing lengths of time.

Intubation and Mechanical Ventilation[2]

Patients who show a sharp progressive rise in the $PaCO_2$ with a pH less than 7.2 on controlled oxygen therapy, or those whose dangerous hypoxia stands unrelieved on conservative therapy or NIPPV, are best intubated and put on mechanical ventilator support. The indications for endotracheal intubation and ventilator support are listed in Box 9. Selection of cases for this mode of treatment is difficult. It would be disastrous for a patient and his family if after starting mechanical ventilation, it becomes impossible to wean the patient off ventilator support. In our opinion, the best indication whether to opt for invasive ventilator support or not, is the activity and state of health of the patient under basal conditions. If the patient's activity was hopelessly poor under basal conditions to start with (i.e. he was more or less confined to his bed due to poor respiratory reserve), it is unwise to opt for invasive ventilator support, and the family should be advised accordingly. If he was reasonably

Table 1: Principles of mechanical ventilation in patients with COPD with acute respiratory crisis

Ventilator settings	*Objectives*
Low tidal volumes of 350 mL (6–7 mL/kg) MV <5–6 L/min	• Prevents overinflation • Prevents dynamic hyperinflation and progressive increase in auto-PEEP
Rate: 12–14/min	• Decreases peak inflation pressure • Reduces risk of barotrauma
Flow rate 40–60 L/min	
I:E ratio of 1:3	• Allows good distribution of inspired gas, allows time for expiration
FiO_2 of 50–70%	• Allows quick correction of hypoxia
Sedate or use pancuronium	• Allows machine to take over, and prevents clashing with the machine

Note: (1) Lower $PaCO_2$ very gradually over 24 hours or even longer to 50 mm Hg—a PaO_2 of 60 mm Hg suffices. (2) If weaning is difficult, use pressure support ventilation.
Abbreviations: COPD, chronic obstructive pulmonary disease; PEEP, positive end-expiratory pressure; I:E ratio, inspiratory:expiratory ratio; MV, minute ventilation; $PaCO_2$, arterial carbon dioxide tension.

active prior to the crisis that brought him to the ICU, he should be offered ventilator support.

Endotracheal intubation in patients showing poor response to antibiotics, bronchodilators, physiotherapy and controlled oxygen therapy, offers two advantages: (1) it allows proper access for suctioning of respiratory secretions and (2) it allows mechanical ventilator support.

Mechanical ventilation is difficult in patients with chronic airways obstruction. We prefer and recommend the assist-control mode in patients with severe ARF, so that total support and appropriate choice of ventilator settings can be provided. Sedation and rarely, neuromuscular paralysis may be necessary for effective respiratory support. As recovery proceeds, or in patients who are not very ill, PSV may be used. The principles for successful ventilation are outlined above (Table 1).

- Small tidal volumes of 300–400 mL are used with minute ventilation not exceeding 5–6 L/minute. Lung protection measures require that peak pressures are not unduly high and that the plateau pressure does not exceed 30 cm H_2O. The FiO_2 is increased to 50–60% so that dangerous hypoxia is quickly corrected. It is unnecessary to aim for an oxygen saturation greater than 90%. The low tidal volumes prevent dynamic hyperinflation, thereby preventing a further increase in auto-PEEP, which is invariably present in these patients (see Section Pathophysiology). Low tidal volumes also lead to lower peak inflation pressures. This is a great advantage, as high peak pressures, if transmitted to the intrapleural space, cause a sharp reduction in the venous return and the cardiac output, and can produce sudden severe hypotension. In fact, hypotension should be carefully looked out for, particularly after starting ventilation. A fall in the arterial pressure should prompt one to further reduce the inflation pressure by further reducing the tidal volume. The blood pressure should also be raised by volume expansion or by using inotropic support. Once the patient is on mechanical ventilation with the hypoxia corrected by a high FiO_2, an increase in $PaCO_2$ need not be feared. Under these circumstances, death usually does not occur due to a high $PaCO_2$.

Sensitivity

The optimal triggering threshold is difficult in an acute COPD crisis in the presence of dynamic hyperinflation (i.e. auto-PEEP). This is because the patient has to generate a negative pressure at least equal to the level of auto-PEEP before interfacing with the preset sensitivity on the ventilator. If the auto-PEEP is high, the required inspiratory effort (before reaching trigger sensitivity) to initiate airflow is significant and this can lead to patient-ventilator dyssynchrony. Yet, if the trigger sensitivity is kept very low, the ventilator could be triggered very frequently and inappropriately. If the auto-PEEP is significantly raised, extrinsic PEEP is applied at a level well below the level of the auto-PEEP. This helps to reduce the effort needed to initiate inspiratory flow.

Ventilator requirements are so adjusted so as to bring down the raised $PaCO_2$ level very slowly over 24–48 hours. It is generally unnecessary to reduce the $PaCO_2$ to less than 50 mm Hg unless the basal $PaCO_2$ levels were normal. A sudden drop in the $PaCO_2$ is dangerous as it causes a sudden shift from respiratory acidemia to metabolic alkalosis and alkalemia. This can precipitate dangerous arrhythmias and cause sudden death.

- The flow rates used in such patients are usually between 40 L/minute and 60 L/minute, and the inspiration:expiration ratio is initially set at 1:3.
- Patients should not be allowed to clash with the machine; they can be given a neuromuscular relaxant, or sedated once they are put on ventilator support. Paralytic agents should if possible be avoided or used sparingly. The combined use of corticosteroids and muscle relaxants often causes a neuropathy or a neuromyopathy, characterized by extreme weakness of the extremities. The respiratory muscles may also be involved causing difficulties in weaning.
- Mechanical ventilator support is generally necessary for a period of 3–7 days. The maximum period over which we have used ventilator support, and then finally succeeded in weaning the patient, has been 6 weeks. An elective tracheostomy is preferred if ventilator support needs to be extended for more than 7 days, or if the patient has thick copious secretions which cannot be easily suctioned through the endotracheal tube.
- Weaning is generally carried out by the traditional methods. We have used intermittent mandatory ventilation, and

Box 10: Complications during acute respiratory failure in COPD

- Pulmonary infection
- Fluid, electrolyte and acid-base disturbances
- Respiratory acidosis with hypokalemic metabolic alkalosis
- Severe water logging can occur due to salt and water retention
- Cardiac arrhythmias
- Right-sided heart failure
- Hypotension if there is marked auto-PEEP
- Pneumothorax
- Complications due to mechanical ventilation
- Gastrointestinal bleeds
- Neuromyopathy caused by steroids, steroids and muscle relaxants or due to prolonged critical care (critical care neuromyopathy)
- Pulmonary thromboembolism
- Mental depression

Abbreviations: COPD, chronic obstructive pulmonary disease; PEEP, positive end-expiratory pressure.

PSV, but have never been totally convinced of their absolute necessity. The patient is taken off ventilator support when he can maintain an adequate gas exchange on his own. This generally happens when infection has been controlled, airways obstruction has decreased, and V/Q abnormalities have been significantly rectified.

Older patients with IHD often need careful cardiovascular support. The presence of associated LV failure with pulmonary edema, together with generalized water retention is not uncommon in these patients. It is indeed remarkable how good ventilator support with improvement in blood gases initiates a diuresis in these patients, even though earlier use of large doses of furosemide might have been ineffective. Correction of severe hypoxia and hypercapnia are probably responsible for the improved cardiac-cum-renal function and diuresis.

- ❑ Expert nursing, humidification of inspired oxygen and persistence with the regime outlined earlier, are all essentials of good respiratory care in these patients.

Treatment of Right Heart Failure

Patients suffering a severe exacerbation of COPD often go into right heart failure with edema of the feet and legs and with distended jugular vein. Intravenous furosemide is useful; digoxin is however of not much use and may well trigger arrhythmias. At times the edema is massive and appears unresponsive to diuretics. This is particularly observed in patients who are severely hypercapnic. Ventilator support which lowers the $PaCO_2$ to less than or equal to 50 mm Hg is invariably associated with significant diuresis, the patient becoming edema free within a few days. Patients in right heart failure should always be given prophylactic anticoagulant therapy, preferably with low molecules weight heparin.

Box 11: Management of acute respiratory crisis in patients with COPD

- Improve ventilation, correct ventilation-perfusion mismatch, relieve severe hypoxia and correct low pH—
  - Controlled oxygen therapy (24–30% oxygen)
  - Treat infection with antibiotics
- Relieve airways obstruction—nebulize with duolin 6–8 hourly, ipratropium bromide 12 hourly—
  - Use of corticosteroids—IV or orally; nebulize with 1 mg budesonide 12 hourly
  - Theophylline
- Physiotherapy to help drain copious secretions and prevent sputum retention
- Ventilator support when so indicated
- Cardiovascular support when necessary
- Treat complications encountered during acute respiratory failure—
  - Correct fluid and electrolyte disturbances
- Management of cardiac complications, e.g. arrhythmias, hypotension, right-sided heart failure and pulmonary thromboembolism—
  - Treat GI bleeds
  - Drain even a shallow pneumothorax

Abbreviations: COPD, chronic obstructive pulmonary disease; GI, gastrointestinal.

TREATMENT OF COMPLICATIONS DURING ACUTE RESPIRATORY FAILURE IN EXACERBATION OF COPD

A number of complications may arise in critically ill patients with ARF resulting from an acute exacerbation of COPD. These are listed in Box 10. These should be promptly diagnosed and treated. The most dangerous complications outside the respiratory system are cardiac arrhythmias and hemodynamic instability.

Cardiac Arrhythmias

Cardiac arrhythmias are frequently observed in these patients. Supraventricular tachycardia, multifocal atrial tachycardia and atrial fibrillation are common; atrioventricular (AV) dissociation and multiple ventricular extrasystoles may also occur. The mortality rate is significantly higher in patients having arrhythmias.

Hemodynamic Instability

Patients with COPD often suffer from pulmonary hypertension. An acute exacerbation of COPD worsens pulmonary hypertension due to hypoxic vasoconstriction, dynamic hyperinflation, or the presence of auto-PEEP during mechanical ventilation. A sharp increase in pulmonary artery pressure leads to severe right ventricular dysfunction, right-sided heart failure, with a fall in both systolic and mean arterial blood pressure. An IV fluid challenge expands the intravascular

pulmonary bed and improves right ventricular pump function. It should be the initial step in the management of hypotension and hemodynamic instability in an acute crisis of COPD. If the hemodynamic state fails to improve, inotropic and/or vasopressor support is necessary. Ventilator adjustments to reduce dynamic hyperinflation and auto-PEEP are also necessary.

The management of acute exacerbation of COPD is outlined in the Box 11.

PROGNOSIS

The prognosis for patients treated in the ICU is unsatisfactory, particularly so if the patients have received invasive ventilatory support. The mortality rate in the above patients is as high as 25% with a 1 year mortality quoted at 39%.[13,14]

CHAPTER 32

Acute Lung Injury and Acute Respiratory Distress Syndrome

Zarir F Udwadia *MD, FRCP (London), MNAMS, FCCP (USA). Consultant Physician, P.D. Hinduja National Hospital, Breach Candy Hospital and Parsee General Hospital, Mumbai, Maharashtra, India, with* ***FE Udwadia***

GENERAL CONSIDERATIONS

The acute respiratory distress syndrome (ARDS) is an important condition characterized by noncardiogenic increased permeability, inflammatory pulmonary edema, with diffuse alveolar damage; it leads to hypoxemic respiratory failure necessitating ventilator support and prolonged intensive care.

The first description of what probably was ARDS was given by Osler in his Textbook of Medicine in 1927. He wrote of uncontrolled septicemia leading to pulmonary edema and went on to describe the clinical features and autopsy findings very nearly as we know them today. In 1967, Ashbaugh, Bigelow and Petty[1] reported in the Lancet the occurrence of noncardiogenic pulmonary edema and acute respiratory failure in a number of diverse pathologies not directly involving the lungs. They termed this condition the adult respiratory distress syndrome. Semantically speaking, this was an unfortunate term. The syndrome can occur at all ages and is not related in its pathogenesis and pathology to the respiratory distress syndrome of the newborn. Also, the connotation of respiratory distress is both vague and common to numerous other unrelated pathologies in cardiorespiratory medicine. The syndrome is now termed the acute respiratory distress syndrome (ARDS). Semantic confusion would have been avoided if from the very outset the condition had been termed acute lung injury (ALI) which could then have been graded as mild, modarate or severe. Since 1967, the syndrome has been reported from many countries, including India.[2] The precipitating factors have been recognized and the pathology of the lung has been elucidated. However, the pathogenesis after more than 40 years of research remains unclear and the mortality in spite of expert intensive care, even today is as high as 30–60%.

EPIDEMIOLOGY

The incidence of ARDS even in Western countries has not been clearly established. The National Heart, Lung and Blood Institute sponsored ARDS Network of 20 hospitals estimated that the incidence could be as high as 64 cases per 100,000 population. The prevalence in developing countries including India is unknown. ARDS constituted a little over 4% of intensive care unit (ICU) admissions in our unit over a 5-year period. It is unquestionably a problem that is likely to be encountered with increasing frequency by all physicians who look after critically ill patients.

DEFINITION AND CONCEPT

ARDS is characterized by (1) an antecedent history of a precipitating condition; (2) respiratory distress and refractory hypoxemia not responding satisfactorily to supplemental oxygen and invariably necessitating the use of mechanical ventilatory support; (3) radiographic evidence of newly evolving bilateral pulmonary infiltrates and (4) pulmonary artery occlusion pressure (PAOP) less than 18 mm Hg in the presence of a normal colloid oncotic pressure.

The physiological changes underlying the above clinical definition include a reduced functional residual capacity (FRC), stiff lungs (reduced pulmonary compliance), increased ventilation-perfusion inequalities, an increase in the right to left shunt within the lungs and an increase in the extravascular water content of the lungs with, as already mentioned, a normal PAOP. *The underlying pathological abnormality is damage to the alveolar capillary membrane with increased capillary permeability, leading to edema, inflammation and subsequent fibrosis.*

Table 1: The American-European Consensus Definition of acute lung injury (ALI) and acute respiratory distress syndrome (ARDS)

ALI	*ARDS*
Acute onset respiratory failure	Acute onset respiratory failure
Bilateral chest infiltrates on frontal radiographs	Bilateral chest infiltrates on frontal radiographs
PaO_2/FiO_2 <300	PaO_2/FiO_2 <200
Absence of elevated left heart filling pressure (PAOP <18 mm Hg)	Absence of elevated left heart filling pressure (PAOP <18 mm Hg)

Abbreviations: PaO_2, arterial blood gas oxygen tension; FiO_2, fraction of inspired oxygen; PAOP, pulmonary artery occlusion pressure.

The American-European Consensus Conference in 1994[3] clinically defined and distinguished between ALI and ARDS, so as to avoid semantic confusion. The American-European Consensus Definition of ALI and ARDS is given in Table 1.

A more recent definition has been proposed through a Delphi method. This definition again primarily relies on hypoxemia [arterial blood gas oxygen tension (PaO_2)/fraction of inspired oxygen (FiO_2) <200, with a positive end-expiratory pressure (PEEP) >10 cm H_2O], and the presence of bilateral chest infiltrates as detected on chest radiography. All definitions exclude the presence of unilateral lung injury and the presence of cardiogenic pulmonary edema detected either through clinical judgment or through measurement of PAOP.

Till very recently the most widely accepted definition of ARDS was that proposed by the American-European Consensus Committee (AECC) in 1994. However, the reliability and validity of this definition has been recently questioned. In 2011, a panel of experts (initiated by the European Society of Intensive Care, and endorsed by the American Thoracic Society) developed the Berlin Definition.[4] A draft definition proposed three mutually exclusive categories of ARDS based on degree of hypoxemia—

1. Mild (PaO_2/FiO_2 <300 mm Hg).
2. Moderate (PaO_2/FiO_2 <200 mm Hg).
3. Severe (PaO_2/FiO_2 <100 mm Hg).

Four ancillary variables for severe ARDS were considered: (1) radiographic severity, (2) lung compliance (40 mL/cm H_2O), (3) PEEP (>10 cm H_2O) and (4) corrected expired volume/minute (10 L/minute). The draft definition was empirically evaluated using patient-level meta-analysis of 4,188 patients with ARDS from four multicenter clinical data sets and 269 patients with ARDS from three single-center data sets. It was observed that the four ancillary variables did not contribute to the predictive validity of severe ARDS for mortality and were removed from the definition.

The three mutually exclusive stages of categories of ARDS as proposed by the Berlin Definition: (1) mild, (2) moderate and (3) severe ARDS were shown to be associated with increasing mortality.

- Mortality in mild [27%; 95% confidence interval (CI), 24–30%].
- Mortality in moderate (32%, 95% CI, 29–34%).
- Mortality in severe (45%; 95% CI, 42–48%).

Median ventilator free days declined with the severity of ARDS.

Compared to the AECC definition, the final Berlin Definition had better predictive validity for mortality.

Unquestionably, there is a definite advantage to an internationally accepted Definition, whether it be the AECC definition or the Berlin Definition. However, all definitions of ARDS have lacunae and limitations. These need to be considered for a balanced perspective of the syndrome.

- The present definition does not include any etiology or responsible risk factors. Perhaps this is because there are many (and a growing number of) background risk factors—some common and others uncommon. Also there may be more than one responsible factor in a patient.
- Though ARDS signifies noncardiogenic pulmonary edema, patients with a background of left ventricular dysfunction and raised left atrial pressure may fortuitously suffer from a risk factor such as sepsis which could further evolve into ARDS. Both ARDS and cardiogenic pulmonary edema may thus coexist. This is uncommon, but has been observed in our ICU. Again, in the natural history of ARDS due to severe sepsis, cardiac function is often seriously compromised with a sharply reduced ejection fraction and raised filling pressures. When a patient is seen for the first time at this juncture, diagnosis is difficult.
- Bilateral chest infiltrates have been taken as a surrogate marker for the increased permeability inflammatory pulmonary edema that characterizes ARDS. Meade and colleagues[5] have shown that the specificity of chest radiographs in indicating inflammatory edema is questionable. Similar infiltrates on a chest radiography can occur with atelectasis, consolidation, interstitial and intra-acinar edema
- The concept of ARDS as stated by the American-European Congress Conference is narrow in its perspective. An expanded concept should include not only the severity of the ALI, but also the background factor causing or precipitating the syndrome, and most importantly the associated or evolving dysfunction of organ systems. *Most investigators consider ALI/ARDS as merely one facet of the multiple organ dysfunction syndrome.*
- The diagnostic accuracy of the different definitions of ARDS has been recently assessed using as a reference or gold standard the finding of diffuse alveolar damage at autopsy. The commonly accepted criteria for the diagnosis of ARDS as stated by the American-European Congress Conference showed an acceptable sensitivity (0.83%) but a poor specificity (0.51%).

We therefore feel that the correct definition of ARDS is still an unsettled issue. Randomized trials using different ventilatory

and other strategies to test for improved survival have been based on enrolling patients according to a given definition. It is obvious that an inappropriate definition of ARDS would lead to inappropriate enrollment of patients in trials, which in turn could lead to biased and misleading results.

ETIOLOGY

A variety of clinical disorders and risk factors can lead to ALI and ARDS. The incidence of various risk factors in relation to ARDS will depend on the geographical areas and the population that is studied. In India and in other tropical developing countries in addition to the risk factors observed in the West, there are special important risk factors chiefly confined to tropical poor countries.

The various clinical disorders that can lead to ALI or ARDS may do so by directly involving the lung (direct injury), or may involve the lung indirectly (indirect injury). Our experience on ARDS with regard to etiology and mortality in relation to each etiological factor is summarized in Table 2.

In 243 patients of ARDS studied over several years in our ICU, direct injury was the etiological factor in 82 patients; indirect injury was the causative factor in 105 patients; 56 patients developed ARDS due to fulminant infections and problems peculiar to the tropical and developing countries of the world—for convenience these 56 patients were categorized under ARDS due to tropical problems. The first two groups of patients for convenience were categorized under nontropical problems, i.e. problems more or less common to the whole world. Though the exact incidence of various clinical disorders causing ALI/ARDS in different critical care units in India may vary for several reasons, the nature of risk factors is by and large common to critical care units in the large metropolitan centers of the country.

The most important cause of direct injury perhaps all over the world is acute pulmonary infection (chiefly bacterial or viral pneumonia).[6] Aspiration pneumonia is also an important risk factor, both aspirated gastric acid and enzymes contributing to lung injury. After aspiration, lung injury may take some hours to evolve and manifest. Direct trauma to the chest with contusions within the lung is an important cause particularly in trauma units. Polytrauma even when not directly involving the chest is an even more important cause and is probably due to inflammatory mediators released from trauma sites acting on the lungs.

Sepsis is unquestionably the most important cause of ALI/ARDS all over the world.[7] In sepsis, ALI and ARDS form merely one facet of the multiorgan dysfunction syndrome. The incidence of ALI and ARDS in severe sepsis or septic shock is over 25%. Sepsis not only initiates ALI but also perpetuates it. Even when ARDS is caused by a direct injury or insult to the lung, sepsis may subsequently supervene as a major complication and can worsen lung injury and cause multiple organ dysfunction. When sepsis is the indirect cause of ALI, the source of sepsis is most frequently intra-abdominal. On the other hand, when sepsis is a supervening complication in a patient suffering from ALI due to any other etiology, the source of sepsis is most frequently within the lung itself (Fig. 1).

Acute pancreatitis, burns and poisoning (in particular organophosphorus poisoning) are other important causes of ARDS.

Table 2: The etiology of acute respiratory distress syndrome (ARDS) as observed in our unit with observed mortality for each etiological factor. Note the difference in mortality between ARDS and multiple organ dysfunction syndrome (MODS) in tropical problems and nontropical problems

	Total	*Expired*	*Mortality (%)*
Total number of patients	243	128	53
Patients with tropical problems	56	15	27
Patient with nontropical problems	187	113	60
Patients with tropical problems (N = 56)	*Total*	*Expired*	*Mortality (%)*

Miscellaneous	17	10	59
Total	105	66	63

Fig. 1: Acute lung injury in a patient who developed peritonitis following a cesarean section

There are a number of varying miscellaneous causes being reported with increasing frequency from different parts of the world. Among these, multiple blood transfusions head the list.[8] ARDS following multiple blood transfusion has been reported in both trauma patients as also in nontrauma patients such as patients transfused following massive gastrointestinal bleeds. In trauma patients, systemic inflammatory mediators may perhaps play a greater or equal role as multiple blood transfusion in causing ALI/ARDS. Current evidence suggests that the risk of lung injury increases with the duration of stored blood.

Transfusion-related acute lung injury (TRALI) resembles ALI/ARDS, yet is not the same.[9] This form of injury can be caused by transfusion of even small quantities of whole blood or any blood product. The cause is believed to be due to passively transfused antibodies that act as leukagglutins attaching to antigens on the recipient leukocytes, thereby causing lung injury, TRALI manifests with breathlessness during or after transfusion of whole blood or a blood product accompanied by shadows in mid and lower zones of both lung fields. Tachycardia and a fall in oxygen saturation are often observed. TRALI is often mistaken for acute left ventricular failure.

Tropical Infections and Problems[10,11]

It is pertinent and important to briefly outline tropical problems causing ALI and ARDS. These, in our experience, include fulminant *Plasmodium falciparum* infections, severe tetanus, severe typhoid infection, severe dengue, fulminant Gram-negative infection following ingestion of contaminated food, acute miliary tuberculosis, acute disseminated hematogenous tuberculosis, fulminant amebic infections of the liver and large bowel, fulminant leptospirosis, melioidosis, hemorrhagic fevers and rabies. Severe organophosphorus poisoning is the most frequently encountered poisoning causing ARDS in Western India. In the north, aluminum phosphide (added generally for the preservation of food grains) poisoning is an important cause of severe ARDS which invariably ends fatally. Each of these tropical problems can lead not only to ARDS, but to progressive multiple organ failure and death.[12] The most important of these causes are fulminant *P. falciparum* infections, tetanus, fulminant dengue, acute leptospiral infection, fulminant *Bacillus typhosus* infection, acute miliary tuberculosis and acute hematogenous disseminated tuberculosis (Figs 2 to 8).

The following clinical forms of ALI/ARDS have been noted in relation to severe *P. falciparum* malaria—

- Acute pulmonary edema due to hyperpyrexia (temperature >107°F).
- Progressive bilateral shadowing within the lungs characterized physiologically by marked ventilation-perfusion inequalities, but by only a slight increase in the right to left shunt within the lungs—recovery is possible with good management.
- Progressive bilateral fluffy shadows characterized physiologically by a marked increase in the right to left shunt—prognosis of patients in this category is grim.
- Acute respiratory distress syndrome caused by disseminated intravascular coagulopathy complicating falciparum infection.
- Acute respiratory distress syndrome due to aspiration of gastric contents in obtunded patients.

The time from the original insult (direct or indirect) to the development of full-blown ALI has been studied in many large series. In Petty's original group, it ranged from 1 hour to 96 hours. In a comprehensive, recent epidemiological study, 80% of patients had developed ALI within 48 hours of the initial insult and 90% by 80 hours. This latent period offers a window of opportunity for therapeutic interventions, when effective blockers of the inflammatory process can be identified. Indeed, today there is a massive search for circulating markers of ALI which can be identified in the serum or bronchoalveolar lavage fluid.

PATHOLOGY

The work of Gattinoni and his colleagues on CT scans in ARDS[13] has brought forth important new concepts. The first of these concepts is that the lung in ARDS is not homogeneously affected. The most affected part of the lung is the most dependent portion. This dependent area is consolidated and represents core disease, generally constituting about 24% of lung weight. The part or zone above this dependent portion is collapsed lung, the collapse being due to the weight of inflammatory edema which is the hallmark of ARDS; still above the collapsed lung and the zone of inflammatory edema, is the zone of normally aerated or even overventilated

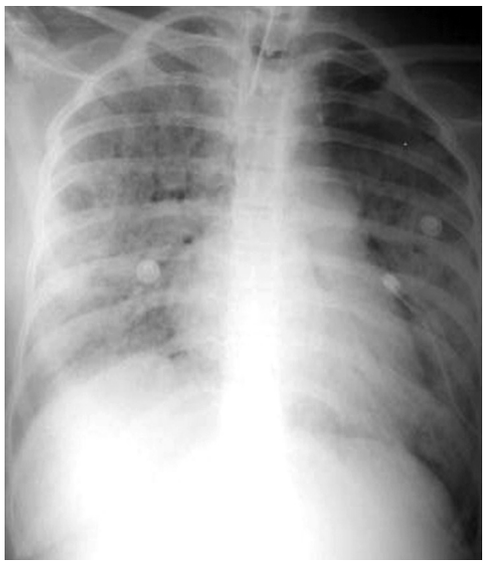

Fig. 2: Acute lung injury in a patient with acute disseminated hematogenous tuberculosis (TB). This patient presented with pyrexia of unknown origin, and rapidly deteriorated, developing ARDS and multiorgan failure. A fiberoptic bronchoalveolar lavage (BAL) was done and demonstrated the presence of acid-fast bacilli (AFB)

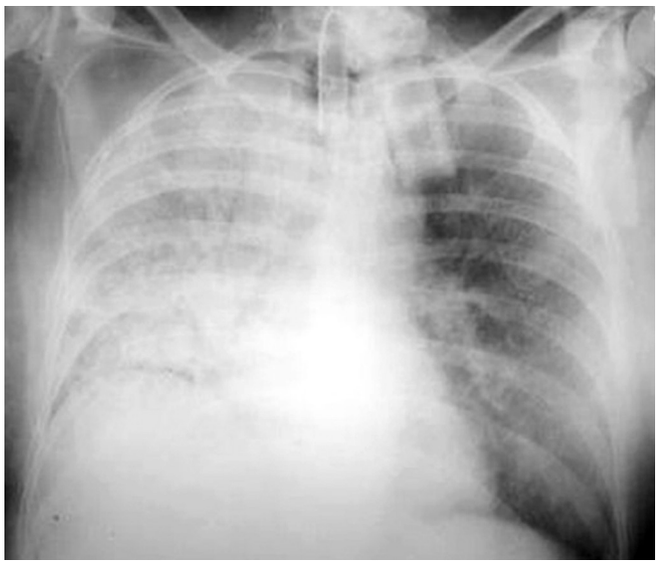

Fig. 3: Acute respiratory distress syndrome (ARDS) in a patient with fulminant *P. falciparum* infection, though both lungs are involved, one seems more involved than the other

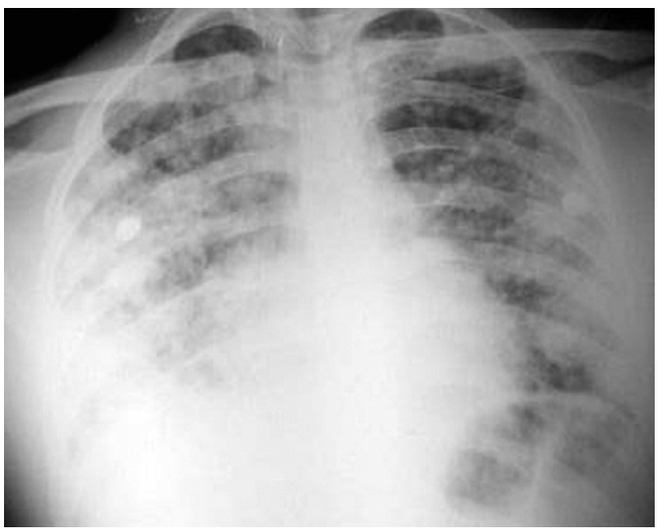

Fig. 4: ARDS in typhoid; note extensive bilateral shadowing

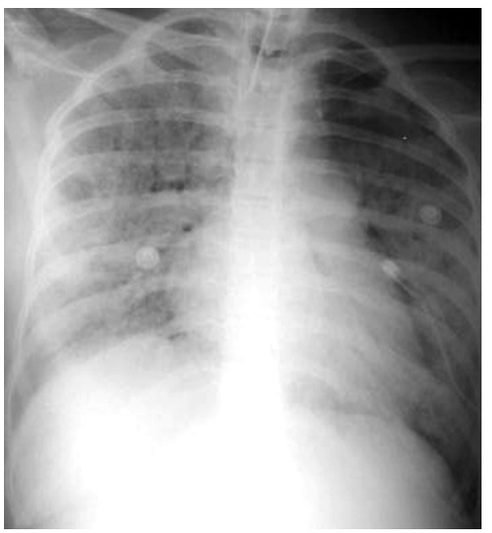

Fig. 5: ARDS in tetanus

lung. The extent of the zone constituting collapsed lung varies. Of importance is the fact that this collapsed lung is capable of being opened up, that is to say it is recruitable by ventilatory measures (raising inspiratory pressure from +5 cm to 45 cm H_2O). The greater the recruitability, the greater the inflammatory edema, the more severe the disease and worse the prognosis. The lesser the recruitability, the lesser the inflammatory edema; the disease is then milder and the prognosis better (Figs 9 and 10).

The above views put forth by Gattinoni not only allow a better conceptualization of ARDS, but also better prognostication, and perhaps most importantly may further guide ventilatory strategies in the management of this syndrome.

The basic pathological feature is damage to the alveolar capillary membrane leading to an increased permeability, inflammatory interstitial and alveolar edema, alveolar atelectasis, consolidation and diffuse alveolar damage. Three overlapping phases are observed—

1. Exudative phase in which there is an alveolar exudate with hyaline membrane formation along the alveolar ducts and within the alveoli.
2. Proliferative phase in which there is a proliferation of inflammatory cells, lymphocytes and type 2 pneumocytes. Organization of the inflammatory exudate combined with damage to the surfactant leads to obliteration of air spaces, atelectatic alveoli and a poorly compliant lung.

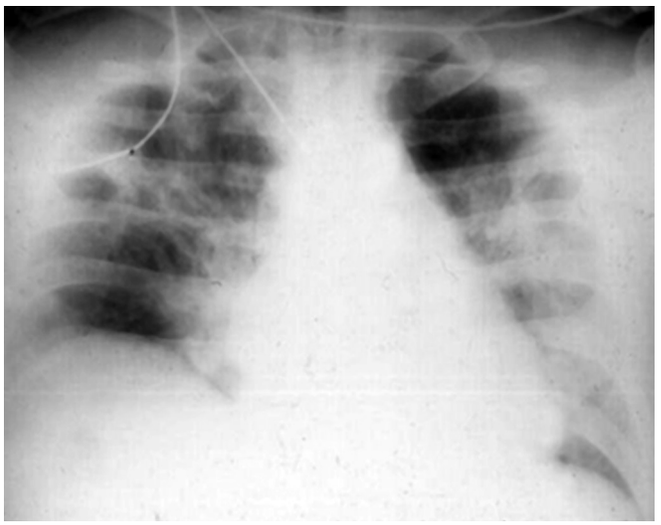

Fig. 6: ARDS in malaria, showing extensive bilateral fluffy shadows

Fig. 7: Acute respiratory distress syndrome (ARDS) in a patient with very severe tetanus

3. Fibrotic phase which follows soon upon the proliferative phase, and is characterized by fibroblasts laying down fibrous tissue that strangles alveoli, and further reduces pulmonary compliance.

Severe lung injury distorts the pulmonary vasculature.

Distortion with remodeling of the vasculature is due to fibrous tissue formation, thromboembolism and increased muscularization with thickening and intimal fibrosis of the larger arteries. Thrombi may be present in the microcirculation and in the larger vessels. They may form in situ, or may have an embolic source. The end-result is an obstructed, distorted pulmonary circulation with increased pulmonary vascular resistance, causing pulmonary hypertension.

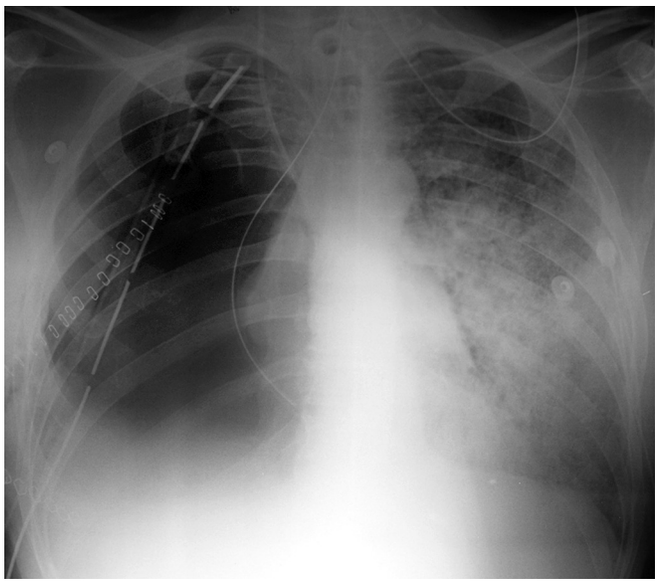

Fig. 8: Acute lung injury in a patient with acute disseminated hematogenous tuberculosis (TB). This patient presented with pyrexia of unknown origin, and rapidly deteriorated, developing ARDS and multiorgan failure. A fiberoptic bronchoalveolar lavage (BAL) was done and demonstrated the presence of acid-fast bacilli (AFB)

PATHOGENESIS

The pathogenesis of ALI continues to remain unclear. Even so, current research allows a better comprehension of what transpires in this syndrome at a cellular and molecular level. Research into molecular genetics has revealed a complex network of interacting factors at the cellular level. It is clear that the cascade of mediators is far more complex than we thought, and many of yesterday's putative mediators are in reality modulators and regulators that fine-tune the inflammatory cascade, rather than cause it. Flowchart 1 illustrates the basic steps in the pathogenesis of ALI and organ failure.

Role of Cytokines, Neutrophils and the Coagulation System[14]

Cytokines, which are cell-derived peptide compounds, are the main mediators. Recombinant cDNA technology has permitted identification of the existence, structure and function of several cytokines. The cytokine on which most attention is currently focused is the tumor necrosis factor (TNF). This cytokine has a molecular weight of 17 kD and is released from macrophages in response to Gram-negative bacterial endotoxin. TNF is one of the main mediators of the septic state. After injection of endotoxin into animals or humans, TNF can be detected in the serum, the levels peaking at 2 hours. When TNF is infused into the sheep model, ALI is produced. Three other cytokines of importance mediating inflammatory response include neutrophil-activating peptide (NAP), interleukin-6 (IL-6), IL-8 and macrophage inflammatory proteins 1 and 2 (MIP 1 and 2). The neutrophil plays a vital role in the inflammatory response, and TNF is the

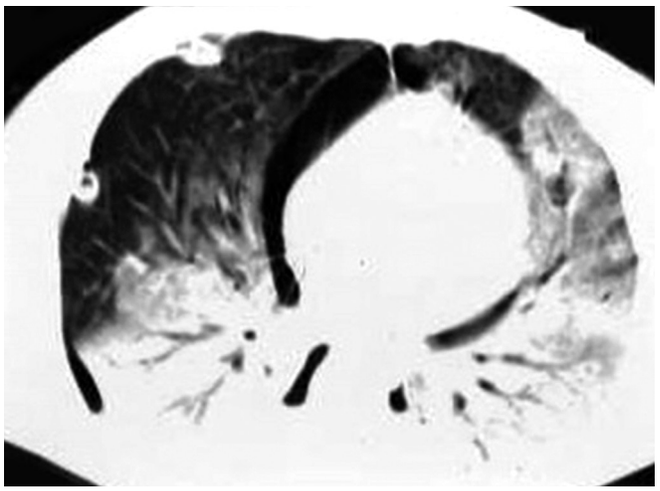

Fig. 9: High-resolution computed tomography (HRCT) of the chest in ARDS. The most dependent part of the lung is dense and consolidated; above this is a collapsed zone, the collapse being due to the weight of inflammatory edema; right on top is normally aerated lung

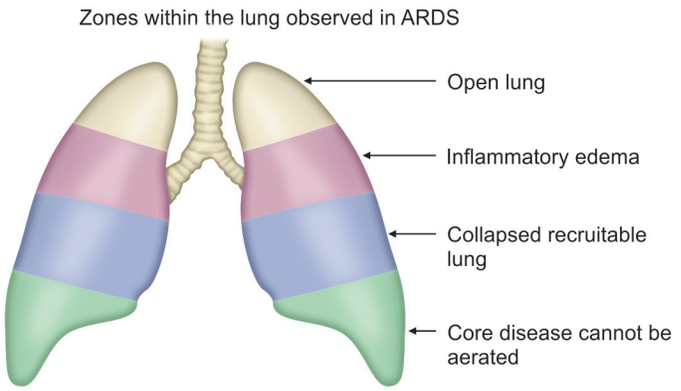

Fig. 10: A schematic representation of 'zones' within the lungs in ARDS. The most dependent zone is consolidated lung which cannot be aerated; above this is collapsed but recruitable lung; still above is the zone of inflammatory edema, the weight of which is responsible for the zone of collapsed recruitable lung; right at the top is normally ventilated or even hyperventilated lung

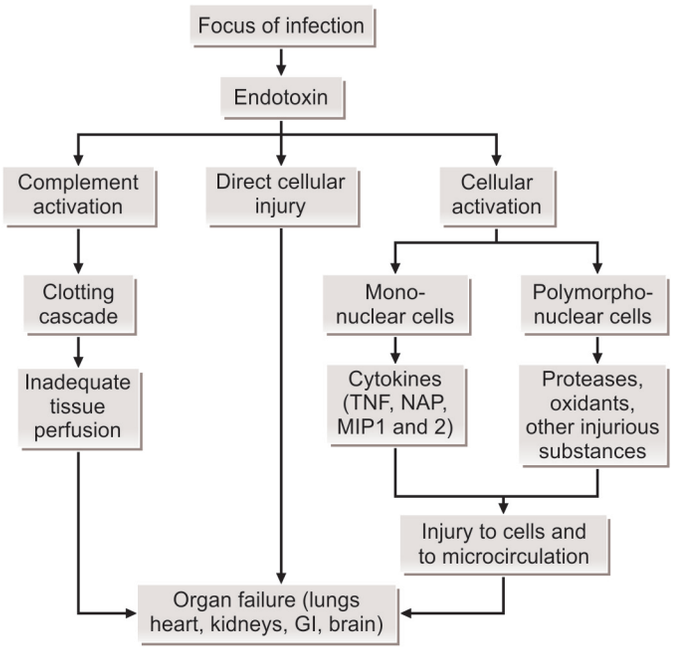
chief mediator that promotes adherence of the neutrophils to the vascular endothelium and together with IL-8 causes and enhances neutrophil activation. The primed neutrophils degranulate, releasing proteases, reactive oxygen species, leukotrienes, all harmful to lung structure and function. The lipid mediators and platelet-activating factor also enhance inflammation.

The activation of the coagulation and complement systems promotes coagulation and decreases fibrinolysis. Endothelial damage results in pulmonary edema with a disturbance in pulmonary microcirculation. The end result is increasing respiratory failure with an increasing poverty of gas exchange, often leading to death. As mentioned earlier, changes in the lung often form just one facet of similar changes in other organs of the body.

Flowchart 1: Pathogenesis of acute lung injury and organ failure in sepsis



Abbreviations: TNF, tumor necrosis factor; NAP, neutrophil-activating peptide; MIP, macrophage inflammatory protein; GI, gastrointestinal.

There is a complex, poorly understood interaction at the molecular and cellular level as the syndrome continues to evolve. This interaction and inter-relation will continue to be the subject of future research.

Unfortunately there is no definite biomarker which can reliably identify patients at risk, or assess the prognosis in ARDS. IL-6 and IL-8 can be found in alveolar fluid and in plasma but these are nonspecific markers of lung inflammation. The ARDS network trial[15] showed that high levels of IL-6 and IL-8 were associated with increased morbidity and mortality and that the strategy of using low tidal volumes attenuated the inflammatory response of the disease, suggesting that alveolar stretch is linked to and perhaps worsens the inflammatory response.

Alterations in Cardiopulmonary Physiology

The pulmonary edema, atelectasis, proliferation of inflammatory cells and increasing fibrosis occurring as a result of injury, produce a fall in the total lung capacity and FRC by 50%. The low lung recoil pressure at FRC leads to early closure of the small airways, with further alveolar collapse, necessitating high inflation pressures to expand or reinflate the lungs. The physiological consequences are an increase in the right to left shunt within the lungs due to perfusion of atelectatic alveoli, increased ventilation-perfusion inequalities, increase in dead space and increasingly noncompliant or stiff lungs. Injury as stressed earlier may be mild, moderate or severe. Of equal importance is the fact that even in severe injury, the lungs are not evenly or homogeneously affected. Computerized tomography (CT) as mentioned earlier has demonstrated a

three-zone model of the lung. This three-zone model of the lung in ARDS has already been discussed under Pathology.

Severe lung injury is sooner or later associated with increasing pulmonary hypertension. The latter is due to hypoxia and to an obstructed, distorted pulmonary circulation. The resultant increase in right ventricular afterload can not only lead to right heart failure, but also cause a shift of the septum to the left. The septal shift can significantly reduce left ventricular filling and stroke volume.

Myocardial dysfunction is an important feature of ALI. It is contributed to by a circulating myocardial depressant factor (probably the same as TNF) in patients with sepsis. A significant fall in cardiac output is frequently observed in these patients, particularly when the mean pulmonary artery pressure exceeds 35 mm Hg. A fall in cardiac output, particularly when combined with a low oxygen tension in arterial blood, can cause a significant reduction in oxygen transport or delivery (DO_2) to the tissues. A decreased DO_2 in association with a possible abnormality of oxygen uptake by the tissues, so frequently observed in ARDS, invariably spells disaster.

CLINICAL FEATURES

Against a background of one of the etiologies mentioned earlier, the patient with ARDS presents with rapidly worsening dyspnea and restlessness. On examination, such a patient has tachycardia, tachypnea and increasing hypoxemia despite supplemental oxygen. Auscultation reveals scattered crackles and occasionally a wheeze. The condition may evolve rapidly over a few hours, or may take a few days to reach its maximum intensity. Respiratory distress is obvious, and the accessory muscles of respiration are active. Cyanosis may occur, but is not always clinically evident in spite of severe hypoxemia.

In the early stages, a slight but disproportionate tachypnea may be the only warning sign of early ALI, and in an appropriate setting this must never be ignored, even in the absence of auscultatory crackles, and with a normal chest X-ray. An important warning diagnostic feature in the early phase is a slight fall in the PaO_2 and an increased alveolar-arterial oxygen gradient.

As the respiratory failure worsens, one or more other organ systems may show signs of dysfunction and failure. This is in keeping with the current concept that ALI is a multisystem disease, with the changes in the pulmonary endothelium mirroring widespread endothelial damage in other organs.

DIFFERENTIAL DIAGNOSIS

The lack of specificity in the radiological picture and in the diagnostic features proposed by the American-European Congress Conference have already been commented upon. The differential diagnosis includes—

- Other causes of air space consolidation—multiple pulmonary infarcts, multiple areas of atelectasis (as after major upper abdominal or cardiothoracic surgery), pneumonia, atypical pneumonia, Legionnaire's disease, alveolar hemorrhage, alveolar proteinosis, eosinophilic pneumonia and bronchiolitis obliterans with organizing pneumonia (BOOP).
- Acute exacerbation of previously unrecognized low-grade interstitial lung disease or acute interstitial pneumonia. The latter may be impossibly difficult to differentiate from ARDS without a lung biopsy.
- Cardiogenic pulmonary edema. Cardiac enlargement, the presence of more centralized edema, Kerley's lines, help in radiological differentiation. Clinical history and examination of the cardiovascular system are of critical importance. In difficult problems, a Swan-Ganz catheter may be used to determine PAOP. It is to be noted that in intra-abdominal pathologies, the rise in intra-abdominal pressure may cause a rise in the PAOP and mislead the clinician.

COMPLICATIONS

Death is uncommon from severe refractory hypoxia, provided the patient receives good ventilator support. In our unit, it occurs in not more than 10% of patients.

Nosocomial Pneumonia[16]

This is an extremely important complication. The incidence of this complication in severe ALI (ARDS) varies in different units, and in our ICU is about 15%. The incidence increases with the length of time on ventilator support, and is most marked when ALI is due to severe abdominal sepsis. It is less than 5% when ALI is caused by a direct insult, e.g. inhalation of noxious fumes, near-drowning, chest trauma, even when ventilator support is prolonged for weeks.

The lung injury per se, together with improper ventilatory management (such as use of high inflation pressures, high V_{Ts}, high FiO_2), and the prolonged use of PEEP, also probably impair local immune and other defense mechanisms within the lung, and predispose to iatrogenic infection and sepsis. Background illnesses which impair immune function and malnutrition either present before the ALI or occurring during the evolution of the syndrome are other important predisposing factors. Colonization of the upper respiratory tract and of the GI tract by Gram-negative organisms remains an important source of infection.

The diagnosis of nosocomial pneumonia is difficult in the presence of shadows caused by atelectasis and edema. We have missed a good-sized lung abscess causing an empyema in a patient with ARDS due to severe tetanus, the diagnosis being apparent only at autopsy. Suspicion of a nosocomial infection should prompt a CT of the chest which may reveal an abscess or an empyema undetected on an X-ray. The choice of antibiotics in the management of nosocomial pneumonia is empiric, and will depend on the nature of bacteria causing nosocomial pneumonia and their sensitivity to antibiotics in a critical care unit.

Multiple Organ Dysfunction[17]

The better and more intensive the care offered to the patient, and hence the longer he is kept alive, the more often is the complication of multiple organ dysfunction observed. It occurs early and most frequently when sepsis is the cause of ALI. It can however complicate the course of ALI from any cause.

In our experience, renal dysfunction occurs in 30–40% of patients, cardiovascular dysfunction necessitating inotropic support in 50–70% of patients, and liver cell dysfunction occurs in about 50% of patients. Complications and dysfunction involving the GI tract are observed in 20–30% of patients. There is an obvious inter-relation between various organ systems, so that impairment of one organ system induces, amplifies and modulates impairment in other organ systems.

Translocation of bacteria from the lumen of the gut to the lymphatics, peritoneal cavity and even the bloodstream, plays an important role in perpetuating the inflammatory cascade that underlies multiple organ dysfunction. This is observed when the protective barrier normally provided by the wall of the gut is breached. The problem is markedly worsened in the presence of associated liver cell dysfunction. In fact when ARDS occurs against the background of liver cell failure, death invariably results.

INVESTIGATIONS (BOX 1)

Chest X-Ray

The chest radiograph shows interstitial edema in the early stages and full-blown pulmonary edema in established cases. The pulmonary edema causes bilaterally symmetrical shadowing, but the shadowing may initially be predominantly unilateral, depending on the position of the patient. The absence of cardiomegaly, of Kerley's lines and of vascular redistribution towards the upper lobes, help distinguish the pattern from cardiogenic pulmonary edema. The absence of lobar consolidation helps differentiate it from infection. Having said this, cardiac failure, pneumonia and pulmonary emboli may all cause diagnostic confusion. ARDS does not necessarily involve both lungs symmetrically; one lung may be considerably more involved than the other. This adds to the problem of effective ventilation.

Arterial Blood Gases

Blood gas estimation is essential in the initial diagnosis and subsequent monitoring of ALI. In the initial stages, varying degrees of hypoxia are seen with hypocapnia. In late stages, hypercapnia may be seen. The pH disturbances range from respiratory alkalosis in the initial stages, to respiratory acidosis and metabolic acidosis in the later stages. The hypoxia is refractory to supplemental oxygen, indicating that in addition to ventilation-perfusion mismatch, increased right to left shunt and dead space ventilation also play major roles.

Box 1: Investigations in acute lung injury/acute respiratory distress syndrome (ALI/ARDS)

- Chest X-ray
- Arterial pH and blood gases
- Hemodynamic measurements using a Swan-Ganz catheter in selected cases
- Pulmonary compliance
- Routine biochemistry to evaluate other organ dysfunction
- Full bacteriological screen—
  - Blood culture
  - Urine culture
  - Culture of tracheal aspirates
  - Culture of bronchoalveolar lavage (BAL)
  - Culture of any other secretions/discharges

Hemodynamic Measurements

The insertion of a Swan-Ganz catheter is not essential for the diagnosis of ALI; however, it may on occasion be the only way to conclusively distinguish ALI from cardiogenic pulmonary edema. Insertion of a Swan-Ganz catheter may also prove invaluable in the management of an individual patient. Much has been written concerning the wisdom of invasive monitoring in such patients, and there are some who feel that this technology may itself contribute to poor patient outcome. We now use the Swan-Ganz catheter infrequently. A Swan-Ganz catheter should only be inserted by doctors familiar with its use to obtain specific answers to specific diagnostic or therapeutic dilemmas—for example, assessing the adequacy of volume resuscitation, for titrating inotropic support, for assessing left ventricular dysfunction, degree of intrapulmonary shunting or assessing adequacy of DO_2 in problem patients.

Pulmonary edema with pulmonary wedge pressure less than 18 mm Hg in the presence of a normal colloid oncotic pressure is diagnostic of ALI (ARDS).[18] It should be noted that estimations of wedge pressure may be affected by the position of the catheter tip (which should be below the left atrium in zone 3 lung), and the presence or absence of PEEP. All patients, ill enough to require a Swan-Ganz catheter, are ill enough to require at least 10 cm H_2O of PEEP. In critically ill hypoxemic patients, it may not be wise to switch off PEEP even while the necessary hemodynamic measurements are being made. Some authors have advocated subtracting 50% of the PEEP value from the measured wedge pressure, but a study by Teboul and associates[19] suggested that PEEP did not affect the correlation between wedge pressure and left ventricular end-diastolic measurements, even in patients with severe ALI. To avoid iatrogenic complications, we prefer to remove a Swan-Ganz catheter within 3 days.

Pulmonary Compliance

Lung compliance is usually decreased to less than 30 mL/cm H_2O. Compliance can easily be measured in patients on mechanical ventilator support.

Routine Tests

Tests for evidence of other organ dysfunction, e.g. renal, hepatic, hematological parameters, should be done.

Full Bacteriological Screen

This should include blood culture, cultures of tracheal aspirates and in some patients with nosocomial pneumonia, culture of bronchoalveolar lavage fluid or culture of protected brush samples obtained bronchoscopically to determine the nature of the infecting organism. Cultures of urine and other body secretions and discharges are also necessary.

MORTALITY AND PROGNOSIS

Some studies suggest a fall in mortality figures in ARDS compared to earlier years. But mortality depends on the population under study. Even in the ARDS network study[20] of 861 patients, the mortality of 31% in the group using lung protection measures (6 mL/kg V_T) is significantly underestimated because many severely ill patients were excluded—those with advanced liver disease, bone marrow transplant, severe chronic respiratory disease, burns greater than 30% body surface area (BSA) and those not expected to live more than 6 months.

Mortality remains quite high on population based studies. Several multicenter studies in France,[21] Sweden,[22] Australia,[23] and Argentina[24] defined mortality and prognostic variables in observational population based studies rather than clinical trial participants. Mortality varied—32% in ALI to 58–60% in ARDS. The highest mortality, close to 60%, was from the French study.

In other studies, mortality was highest in sepsis (43%), intermediate in pneumonia (36%) or aspiration (37%), lowest in multiple trauma (11%). Low tidal volumes were effective in reducing mortality across all cases of ALI/ARDS.[25]

Four factors determine prognosis in ALI/ARDS—

1. Severity of the lung injury (judged by PaO_2/FiO_2 ratio).
2. Nature and severity of the precipitating factor.
3. Presence and degree of dysfunction of other organ systems.
4. Background or associated disease.

In our experience, prognosis depends less on the severity of ALI and more on the other three factors listed above. Uncontrollable sepsis, particularly uncontrollable intra-abdominal sepsis, has a hopeless prognosis with a 100% mortality. Severe sepsis even when controlled can set into motion a chain of events that may carry a mortality of greater than 60%. Prognosis is worse in the presence of septic shock. On the other hand, direct injury to the lungs as in drowning, inhalation of noxious fumes, mild to moderate aspiration of gastric contents, in our experience, has a mortality of less than 20%, provided there is no nosocomial infection and no other major complication. Severe nosocomial pneumonia occurring in ARDS has a mortality of about 30%.

In the West,[26] the reported mortality for single organ failure is 15–30%, for two organ failure it is 45–55%, and for three or more organ failures lasting for more than 4 days, greater than 85%. In our experience, we have found this true only for Gram-negative sepsis. These figures are unnecessarily pessimistic and are not true when multiple organ failure complicates fulminant *P. falciparum* infection, fulminant tetanus and other severe tropical infections. Fulminant tetanus with excellent intensive care has a mortality of less than 10%, and in fulminant *P. falciparum* infection the mortality even with severe prolonged multiple organ dysfunction is below 30%.

MANAGEMENT

Despite the many recent advances in intensive care, severe ARDS continues to carry an overall mortality of 30–60%. As mentioned earlier, patients with ALI and ARDS do not usually die of respiratory failure (only 16% of all deaths in one large series were due to refractory hypoxemia and hypercapnia).[27] The majority of patients die of sepsis and multiple organ failure. Intensive care is mandatory for efficient management. The following management principles apply—

Treatment of the Underlying Condition

This should be identified promptly and treated aggressively. Unfortunately the treatment of many diseases causing ARDS is largely supportive. Sepsis is an important exception and should be promptly recognized and treated. Studies have shown that the prompt use of an appropriate antibiotic or antibiotics significantly improves morbidity and mortality. Surgical drainage of an abscess and prompt surgery for abdominal sepsis are mandatory. Specific therapy for fulminant tropical problems causing ARDS should be immediate—in particular the use of artemisinin and/or quinine for severe *P. falciparum* infections.

Respiratory Support

This forms the cornerstone in the management of ALI and ARDS. Yet it needs to be stressed that mechanical ventilation is purely supportive, allowing the lungs time to recover from the acute insult. Mechanical ventilation in patients with severe ALI (ARDS) presents complex problems and difficulties. To be effective, the intensivist must be aware of the changes in cardiorespiratory physiopathology, the interaction between the heart and the lungs, the importance not only of effective gas exchange but also of efficient DO_2 and the dangers and complications of ventilator support.

Initiating Ventilator Support

There are two important indications for initiating ventilator support in an evolving ARDS. The first is progressive hypoxemia not responding to oxygen inhalation; the second is a marked, unsustainable increase in the work of breathing, as when the respiratory rate is greater than 35–40/minute and

the minute-volume exceeds 12 L/minute. A lowered lung compliance adds even more to the work of breathing. Under the above circumstances, it is best to electively intubate and initiate ventilatory support even if the PaO_2 is greater than 60 mm Hg on supplemental oxygen. Elective intubation and ventilatory support are also preferred in the presence of hemodynamic instability, and if for any reason the patient is unable to maintain and protect the airway.

Noninvasive Ventilator Support

Severe ALI (ARDS) always needs intubation and mechanical ventilation. A very small subset of patients with mild ALI may however be adequately oxygenated with the help of continuous positive airway pressure (CPAP) or by the use of a bilevel positive airway pressure (BiPAP) ventilator, using a tight fitting face mask. A recent multicenter observational study[28] has reported the merits of noninvasive ventilation (NIV) in early ARDS from three ICUs in Italy and Spain. One-third of the patients were given NIV (the remaining two-thirds were already intubated and ventilated). The NIV patients had less ventilator-associated pneumonias and a lower mortality. This was not a randomized controlled trial, and though the study showed that NIV was effective in early cases, no definite conclusions are possible.

If NIV is decided upon, CPAP levels are kept between 10 cm and 12 cm of H_2O. In order to maintain intrathoracic pressure at the required level of CPAP throughout the respiratory cycle, high gas flows in excess of 70 L/minute are required. With a BiPAP machine, reasonable initial ventilator settings are expiratory positive airway pressure (EPAP) of 7–10 cm H_2O and inspiratory positive airway pressure (IPAP) of around 15–18 cm, the settings being adjusted both for patient comfort and for providing and maintaining an arterial oxygen saturation of greater than 90%. Noninvasive mechanical ventilation in patients with mild ALI recruits collapsed alveoli, increases the FRC and lung compliance, thereby unloading the respiratory muscles and reducing the work of breathing. A good response to noninvasive positive pressure ventilation is generally observed within 30 minutes of its initiation and is characterized by improved oxygen saturation, a fall in respiratory rate and less patient distress. An inability to maintain SaO_2 to greater than or equal to 90% or the presence of hemodynamic instability or a worsening clinical state are indications for intubation and mechanical ventilation.

Dangers of Endotracheal Intubation in ALI and ARDS

The major danger during intubation is a severe increase in hypoxia, in an individual who is already hypoxic to start with. Hemodynamic instability and the danger of gastric aspiration form additional risks during intubation.

Endotracheal intubation should therefore be performed by an expert, preferably with the patient awake, using mild sedation with a benzodiazepine or a narcotic. In an acute crisis, succinylcholine along with intravenous propofol may be used.

Changing of the endotracheal tube in a patient with ARDS following rupture of the cuff or due to obstruction of the tube is also risky. A sudden loss of PEEP during this procedure may cause rapid desaturation with dangerous sequelae.

Principles of Mechanical Ventilation[29]

The last several years have seen the evolution of two fundamental concepts in the ventilatory support of patients with ARDS. First is the prevention of overdistension of the alveoli by limiting V_T and the pause pressure. Second is to choose a level of PEEP which is sufficiently high to prevent derecruitment of the alveoli at end expiration. *The fundamental concepts that guide ventilator support in ARDS are these two lung protection goals.* Avoidance of oxygen toxicity to the lungs and prevention of hemodynamic instability of the cardiovascular system are two other important conditions guiding ventilator support in these patients.

Limiting tidal volume The lung protection strategies have been firmly established following the result of the landmark ARDS Clinical Trials Network.[20] In this large prospective RCT, patients were randomly assigned to receive a V_T of 6 mL/kg of predicted body weight or 12 mL/kg of predicted body weight. The plateau pressure (the airway pressure under no flow conditions maintaining the V_T) in those receiving V_T of 6 mL/kg was not to exceed 30 cm H_2O. If it did so, the V_T was further reduced to 5 mL/kg of predicted body weight or even to a minimum of 4 mL/kg of predicted body weight. Patients receiving the lower V_T had a lower mortality (31%) compared to those receiving higher V_T (mortality 40%). There was relative reduction in mortality of 22%.

The established principle is therefore to use low tidal volumes (6 mL/kg) and ensure that the pause pressure does not exceed 30 cm of H_2O when using a volume regulated mode of ventilatory support. This strategy prevents overdistension of alveoli and undue increase in intra-alveolar pressure. In fact, large tidal volumes (10–15 mL/kg) in patients with ARDS are dangerous. It is accepted that overdistension of alveoli in these patients can cause an amplification of the already existing lung injury (volutrauma), presumably by increasing edema and pulmonary cytokine production. In addition to volutrauma, high intra-alveolar end-inspiratory pressures can lead to an increased incidence of barotraumas. The concept of barotrauma is not new, but its spectrum includes not just pneumothorax, but also pneumomediastinum, interstitial emphysema, subcutaneous emphysema and pulmonary hemorrhage. A frequent consequence of a limitation of the V_T in the above manner is a rise in the $PaCO_2$ to above 40 mm Hg. The $PaCO_2$ is allowed to rise—a condition called permissive hypercapnia.

The difference in mortality between the low V_T group and the high V_T group in the ARDS network trial was related to a greater reduction in IL-6 levels in patients with low V_T. Ranieri and coworkers[30] have also shown lower levels of TNF, IL-1, IL-6 and IL-8 in the bronchoalveolar lavage fluid of patients treated with the lung-protective ventilatory strategies, when

compared to patients treated with the more conventional ventilatory techniques. These cytokines can produce further lung injury; they also gain entry into the bloodstream and produce injury at distant sites, perhaps contributing to multiple organ dysfunction and multiple organ failure.

Use of PEEP

Positive end-expiratory pressure is not a new ventilatory strategy but a mainstay of oxygenation in ALI and ARDS ever since the original description of the syndrome. It acts by recruiting collapsed alveoli, restoring FRC to normal and thus increasing compliance. It also causes redistribution of lung water within the alveolar space, improving ventilation/perfusion (V/Q) mismatch and decreasing the shunt and venous admixture. By improving oxygenation, PEEP allows the oxygen concentration delivered to the patient to be reduced, thus decreasing the chances of oxygen toxicity, which in itself can worsen lung injury.

Of recent interest, is the likelihood that PEEP, if properly adjusted, also prevents further lung injury during mechanical ventilation of patients with ARDS. How does it do so? The concertina effect of opening of the alveoli during the inspiratory phase of mechanical ventilation, followed by well-nigh total closure of alveoli during the expiratory derecruitment, generates strong shear forces that worsen and perpetuate lung injury. Choosing the exact level of PEEP that can prevent the derecruitment of alveoli during mechanical ventilation is a difficult but an important lung protection goal in patients with ALI and ARDS. In the ARDS network trial, the level of PEEP and FiO_2 was adjusted with a predetermined PaO_2/FiO_2 ratio in a stepwise fashion, so as to keep the PaO_2 and SaO_2 at a satisfactory desired range. Ideally PEEP should be individualized for each patient. One can attempt to do so by plotting the pressure volume curve in a given patient, noting the upper and lower inflection points and adjusting the PEEP level at 1–2 cm above the lower inflection point. There is however often an observer difference in determining the exact lower inflection point (which is a slope rather than a point). Again the pressure-volume curve relates to the whole of the lung but does not reflect regional differences (some alveoli are overdistend, others collapsed or consolidated). It is obvious that PEEP is more likely to be useful in patients with ARDS where a good proportion of the affected lungs are recruitable. On the other hand, if in a patient the recruitable lung is very small, PEEP will be of little use. In fact, it may be harmful as it may only serve to overdistend alveoli and thus contribute to lung injury. Gattinoni determined the degree of recruitability of lungs through CT studies, a luxury denied to most ICUs in the developing world. Perhaps the simplest approach is to use the least PEEP that provides adequate oxygenation at an FiO_2 of less than 0.6, starting with a PEEP of 10 cm and as far as possible not exceeding 15 cm, as the risk of barotrauma particularly in Indian patients is then significant. If oxygenation does not improve as judged by the PaO_2/FiO_2 ratio, and if there is no increase in compliance, PEEP should be reduced and not allowed to exceed 5 cm H_2O.[31]

Three large randomized control trials (ARDS network trial, LOV study, ExPress study)[32,33] have compared the effects of higher PEEP to lower PEEP levels. All demonstrated increased oxygenation in the higher PEEP group, but there was neither a decrease in mortality nor in ventilator free days. This suggests that the use of modest PEEP levels is to be generally preferred and is adequate to prevent ventilator-induced lung injury. High PEEP may perhaps open more atelectatic alveoli but overdistended normal alveoli, contributing further to lung injury.

Ventilator Modes

There are a large number of modes offered by currently available ventilators. These include volume control ventilation, pressure control ventilation, airway pressure release ventilation, high-frequency oscillatory ventilation (HFOV) and open lung ventilation. Whichever mode one uses, the focus should be on preventing alveolar overdistension, countering alveolar derecruitment, minimizing cardiovascular instability and avoiding oxygen toxicity. The volume controlled mode (with lung protection strategies) was used in the ARDS network trial and remains the one most commonly adopted. There is no evidence to suggest that any of the other ventilatory modes are superior to the volume controlled mode in the management of ARDS. Many units use the pressure controlled mode; it is important when using this mode to ensure low V_T (6 mL/kg body weight) and not to exceed a peak pressures of 30 cm H_2O. Inverse ratio respiration has been used generally with pressure controlled ventilatory support. The inspiration expiration ratio should be preferably 1:2 or 1:1 and not lower. The increased inspiratory time may allow better oxygenation in these patients.

High-frequency oscillatory ventilation theoretically should offer lung protection as the tidal volumes delivered are very small (less than the dead space) and at a high frequency, gas exchange being promoted by diffusion. Its efficacy as a ventilatory mode in children is generally accepted. It remains to be established whether it reduces morbidity and mortality in ARDS when compared to the lung protection strategies adopted with the volume controlled mode. A multicenter RCT studying HFOV called the Oscillation for ARDS Treated Early (OSCILLATE) Trial Pilot Study organized by Canadian Critical Care Trials Group (CCCTG) has been completed.[34] It concludes that in adults with moderate to severe ARDS, early application of HFOV, as compared to low tidal volume ventilation with a high PEEP, does not reduce, and may increase the in-hospital mortality.

Use of Prone Position

The prone position was used to improve oxygenation in ARDS within a decade of the first clinical description of this syndrome. When patients are in the prone position as compared to the supine position, oxygenation improves in over 60% of patients with oxygen ratios (PaO_2/FiO_2) being significantly higher. This improvement in oxygenation is due

to an increase in the functional residual capacity, decreased atelectasis and improved ventilation perfusion ratios. Briefly, the prone position results in improved oxygenation by increasing functional lung. However, despite improved oxygenation, several randomized trials in the past have shown that the prone positioning did not reduce overall mortality.

In contrast to the previous studies, Guerin and colleagues[35] have recently reported excellent results in the Proning Severe ARDS Patients (PROSEVA) randomized trial. This was a multicenter trial of prone ventilation in patients with severe ARDS. The 28-day mortality with prone positioning had halved (16% vs 32.8% with supine ventilation), an excellent treatment effect. Prone position was applied for 73% of the available time, patients being returned to the supine position once a day, whereas in the previous trials prone position was applied merely 30% of the day. In the PROSEVA trial prone position resulted in better oxygenation, lower oxygen requirements and more ventilation-free days. The mortality among controls (32.8%) was similar to the mortality of 25–40% observed in various previous trials.[36]

These results cannot be ignored. There are however two caveats: (1) the study group in the PROSEVA trial was a highly selective group of severe ARDS patients and (2) the prone position, though conceptually simple, poses many challenges in nursing and patient management. It can lead to various problems—kinking, dislodgement of the airway, intravascular lines, drainage tubes, as also serious pressure sores on the face. It should therefore be attempted only in units trained to manage prone-positioned patients.

It appears from the work of Guerin and colleagues[35] that the prone position used early in the natural history of severe ARDS, for the greater part of the day, significantly reduces mortality. These results however need to be confirmed by other centers.

Permissive Hypercapnia

When patients with ARDS are ventilated with the lung protection goal of low V_T and pressure limited ventilation, alveolar hypoventilation frequently occurs, causing a rise in $PaCO_2$ to 60–70 mm Hg or even more. Increasing $PaCO_2$ with respiratory acidosis can have potential adverse physiological effects such as arrhythmias, cardiovascular and central nervous system depression. However, these effects are not generally encountered in clinical practice. In fact, high $PaCO_2$ levels seem to be very well-tolerated in adequately sedated patients. Most clinicians and intensivists favor permissive hypercapnia to the injurious effects of overdistended alveoli and high inspiratory inflation pressures. The $PaCO_2$ in permissive hypercapnia should preferably be allowed to rise slowly at the rate of 10 mm Hg/hour. Hypercapnia needs correction only if there is a significant fall in the pH. In the ARDS network trial, if the pH fell to less than 7.30, the respiratory was rate was increased till the pH was greater than 7.30 or the respiratory rate equaled 35/minute. If the pH was less than 7.3 in spite of the respiratory rate being increased to 35/minute, an IV bicarbonate infusion was administered. IV bicarbonate may temporarily correct the pH but could add substantially to the CO_2 that needs to be excreted by the patient via the lungs. IV sodium bicarbonate could also lead to volume overload and potassium depletion in critically ill patients who already have an increase in intrapulmonary extravascular water content.

Open Lung Concept

The open lung concept though described first by Lachmann in 1977 has been adopted as a ventilatory strategy for ARDS over a little more than two decades. Gattinoni and coworkers[37] showed that patients with ARDS had multiple areas of atelectasis chiefly in the dependent lung regions, due to reduced volume of the aerated lung. The ventilatory strategy of an open lung opens up the atelectatic areas and keeps them open. Thereby the cyclic shear forces of alveolar opening and closing are minimized and optimal gas exchange is achieved (PaO_2 >450 mm Hg on an FiO_2 of 1). The open lung procedure is always attempted using pressure controlled ventilation with an inspiratory to expiratory (I:E) ratio of 1:1 and with an FiO_2 of 1. To start with PEEP is applied at 15–20 cm H_2O in patients with ARDS, and the lung is opened with slow progressive increase (by 2 cm at a time) in the peak inspiratory pressure up to 40–60 cm H_2O. The opening pressure is the peak inspiratory pressure at which the lung is "opened". The success of recruitment of closed alveoli is gauged either by noting the sudden sharp increase in PaO_2 greater than 450 mm Hg when the lung fully opens up or by the proportional increase in V_T following increase in the peak inspiratory pressure. The peak inspiratory pressure and PEEP are now adjusted to the lowest pressure which keeps the lung open. This lowest pressure is realized when the V_T is stable and the arterial blood gases continue to show a high constant PaO_2. The ideal pressure is generally 15–30 cm H_2O less than the required recruitment opening peak pressure. After opening the lung and finding the lowest pressure to keep it open, the resultant pressure amplitude is minimized and gas exchange maximized. The ventilatory strategy described above enables a reduction in FiO_2 and protects the lung from further injury. It is possible that an open lung is less likely to produce cytokines injurious to itself as also to other organ systems. Transient hypotension and transient desaturation are the most commonly observed side effects during recruitment maneuvers. Serious adverse effects which include barotraumas (1%) and arrhythmias are infrequent.

The open lung strategy, if adopted, should preferably be put to use in the first 24–48 hours of mechanical ventilation in ARDS. Amato and coworkers[38] showed a reduced mortality in ARDS patients using the open lung ventilatory strategy as compared to ARDS patients on conventional modes. The Lung Open Ventilation Study (LOVS)[32] compared the ARDS network protocol to a regimen using pressure controlled ventilation, recruitment maneuvers combined with levels of PEEP of 5–7 cm higher for a given PaO_2 than that used in the ARDS network trial. There was no statistically significant increase in survival in the interventional arm, though no adverse effects were observed.

On current evidence,[39] the routine use of recruitment maneuvers cannot be either recommended or discouraged. Recruitment maneuvers should be considered on an individualized basis in patients with ARDS who have severe life-threatening hypoxia. It is possible that the chief benefit of open lung ventilation may be related more to the low V_T and low peak pressure during ventilation rather than in opening the lung.

Use of Extracorporeal Membrane Oxygenation for ARDS in Adults

Recent advances with extracorporeal membrane oxygenation (ECMO) in the successful management of severe ARDS during the 2009 H1N1 influenza A epidemic has resulted in a renewed interest in this technique.

The only controlled clinical trial comparing ECMO technology versus conventional mechanical ventilation in the management of ARDS is the CESAR trial[40] to which the reader is referred for further details. In this trial, death or severe disability at 6 months occurred in 37% of patients referred for consideration for ECMO, versus 53% for the assigned to management by conventional ventilation. This study was however not a randomized study and the results must be interpreted with caution.

The indications and contraindications for ECMO in severe ARDS are tabulated in Box 2.

It is important that ECMO is undertaken in specialized centers that have experience with this technique. Details of this technique are outside the scope of this book. The reader is referred to the CESAR trial.

Box 2: Indications and contraindications for ECMO in severe ARDS

Indications—
- Severe hypoxemia (PaO_2/FiO_2 <80 despite 15–20 cm PEEP for at least 6 hours in potentially reversible respiratory failure)
- Uncompensated hypercapnia (pH <7.1) in spite of optimal management
- Very high end-inspiratory plateau pressure (>35–45 cm H_2O) despite optimal ventilator management

Contraindications—
- A very high end-inspiratory plateau pressure (>35–40 cm H_2O) or an FiO_2 (>80%) for >7 days
- Unavailable or limited access
- Irreversible organ dysfunction (e.g. brain injury)
- Any condition that contraindicates use of anticoagulant therapy

Other Measures

Fluid balance It is important not to overhydrate the patient as this worsens pulmonary edema. In established ALI/ARDS, we have always preferred to keep filling pressures of the left ventricle on the lesser side of normal (PAOP <12 mm Hg), central venous pressure (CVP) not more than 6 mm Hg provided perfusion of vital organs is satisfactory. The ARDS Network Fluid and Catheter Treatment trial[41] has recently shown that a conservative fluid management strategy increased the mean number of ventilator free days (14.8 vs 12.1). There was a 2.9% reduction in mortality rate in the conservative arm but this was not statistically significant. This study showed that the conservative fluid strategy did not increase the incidence of renal failure or shock. Also, the use of a pulmonary artery catheter or a central venous catheter in monitoring management was associated with the same mortality.

The above strategy applies to patients who are not in shock or whose shock has been effectively countered with appropriate fluid management. Unquestionably a patient in shock will require the initial fluid resuscitation emergency measures outlined in the Chapter Sepsis and Septic Shock.

Other fluid management strategies In the particular setting of hypoproteinemia and ALI/ARDS, the combination therapy of albumin and furosemide may be useful in improving pulmonary physiology.[42] There is however no evidence that outcome is favorably influenced. Hypoproteinemia is a documented risk factor in the development of ALI/ARDS as also for poor outcome in critical illness in general. This in our opinion is reason enough to counter hypoalbuminemia with infusions of albumin in patients with ARDS.

Circulatory support It is important to ensure adequate DO_2 or delivery to the tissues. DO_2 is not only dependent on an adequate PaO_2, but is also dependent on cardiac output and the hemoglobin (Hb) concentration. The Hb concentration should be kept around 10 g/dL with a hematocrit of 35%. Inotropic support should be given even in patients with moderate lung injury. Dobutamine is preferred if the cardiac output is low as it generally does not induce tachycardia. If the systolic blood pressure is less than 90 mm Hg, or if the systemic vascular resistance is low, dopamine is to be preferred. Norepinephrine is often necessary in hypotensive patients.

Supramaximal DO_2 (cardiac index >4.5 L/min/m^2 and DO_2 above 600 mL/min/m^2) was earlier thought to reduce oxygen debt in the tissues, prevent hypoxic injury and organ system failure. This is however by no means certain. It is possible that increasing DO_2 to supramaximal levels reduces mortality in just a subgroup of patients, such as high-risk surgical patients. In our experience and in the experience of most critical care units, supramaximal DO_2 does not reduce mortality in ALI. Volume loading patients with ARDS to maintain PAOP at upper normal limits (15–18 mm Hg) in an attempt to raise the cardiac output, invariably does harm by potentiating the lung injury.

Support to Other Organ Systems

All organ systems often need support, in particular the kidney. Ultrafiltration or dialysis may be necessary to treat volume overload or renal failure.

Nutritional Support

Good nutrition is vital, particularly when ARDS is due to excessively catabolic states as in fulminant tetanus, burns or severe sepsis. Severely catabolic states require a caloric intake of 2,500 or more calories/day, and this could lead to excessive fluid intake in a clinical situation which often necessitates fluid restriction. Under these circumstances, nutritional requirements are sacrificed on a short-term basis to allow fluid restriction. The alternative is to remove additional water by the use of loop diuretics if renal function is good, or by the use of ultrafiltration if renal function is impaired. Enteral feeding is always to be preferred. In the presence of ileus, abdominal sepsis, parenteral feeding becomes necessary.

Prophylaxis for stress ulcers and for venous thromboembolism is important.

Treatment of Complications

These can involve any organ system; they should be promptly diagnosed and treated. Iatrogenic sepsis and nosocomial pneumonias are of ominous significance.

Role of Corticosteroids in ARDS

There continues to be a raging controversy whether low-dose corticosteroids can reduce morbidity and mortality of ALI and ARDS, without increasing the risk of adverse reactions. A number of trials have evaluated the role of corticosteroids in the treatment of ARDS at various stages. It appears that in the late stage of ARDS corticosteroids have no benefit and are associated with adverse outcomes. Use of corticosteroids in early ARDS showed a reduction in organ dysfunction score, lung injury score, ventilator requirement and intensive care stay. There was however no definite evidence of significant reduction in mortality. Most of these trials have been small and have marked heterogeneity. We feel that the role of corticosteroids in ARDS is not convincingly proven to be beneficial. If used it should be restricted to the early stage of ARDS and given in a dose of not more than 50–100 mg 8 hourly of hydrocortisone intravenously. The debate on whether to use or not use corticosteroids in ARDS is likely to continue.[43]

New Potential Therapies for ARDS

Granulocyte-macrophage colony-stimulating factor (GM-CSF) This is another therapy being evaluated as possible treatment for ARDS. GM-CSF is believed to encourage homeostasis of alveolar macrophages and to prevent apoptosis of alveolar epithelium. Further studies will decide the value of this therapy.[44]

Use of beta-2 agonists Beta-2 agonists have been reported to accelerate resolution of pulmonary edema in clinical and experimental studies and hence it was hypothetical that aerosolized beta-2 agonists would improve clinical outcomes in acute lung injuries. However, a multicenter randomized placebo-controlled clinical trial in 282 ALI patients receiving mechanical ventilation showed that aerosolized albuterol did not improve clinical outcome. Their use therefore is not recommended.[45]

Other pharmaceutics measures A great deal of research continues on pharmaceutical measures that could reduce or counter the inflammatory cascade that initiates and perpetuates injury to the lung and other organ systems. The use of anticytokines, anti-TNF antibodies, soluble TNF receptors and cyclooxygenase inhibitors is of unproven benefit. Surfactant replacement, nitric oxide inhalation, platelet-activating factor antagonist, pentoxifylline and anti-proteases have all proved of no avail. None of these drugs can be recommended at this stage.

Immunonutrition Immunonutrition has attracted attention in recent years. Addition of linoleic acid to the diet, as also arginine, glutamine, nucleotides and omega fatty acids, is reported to reduce infection rates in critically ill patients treated with enteral immune-enhanced diets. There is no evidence that these diets influence ultimate outcome.

CHAPTER 33

Acute Severe Asthma

Zarir F Udwadia *MD, FRCP (London), MNAMS, FCCP (USA). Consultant Physician, P.D. Hinduja National Hospital, Breach Candy Hospital and Parsee General Hospital, Mumbai, Maharashtra, India*

INTRODUCTION

Acute severe asthma is characterized by a severe asthmatic attack unrelieved by the repeated use of aerosolized bronchodilators. It is a medical emergency that spells danger and should never be underestimated.[1] Considering that asthma is a widely prevalent disease with incidence rates in the West of around 10% in school children, and around 4–5% in adults, deaths from asthma are relatively rare. What is of more significance is that despite asthma being by definition a reversible disease, deaths still occur with predictable frequency. Data from this country is not available, but in the UK, 2,000–4,000 people die of asthma every year. There is no evidence that the death rate is declining, in fact, most recent studies show that it is on the increase. This increase in death rate applies to every age group and is rising by approximately 4.5% per annum in the 5–34 year age group. An asthma death is always a cause for introspection, because it generally affects previously healthy young adults with no background of other illness. It becomes even more poignant when one reviews the asthma death-audits available. Most of these studies clearly show that up to 80% of all asthma deaths are related to lapses on the part of the patient and the doctor, and are thus potentially preventable. Education of the public and the medical profession is essential in preventing many of these deaths. Some of the patient and doctor related factors that may contribute to asthma deaths are tabulated in Box 1.[2]

Box 1: Points emerging from asthma death studies 1968–1987[3]

I. Patient-Related Factors—
- Most patients dying from asthma have a long history of asthma
- Most have had multiple admissions to hospitals
- Patient compliance is poor
- Patients accustomed to a degree of disability
- Patients unable to gauge severity of an attack
- Underuse of peak flow meters
- Poor control for days/weeks prior to fatal attack

II. Doctor-Related Factors—
- Doctors underestimate severity of the attack
- Objective measurements (PEF, ABG) not made
- Underuse of steroids
- Underuse of beta-agonists
- Overuse of beta-agonists
- Injudicious use of sedatives
- Beta-blockers always contraindicated
- Theophylline levels not monitored

Abbreviations: PEF, peak expiratory flow; ABG, arterial blood gas.

PATHOPHYSIOLOGY OF AN ACUTE SEVERE ASTHMA ATTACK[1]

The airway obstruction in asthma is widespread but uneven in its distribution. It is caused by a combination of thick tenacious mucus-plugging of the smaller airways, bronchial mucosal inflammation and edema, and smooth muscle spasm. The more severe the asthma attack, the greater the tendency to closure of the airways at higher than normal lung volumes. The increase in lung volumes raises the static transpulmonary pressure and results in an increased outward radial traction on the airways that attempts to keep them open. The airway obstruction is reflected in falling peak expiratory flow (PEF) and forced expiratory volume in one second (FEV_1), whilst the increasing lung volume is recognized clinically

and radiologically by a hyperinflated chest, and physiologically by a markedly increased residual volume (RV), functional residual capacity (FRC), total lung capacity (TLC) and RV/TLC. During recovery, hyperinflation may resolve with a fall in TLC occurring before there is much increase in FEV_1 or PEF.

The combination of advanced airway obstruction and hyperinflation results in markedly increased work of breathing. The extreme dyspnea experienced by an asthmatic is a reflection of the difficulty experienced in breathing at high lung volumes for prolonged periods of time. The work of breathing during a severe attack of asthma is estimated at 5–25 times than that performed by normal adults at rest.

The gas exchange abnormalities and the hypoxemia in asthma are a consequence of ventilation-perfusion imbalance. The degree of hypoxemia correlates with the severity of airways obstruction and hence the number of low ventilation/perfusion (V/Q) units. Flenley observed that a partial pressure of oxygen in arterial blood (PaO_2) below 60 mm Hg was usually associated with an FEV_1 of less than 0.5 L.[4] In some lung units the airway obstruction may be complete (e.g. airways in that area completely blocked off by mucus plugs) and then a right to left shunt (Q_S/Q_T) may contribute to the hypoxemia.

In a mild attack or the initial phase of a severe attack, the primary gas exchange problem is hypoxemia accompanied by hypocapnia. The latter reflects the increased alveolar ventilation induced by hypoxia and anxiety. As the attack evolves and airway obstruction worsens, the partial pressure of carbon dioxide in the arterial blood ($PaCO_2$) starts to rise. Whilst the incidence of hypercapnia is low, prompt identification is critical because of the frequent need for mechanical ventilation at this stage. Respiratory acidosis and lactic acidosis are also grave prognostic signs.[3]

CLINICAL FEATURES

The *onset* of an acute severe asthma attack can be dramatic, for example, in the atopic patient suddenly exposed to high concentrations of a provocating allergen, or in a patient markedly sensitive to aspirin. Such a patient may have a catastrophically sudden attack with extreme chest tightness and inability to breathe. More often the acute attack may have been building up over several hours, days or even weeks before the patient is hospitalized. A study by Bellany and Collins revealed that 50% of patients dying of asthma in hospital had been waking up for 5 nights a week, in the week prior to death and as many as 35% had been waking up that often in the previous month.[5] Clearly an intensification of their treatment at this stage (for example, with a short oral course of steroids) might have prevented the fatal attack.

A *history* of wheeze at night, bad enough to wake the patient up, must always be elicited. Worsening of exertional dyspnea and increasing requirement of inhaled beta-agonists with less relief after each puff, are also pointers to a severe attack. The longer the delay in initiating effective therapy and the more protracted the attack, the worse the prognosis in acute severe asthma.

Box 2: Features of a severe attack of asthma

- Inability to complete sentence in one breath
- Disturbance in level of consciousness
- Respiratory rate ≥30/min
- Silent chest
- Cyanosis
- Respiratory muscle fatigue
- Tachycardia ≥110/min
- Systolic paradox ≥15 mm Hg
- PEF ≤30% of predicted or known best
- PaO_2 <60 mm Hg despite supplemental oxygen at 60% FiO_2
- $PaCO_2$ which is normal or high, and rising

Note: Not all these features are necessarily present in a patient.

Abbreviations: PEF, peak expiratory flow; PaO_2, partial pressure of oxygen in arterial blood; FiO_2, fraction of inspired oxygen; $PaCO_2$, partial pressure of carbon dioxide in the arterial blood.

On examination, the patient is distressed and able to speak in short sentences only. He gasps for breath, each breath being accompanied by loud wheezing and sometimes uncontrollable coughing. He is unable to lie flat and usually sits upright or leans forward struggling to breathe. A respiratory rate of 30 breaths per minute or more is a bad prognostic sign. On auscultation of the chest, most patients have loud, widespread inspiratory and expiratory rhonchi, but the occasional patient with severe asthma has a silent chest with hardly any audible breath sounds or rhonchi.[1] A silent chest is another grave prognostic sign and denotes obstruction so severe that there is hardly any airflow. Accessory muscles of respiration are in active use as the patient struggles to overcome the airway obstruction by sternocleidomastoid contraction and intercostal retraction. Cyanosis may be difficult to detect but when present denotes a severe and dangerous attack. Tachycardia is always present and may be worsened by the medication the patient has already taken or received to ward off the attack. A pulse rate over 110 beats per minute denotes a severe attack. The presence of a significant pulsus paradoxus has been shown to reflect lung hyperinflation combined with wide fluctuations in intrathoracic pressure, and when more than 15 mm Hg, reflects a severe attack (Box 2).[1]

DIFFERENTIAL DIAGNOSIS[6]

The axiom "all that wheezes is not asthma" must never be forgotten. Some of the asthma masqueraders are cases of acute left ventricular failure (cardiac asthma), tracheal or large airway obstruction, bronchiolitis, pulmonary eosinophilia, pulmonary embolism, sarcoidosis, carcinoid syndrome, angioneurotic edema, laryngeal spasm (vocal cord spasm) and factitious asthma. In a child admitted to the intensive care unit (ICU) for a first episode of asthma, the possibility of a foreign body obstructing the airway should always be entertained.

MONITORING

Peak Flow Rate

Peak flow rate (PFR) is the most essential, but least frequently performed monitoring test. Peak flow meters are cheap, easily available and portable, and should be present in every doctor's office, casualty department, hospital ward and ICU. Even in a very tachypneic patient a peak flow maneuver can be performed at the bedside (unlike an FEV_1 maneuver), and gives objective evidence of the severity of an asthmatic attack. The peak flow must be measured on admission to the ICU; a PFR less than 30% of the predicted normal or known best, signifies a severe attack. Thereafter, peak flow is measured 1 hour after initiating treatment, and twice a day, throughout hospital stay, ideally pre-nebulization and post-nebulization. Serial peak flow charting gives a good idea of improvement or worsening of the acute attack.[7]

Arterial Blood Gases

Every patient admitted to the ICU for acute severe asthma should have arterial pH and blood gases estimated on admission. Markers of a severe attack are a PaO_2 less than 60 mm Hg, a normal or rising $PaCO_2$ and a respiratory or metabolic acidosis.

Chest Radiography

The usual finding is hyperinflated lungs. The chest X-ray may on occasion show an unexpected pneumothorax or pneumomediastinum. A complicating consolidation or collapse secondary to mucus plugging or allergic broncho-pulmonary aspergillosis may also be detected. Coexisting cardiac failure may also be picked up.

Hematology[1]

A leukocytosis with neutrophilia is a pointer to infection as a possible trigger of the asthma attack. A marked eosinophilia may be a pointer to one of the pulmonary eosinophilia syndromes.

Sputum Analysis[1]

Sputum eosinophilia may give the sputum of an asthmatic a purulent appearance. Hence, a Gram stain and culture should be performed if bacterial infection is suspected.

Electrolytes

Up to 10% of hospitalized asthmatics may have hypokalemia, which in turn increases the risk of potentially fatal arrhythmias.[8] The hypokalemia is usually related to beta-agonist and steroid use.

TREATMENT OF AN ACUTE SEVERE ASTHMA ATTACK (BOX 3)

Oxygen

The majority of asthmatics hospitalized for asthma have hypoxemia of varying degrees of severity at the time of admission. Death when it occurs during an acute asthma attack is almost always a consequence of hypoxemia. Oxygen should be started as promptly as possible. Unlike in patients with chronic obstructive pulmonary disease there is little risk of suppression of ventilatory drive, hence oxygen should be given at high flow rates. The oxygen should be well humidified to minimize bronchial irritation and drying of secretions. Since the main cause of hypoxia in asthma is V/Q mismatch, inspired oxygen concentrations of 35–50% are usually adequate and will reverse the hypoxemia. An oximeter is invaluable in detecting the improvement or deterioration in oxygen saturation as the attack evolves, and repeated arterial punctures are often unnecessary.

Box 3: Management of acute severe asthma

- Oxygen: high flow rates, well humidified
- Nebulized beta-agonists: salbutamol or terbutaline 5 mg in 3 mL N saline; repeat every 1–2 hours initially
- Steroids: intravenous hydrocortisone 200 mg 8 hourly initially
- Intravenous beta-agonists: salbutamol infusion10 µg/min or terbutaline infusion 5 µg/min, if nebulized beta-agonists do not give relief
- Aminophylline: loading dose 6 mg/kg body weight in 20 mL of 5% dextrose intravenously over 20 minutes; subsequent infusion 0.6–0.9 mg/kg/hr via an infusion pump
- Ipratropium: nebulized in a dose of 500 µg every 6 hours
- Adrenaline: 0.5 mL of 1:1,000 solution subcutaneously;* repeat to a maximum of 2 mL
- Ventilatory support

Note: Monitor oxygen saturation, peak flow rates.
Always take chest X-ray on admission, or if there is sudden worsening to exclude a pneumothorax.
*Use when nebulization not available and inhaled beta-agonists have failed. Avoid in patient with ischemic heart disease, hypertension; in elderly patients monitor use carefully.

Nebulized Beta-Agonists

Nebulized beta-agonists are the mainstay of treatment of acute severe asthma. By the time, a patient with severe asthma is hospitalized, metered-dose inhalers will be ineffective because the hyperinflated asthmatic will be too breathless to effectively use his inhaler. These limitations may be overcome by the use of the compressor-driven nebulizer, in which drug delivery is less dependent on a coordinated breathing pattern, and the more prolonged period of administration permits delivery of a larger total dose. Nebulized salbutamol or terbutaline in a dose of 5 mg diluted with 2–3 mL of normal saline must be given promptly. The dose can be repeated every hour initially (watching for excessive tachycardia), and then every 2–4 hours once the patient shows a good response. Theoretically, nebulizers driven by air can worsen hypoxemia if they improve ventilation (by reducing bronchospasm) to a lung unit that is not being perfused, hence they should ideally be driven by oxygen mains, or if driven by a compressor, the patient should simultaneously receive supplemental nasal oxygen.

An oxygen cylinder will not suffice to generate the 6–8 L of gas flow necessary to effectively drive most nebulizers.

Intravenous Beta-Agonists[9]

In severe asthma with extensive small airway mucus plugging, nebulized medication may not be able to reach the affected airways. Hence, the addition of intravenous beta-agonists or aminophylline is recommended in all severe asthma attacks. When given by this route, beta-agonists have a rapid onset of action, but have a high rate of adverse effects, especially tremors and tachycardia, and must be carefully monitored. Salbutamol is given as an intravenous infusion at 10 µg/minute, and terbutaline as an infusion at 5 µg/minute.

Steroids[10]

Every patient requiring critical care for acute asthma, should promptly receive systemic steroid therapy. With the realization that asthma is an inflammatory airway disease, the role of steroids in the treatment of acute asthma has been established beyond doubt. Failure to administer systemic corticosteroids has been cited as a preventable risk factor for death, during an exacerbation of asthma.

Though no study has conclusively shown the benefit of any particular type of steroid over the other, or established any particular optimal dose of steroid, the following generalizations can be made—

- Steroids must be administered early, ideally by the patient himself as soon as his peak flow drops below a pre-specified level (usually <50% of best). If this has not been done, they should be administered as soon as the patient is hospitalized, because they take about 6 hours to act. Available data suggests that a clear benefit from corticosteroids is unlikely to be noticed in the first 6 hours of administration, but may become evident after 6–12 hours of the initial dose.
- In the hospitalized asthmatic patient who does not have a very severe attack and is not vomiting, oral prednisolone in a dose of 40–60 mg given promptly and then repeated daily, may be as effective as intravenously administered steroids.
- In the critically ill asthmatic admitted to an ICU, steroids should be given intravenously in an initial dose of 200 mg of hydrocortisone every 6–8 hours.
- There is no evidence that giving much larger doses significantly speeds up or improves the response. There is on the other hand, the real risk of precipitating an acute steroid myopathy if mega-doses are used initially.
- Complications following a short duration, moderately high-dose course of steroids appear to be minimal even when this has to be continued for 7–14 days.

Aminophylline

Intravenous aminophylline should be started in all severely ill asthmatics admitted to the ICU, especially those who have failed to respond to nebulized beta-agonist and steroids alone.

In patients who are not on oral theophylline preparations at the time of admission, a loading dose of 6 mg/kg body weight diluted in 20 mL of 5% dextrose is given slowly intravenously over 20–30 minutes. The loading dose is increased in smokers (x 1.5) and reduced in patients with pneumonia or cardiac failure (x 0.4), and those with severe hypoxia (x 0.8). The loading dose is best omitted in patients on any form of oral theophylline. Following the loading dose, an infusion is set up at a rate of 0.6–0.9 mg/kg/hour ideally by an infusion pump. The plasma concentration of theophylline must be monitored and maintained within the therapeutic range of 10–20 µg/mL. The bronchodilator effect of theophylline increases when the serum concentrations are maintained at the upper end of the therapeutic range. However, adverse effects also increase and are common at serum concentrations greater than 25 µg/mL. These adverse effects include nausea, vomiting, diarrhea, headache, insomnia, hypotension, cardiac arrhythmias, convulsions and death. Unquestionably, some of the deaths from asthma in most asthma death-audits are linked to theophylline toxicity; hence the drug must be used with the utmost caution, monitoring levels whenever facilities to do so exist. A number of disease states (liver disease, cardiac failure, pneumonia and hypoxemia) and drugs (macrolides and most quinolones) affect theophylline clearance and doses need to be adjusted carefully, and blood levels monitored frequently in these settings.

Adrenaline

Subcutaneous adrenaline is a potent bronchodilator but has the potential to cause cardiac toxicity especially in elderly patients and those with hypertension and pre-existing ischemic disease. Many patients with catastrophic asthma are given preloaded syringes which they can self-administer at the first sign of a severe attack. The usual dose is 0.5 mL of a 1:1,000 solution given subcutaneously. It may be cautiously repeated if the patient is being monitored in an ICU, to a maximum of 2 mL. With the availability, and the ready ease with which nebulized beta-agonists can be administered, adrenaline is now much less frequently used.

Hydration

Many asthmatics are dehydrated during an acute attack because of reduced oral intake and excessive sweating. Adequate hydration with oral and intravenous fluids is essential. As mentioned earlier, oxygen must be well humidified. The efficacy of mucolytics and expectorants is unproven and these are best avoided during an acute attack. Therapeutic bronchial lavage via a bronchoscope in patients on ventilators in an attempt to remove thick mucus plugs, can cause significant desaturation and other complications, and cannot be routinely recommended.

Ipratropium Bromide

Nebulized ipratropium bromide in a dose of 500 µg every 6 hours has some bronchodilator effect, though it is not as

potent a bronchodilator as salbutamol. When these two agents are combined there may be an additive bronchodilator effect. An advantage of ipratropium is that unlike nebulized salbutamol it does not cause any tachycardia.

Antibiotics

Routine administration of antibiotics is not recommended. Though infection is a common trigger, such infections are usually viral.

Magnesium Sulfate[11]

Several studies now show convincingly, that 2 g of Magnesium sulfate ($MgSO_4$) in adults given as a 20-minute IV infusion undoubtedly improves pulmonary function when used as an adjunct to standard therapy. Some studies have shown a trend towards female asthmatics and more severe asthmatics responding better to $MgSO_4$. Because it is a safe and cheap form of therapy, it is worth considering in all refractory cases. A recent study looked at the bronchodilating effects of $MgSO_4$ given via the nebulized route and found that a isotonic solution of nebulized $MgSO_4$ was a useful adjuvant to salbutamol in the treatment of severe asthma in adults.

SUBSEQUENT MONITORING

In addition to subjective improvement in symptoms and signs, objective monitoring of peak flow and oxygen saturation is the best way of assessing the progress of an acute asthma attack. Peak flows are recorded and charted throughout the patient's stay in the ICU. In the initial days, they remain low and morning dips are severe. However, as the asthma stabilizes, the amplitude of these variations gradually decreases, and the peak flow gradually approaches the patient's best or predicted normal.

The PaO_2 returns to normal more slowly than the peak flow and one is often surprised to find some degree of hypoxia persisting for several days after the patient seems to have recovered from an acute attack. Serial measurements of oxygen saturation (SaO_2) are much easier than serial arterial blood gas measurements.

Once subjective and objective improvement occurs, treatment can be gradually scaled down. Intravenous aminophylline is stopped and oral theophylline substituted, intravenous steroids are converted to oral steroids, and nebulized beta-agonists can be replaced by metered dose inhalers. This is the ideal opportunity to teach the patient more about asthma, instruct him about correct inhaler techniques, and give him a self-management plan based on home peak flow recordings.

The patient is usually discharged when he is free of symptoms and peak flows have returned to predicted normal or best, without any of the major diurnal swings that characterize persisting bronchial hyper-reactivity. The first few weeks after discharge from hospital following a severe attack are an unstable period and recurrent attacks and rehospitalization are not uncommon.[12] The patient must have clear, written instructions on his discharge card telling him what to do in case of worsening symptoms. Follow-up in the OPD should ideally be within 2 weeks after discharge.

COMPLICATIONS OF ACUTE SEVERE ASTHMA

The complications of asthma can be divided into those due to the disease itself, and those associated with treatment of the disease. In the former category, we include barotrauma, and all its manifestations like subcutaneous emphysema, interstitial emphysema, pneumomediastinum, pneumothorax and pneumoperitoneum. Collapse, usually of the right middle lobe, is another well-known complication. Arrhythmias are well-recognized complications of hypoxia during an acute attack, and of beta-agonists and theophylline. Hypokalemia too can result from asthma-induced respiratory alkalosis, and from beta-agonists and steroids used in the treatment of asthma. The side effects of large doses of steroids are too well known to enumerate. Acute gastrointestinal bleeds and hypokalemia are the two complications most frequently encountered. Two rarer acute side effects are paradoxical bronchoconstriction that has been reported after intravenous hydrocortisone, methyl prednisolone and even inhaled beclomethasone and budesonide, and acute proximal and distal myopathy in patients receiving large doses of intravenous hydrocortisone. Beta-agonists induce tremors, arrhythmias and hypokalemia when given by the intravenous or nebulized route. The side effects of aminophylline and the special complications that may arise as a consequence of mechanical ventilation are discussed further in this chapter.

VENTILATORY SUPPORT IN ACUTE SEVERE ASTHMA (BOX 4)[13]

Despite all the above measures, a small proportion of patients with acute severe asthma (fortunately no more than 1–2% of all hospitalized asthmatics) will continue to deteriorate and eventually require mechanical ventilation. It must be remembered that even in this select group of asthmatics mechanical ventilation is not therapeutic, but only supportive until bronchodilators and steroids take effect.

INDICATIONS FOR COMMENCING VENTILATORY SUPPORT

- Cardiac or respiratory arrest with apnea or near-apnea.
- Deteriorating level of consciousness with inability to protect the airway.
- Increasing respiratory muscle fatigue.
- Cyanosis or worsening hypoxia (PaO_2 <60 mm Hg) despite maximal oxygen concentrations via face mask [i.e. fraction of inspired oxygen (FiO_2) of 60%].
- Hypercapnia with serial arterial blood gas measurements showing a rising $PaCO_2$. It must be stressed that the arterial blood gas values alone should never dictate when

Box 4: Mechanical ventilation in acute severe asthma

I. Indications—
- Cardiorespiratory arrest with apnea or near-apnea
- Deterioration in the level of consciousness
- Increasing respiratory muscle fatigue
- Worsening hypoxemia despite high oxygen concentrations
- Hypercapnia with rising $PaCO_2$ on serial blood gas estimation

II. Settings—
- Low tidal volumes
- Low respiratory rates
- Low minute ventilation (permissive hypercapnia)
- Prolonged expiratory time

III. Guard against—
- Dynamic hyperinflation (see text)
- High airway pressures
- Hypotension
- Pneumothorax

ventilatory support should commence. Each patient should be evaluated individually; the trend of serial blood gases viewed in context with the clinical condition are far more informative than a single blood gas report viewed in isolation.

HAZARDS IN VENTILATING ASTHMATICS

Even before details of ventilatory support in severe asthma are discussed, it would be prudent to point out that mechanical ventilation though unquestionably life-saving is potentially hazardous and can be directly responsible for significant morbidity and mortality. Death rates in ventilated asthmatics vary from 0–38% in different series, and in a recent review of patients ventilated over a 9-year period in an excellent ICU in the USA, at least one major complication occurred in each and every patient with an overall mortality rate of 22%.[14] Clearly this form of treatment is potentially fraught with danger.

The dynamics of the respiratory system in asthmatics are different from that observed in respiratory failure due to other pathologies. There is little doubt that attempting to ventilate patients with asthma in a manner akin to that used for other lung pathologies has contributed to the high morbidity and mortality in asthmatics. Even with conservative tidal volumes of 500 mL, rates of 12–15/minute and inspiration/expiration (I/E) ratios prolonged to 1:3 to allow adequate time for expiration, the high airway resistance in most severe asthmatics results in the generation of peak airway pressures of 50–60 mm Hg, and the potential for gas trapping and dynamic hyperinflation. Dynamic hyperinflation occurs when a machine preset breath is delivered before the previous expiration is complete, so that the volume of elastic equilibrium is not reached before the next inspiration starts. This results in a positive alveolar pressure persisting at the end of expiration, a phenomenon called occult, intrinsic or auto-positive end-expiratory pressure (auto-PEEP). The degree of auto-PEEP is directly proportional to tidal volume, and inversely related to the expiratory cycle length. Dynamic hyperinflation must be assiduously guarded against when ventilating patients with severe asthma. It can be clinically assessed by direct auscultation (making sure expiration is complete before the next breath is delivered), or by placing a measure-tape around the patient's chest at the level of the nipples, and actually noting the increasing chest girth with each breath, if dynamic hyperinflation is occurring. The most accurate method is to actually measure the amount of auto-PEEP by measuring the pressure deflection when the expiratory tubing is clamped off at the end of expiration (end-expiratory occlusion method). This method should be routinely used to assess the severity of dynamic hyperinflation in any ventilated asthmatic. Another monitor of the severity of dynamic hyperinflation is serial measurements of plateau pressure (P plat). Attempts should be made to keep P plat below 30 cm H_2O.

The two major complications encountered during mechanical ventilation are directly linked to dynamic hyperinflation. These are barotrauma, and circulatory depression with hypotension. Branthwaite in a review on mechanical ventilation in acute severe asthma, stresses that "avoiding death from either tension pneumothorax or acute right heart failure remains the cardinal objective" whilst ventilating severe asthmatics.[15] Barotrauma includes not just pneumothorax, but also interstitial emphysema, pneumomediastinum, subcutaneous emphysema, pneumoperitoneum and tension lung cyst. In a series of 21 episodes of mechanical ventilation for acute severe asthma, pneumothorax occurred in 33%, and was associated with decreased survival.[16] Most episodes of pneumothorax occurred in patients with peak airway pressures exceeding 55 mm H_2O. Hypotension occurred in about 25% of patients in this series. It is caused by high mean intrathoracic pressures impairing venous return and resulting in a fall in cardiac output. The problem may be aggravated by hypovolemia, and by the use of drugs like morphine and diazepam that increase venous capacitance. It can be minimized by maintaining adequate intravascular fluid volume and by shortening the inspiratory phase of ventilation. Hypotension that occurs during the course of mechanical ventilation of severe asthma should always be attributed to excess dynamic hyperinflation until proven otherwise. A brief trial of apnea (30–45 seconds) is usually diagnostic: when hypotension is due to excessive dynamic hyperinflation, period of apnea serves to increase venous return and raise the blood pressure. A favorable response to a trial of apnea should lead to a reduction of the respiratory rate, and increased intravenous fluid administration. If on the other hand, a brief trial of apnea and a fluid challenge fail to promptly improve the blood pressure, then a mechanism other than dynamic hyperinflation is likely. The possibilities then include most ominously, a tension pneumothorax or myocardial depression. Other complications include pneumonia,

atelectasis, arrhythmias, sepsis and complications related to airway management.

VENTILATORY STRATEGIES

Intubation[13]

This should be performed deftly and expeditiously by an expert. Intubation of the critically ill asthmatic involves considerable risk. Many patients have increased bronchospasm and laryngeal spasm during attempted intubation, and hence thorough local anesthetic spray of the pharynx and larynx is important. The patient must be pre-oxygenated, and care taken to avoid gastric aspiration. A large diameter endotracheal tube (ideally ≥8 mm) must be used to minimize airway resistance and facilitate suction. Sedation before intubation is obtained with a small intravenous dose of diazepam (5–10 mg), and if paralysis is needed, pancuronium or vecuronium will suffice.

Controlled Hypoventilation in Acute Severe Asthma

In an attempt to counter the problems posed by traditional ventilation in asthma, Darioli and Perret introduced the concept of controlled hypoventilation in 1984.[17] Realizing that high peak airway pressures were to be avoided at any cost, they set a limit of 50 cm H_2O pressure on the peak inspiratory pressure (Ppk), and achieved this by reducing tidal volume, respiratory rate, minute ventilation and inspiratory flows. This deliberate hypoventilation resulted in $PaCO_2$ levels up to 60–70 mm Hg, which were accepted and tolerated by most patients without complication. Arterial pH was maintained with intravenous sodium bicarbonate if necessary. An adequate oxygen saturation was maintained by increasing the FiO_2 as necessary. Using this strategy in 34 episodes of mechanical ventilation in 26 asthmatic patients, all survived. Equally important, there was no barotrauma in any of their patients. Hypotension, though it occurred in 45% of their cases, was usually transient.

Care of the Ventilated Asthmatic

These patients should be kept well sedated with intravenous diazepam, and if necessary paralyzed with pancuronium or vecuronium. Sedatives, like morphine and meperidine, and paralyzing agents, like d-tubocurarine and gallamine, have histamine-releasing properties and are hence best avoided. Any paralyzing agent used must be cautiously administered. Simultaneous administration of pancuronium with aminophylline may cause serious arrhythmias, and simultaneous administration of pancuronium with steroids has been implicated recently in prolonged residual muscle paralysis and weakness.

Adequate hydration is essential and small doses of normal saline may be instilled down the endotracheal tube in an attempt to liquefy viscid bronchial secretions. Suction must be done efficiently with meticulous care taken to ensure full aseptic precautions.

As mentioned earlier, complicating barotrauma, hypotension and dynamic hyperinflation must be guarded against by frequent checks of auto-PEEP.

Weaning[13]

Most patients do not require prolonged periods of ventilatory support, and once bronchospasm has settled and the asthma attack is felt to have resolved on clinical grounds, weaning may be attempted. Most patients can be easily and successfully weaned. Some units prefer to switch to the pressure support ventilatory mode during the weaning process. Difficulty in weaning may be encountered in patients with respiratory muscle weakness from hypokalemia, hypophosphatemia, excessive use of steroids, and long-term use of neuromuscular blocking drugs.

Unconventional Therapies

Many anecdotal case studies have reported on the use of various anesthetic agents, both intravenous and by inhalation, in the therapy of refractory bronchospasm in the ventilated asthmatic. The drugs used include halothane, ether, isoflurane, enflurane, thiopental, ketamine and droperidol. Heliox (an oxygen-helium mixture) has been tried in eight randomised trials to date, and in the occasional patient with acute severe asthma or brittle asthma can result in dramatic improvement.[18] There have also been reports of extracorporeal membrane oxygenation (ECMO) succeeding when all conventional forms of therapy have failed.

CHAPTER 34

Community-Acquired Pneumonias Requiring Critical Care

Zarir F Udwadia *MD, FRCP (London), MNAMS, FCCP (USA). Consultant Physician, P.D. Hinduja National Hospital, Breach Candy Hospital and Parsee General Hospital, Mumbai, Maharashtra, India, with* ***FE Udwadia***

INTRODUCTION

Pneumonias can be classified into community-acquired pneumonias (CAP), nosocomial pneumonias, pneumonias occurring in the immunocompromised host and aspiration pneumonias. This chapter deals with CAP requiring critical care.[1]

Community-acquired pneumonias are an important cause for hospital admissions. Most pneumonias are managed in the general wards of the hospital. Critical care for CAP may however be necessary under the following circumstances (Box 1)—

- When pneumonia occurs in the very young and the old.
- When it is complicated by acute respiratory failure or shock.
- When a CAP leads to the acute respiratory distress syndrome (ARDS).
- When pneumonia in rare instances is complicated by spread of infection to other organs or systems, notably the pericardium, meninges or the brain.
- When it exists as a complication of another serious illness for which the patient is hospitalized, e.g. a cerebrovascular accident, diabetic ketosis or head injury.
- When it is the result of a fulminant viral or bacterial infection. Fulminant influenzal pneumonia can cause death within 48 hours. Fulminant bacterial infections due to virulent strains of the *pneumococcus*, *Haemophilus influenzae*, or Gram-negative bacilli carry a forbidding mortality in spite of good care and appropriate management. Infections by rare virulent organisms like *Yersinia pestis* and anthrax can cause fulminant infections and quick death. The tubercle bacillus on occasion can cause extensive acute consolidation resulting in a life-threatening illness; the diagnosis is missed if this possibility is not kept in mind.
- When community-acquired pneumonia occurs in an immunocompromised host as in a patient with leukemia, malignancy or acquired immune deficiency syndrome (AIDS), or in a patient who has recently received radiation or is on corticosteroids or cytotoxic drugs.

Box 1: Indications for critical care in community-acquired pneumonia

- At extremes of age
- When complicated by acute respiratory failure or shock
- When followed by ARDS
- When complicated by spread of infection to other organs or systems, e.g. the brain, meninges or pericardium
- When pneumonia occurs as a complication of another serious illness, e.g. head injury, cerebrovascular accident
- When the etiology is a fulminant viral or bacterial infection
- When it occurs in an immunocompromised host

Abbreviation: ARDS, acute respiratory distress syndrome.

ETIOLOGY

There is a paucity of data on the etiology of CAP from developing countries in general and India in particular. The high cost of routinely performing microbiological and serological tests in all patients with CAP is probably the main reason for this. Moreover, the cost effectiveness of making such an exact microbiological diagnosis of CAP remains debatable even in the West. Empirical antibiotics, started promptly, according to guidelines would be the preferred approach, but guidelines

from the West cannot be blindly transposed to India without some idea of local epidemiology. A recent prospective study of 100 adult patients hospitalized in two major Mumbai hospitals was the first attempt to determine the etiology of CAP in this country.[2] Despite an array of costly laboratory tests being performed, no organism could be detected in 42% of patients. 23% of patients had *Streptococcus pneumoniae* isolated, whilst 'atypicals' accounted for 19% of cases (*Chlamydia* 11%, *Mycoplasma* 5% and *Legionella* 3%). *H. influenzae* and *Moraxella cattarrhalis* accounted for 9% and 6% of cases respectively, whilst Gram-negatives accounted for only 5% of all cases. These findings and the overall ranking of pathogens are remarkably similar to data from most Western series.[3]

Community-acquired pneumonias occurring against a background of chronic lung disease can produce critical illnesses and often precipitate respiratory failure. Acute on chronic respiratory failure is most frequently observed when acute pneumonia occurs in a patient with chronic bronchitis or in a patient with bronchiectasis. Pneumonia in these patients is most often due to the *Pneumococcus*, *H. influenzae*, or to Gram-negative organisms.[4]

RECENTLY DESCRIBED VIRAL PNEUMONIAS

Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) is a viral respiratory illness (incubation period 2–4 days) caused by the corona virus. It was first reported in Asia in 2003 and over the next few months spread to North and South America, Europe and Asia (including India) before it was contained. Of a total of 8,098 people infected, 774 of them died. The spread was by close person to person contact through droplet infection. The symptoms are common with other respiratory viral infections—high fever, headache, bodyache, breathlessness, cough. Pneumonia involving one or both lungs and ARDS were observed in severe cases. The mortality as mentioned above was high in patients who developed pneumonia and ARDS. Critical care and the need for ventilator support were necessary in these severely ill patients.

The Middle Eastern Respiratory Syndrome—Corona Virus

The Middle Eastern Respiratory Syndrome—Corona Virus (MERS—CoV) was reported by the World Health Organization (WHO). The outbreak arose in the eastern province of Saudi Arabia, a total of 23 cases being reported between April and May 2012. It has been reported from other countries in the Middle East but yet there is no confirmed report of this respiratory viral infection in India. The spread is by close person to person contact, spread being through droplet infection.

The infection (which has an incubation period for 2–10 days) ranges from mild to fulminant, the clinical syndrome being very similar to SARS. An initial phase of non-specific fever, non-productive cough and occasional diarrhea lasting for several days may progress to a fulminant pneumonia requiring critical care and ventilator support. Radiological findings in patients with pneumonia show unilateral or bilateral infiltrates and in the very severe cases diffuse reticulonodular shadows. There was a 65% case mortality in this outbreak. This is of great concern, as there is a definite risk of this viral infection having a larger spread in the years to come.

PATHOGENESIS[5]

This varies with the infecting organism. Aspiration of organisms resident in the nasopharynx is responsible for *Pneumococcal pneumonia*, as also for pneumonia caused by other Gram-positive and Gram-negative organisms. Viral infections are generally due to inhalation of infected droplets from other patients. Inhalation of water droplets contaminated with Legionella produce a Legionella infection. Hematogenous infection from a distant source of sepsis can also produce pneumonia. *Staphylococcal pneumonias* and Gram-negative pneumonias are occasionally caused by hematogenous infection.

CLINICAL FEATURES[6]

Fever, prostration, respiratory distress, cough with signs of consolidation over a lobe and a polymorphonuclear leukocytosis are the classic features of pneumonia. Signs of consolidation include an impaired percussion note, bronchial breathing and respiratory crackles over the involved lobe. None of these signs may be evident, if the pneumonia is close to the hilum or is centrally placed within a lobe. Inspiratory crackles localized to a lobe should be looked out for carefully in a suspected case. This may be the only physical finding in the chest in a fulminant pneumonia. An X-ray chest is of course diagnostic. The shadow produced by a consolidation may not be always evident in the very early stage of the natural history of pneumonia. The British Thoracic Society in 1987 identified three core features that could easily be checked at admission and which were of great prognostic value.[7] They were—

- Respiratory rate greater than 30/minute.
- Diastolic blood pressure (BP) less than 60 mm Hg.
- Blood urea greater than 7 mmoL/L.

Patients with two or more of these core features had a 21 times higher risk of death. Besides, this simple bedside rule had a sensitivity of 88%, specificity of 79% and a high negative predictive value of 99%. Other features of grave prognostic import were mental confusion or obtundation, hypoxia (PaO_2 <55 mm Hg) and the presence of metabolic acidosis (pH <7.2). Pointers to the severity of pneumonia are listed in Box 2.

There are a few important variations in the clinical picture described above (Box 3).

- In some pneumonias, non-respiratory symptoms predominate and confuse the picture. A lower lobe pneumonia may present with acute abdominal pain and may mimic an acute abdomen. A wrong diagnosis of acute appendicitis

Box 2: Pointers to severity of community-acquired pneumonia

- Age >60 years
- Associated with pre-existing serious illness
- Respiratory rate >30/min
- Systolic blood pressure <80–90 mm Hg
- Mental confusion
- WBC count <4000/mm^3
- PaO_2 <55 mm Hg on oxygen; $PaCO_2$ >48–50 mm Hg
- Metabolic acidosis pH <7.2
- Chest X-ray shows multilobe or spreading shadows
- Spread of infection to pericardium or meninges
- Multiple organ dysfunction syndrome present

Box 3: Unusual presentations of acute life-threatening community-acquired pneumonias

- Predominance of non-respiratory symptoms, e.g. acute abdominal pain in case of lower lobe pneumonia
- Subtle manifestations (tachycardia, increased respiratory rate, mental confusion, rapid clinical deterioration) seen sometimes in old, debilitated patients
- Acute delirium, confusion, disorientation
- Multisystem involvement (hepatitis, diarrhea, hypotension, SIADH, renal involvement) mainly in *Legionella pneumonia*; can also occur in other pneumonias
- Atypical manifestations in *Mycoplasma pneumonia*
- Acute respiratory distress, inspiratory crackles similar to the acute form of interstitial pulmonary fibrosis, bilateral pulmonary shadows, with rapid progression to acute respiratory failure, is a rare manifestation of tuberculous pneumonia

Abbreviation: SIADH, syndrome of inappropriate antidiuretic hormone.

or acute hepatitis is frequently made, particularly in children and young adults.

- Life-threatening CAP in old debilitated patients may present with subtle manifestations. Tachycardia, an increased respiratory rate, mental confusion, and a rapid deterioration in the clinical state leading to death may be observed.[8]
- Acute delirium, with confusion and disorientation may occur with any acute pneumonia. It especially occurs with Legionella infection. Multisystem involvement can occur with any pneumonia but again is often present early with acute Legionella infection. Hepatitis, diarrhea, hyponatremia, syndrome of inappropriate antidiuretic hormone (SIADH), and renal involvement occurring in a patient with consolidation should suggest the diagnosis of a Legionella infection.[9]
- The commonest atypical pneumonia is probably a mycoplasmal infection. Acute myocoplasmal infection (like Legionella infection) can also rarely cause multisystem involvement. Cold agglutinins are positive in about 50% of patients with mycoplasmal pneumonia.[10]
- Acute tuberculous pneumonia can present with bizarre manifestations. An unusual presentation is that of acute respiratory distress, bilateral shadows in the lungs with inspiratory crackles indistinguishable from those seen in interstitial pulmonary fibrosis (Fig. 1). There is cough but no sputum for examination. The patient can progress to quick acute respiratory failure with a low PaO_2 (<60 mm Hg), even on supplemental oxygen. The diagnosis is impossible without an examination of bronchoalveolar lavage samples, which show acid fast bacilli, or without a transbronchial and in rare instances, an open lung biopsy. The biopsy shows tubercles on histopathological examination, and acid fast bacilli on appropriate staining of tissue sections.

COMPLICATIONS (BOX 4)

The most important complication is acute respiratory failure. There is often a large shunt from right to left in pneumonia, particularly when more than one lobe is involved. This leads to a marked fall in the PaO_2 even when the patient is on oxygen at 4–6 L/minute. Acute respiratory failure can also occur because of the evolution of the acute respiratory distress syndrome following upon a fulminant lobar pneumonia (Fig. 2). Multiple shadows in both lungs, with a large right to left shunt following a lobar consolidation, is now invariably thought to be due to acute lung injury, ARDS, and not to spreading infection in the lungs.

Acute life-threatening pneumonia is a source of sepsis.[11] All the complications of the sepsis syndrome may be observed. These include hypotension, septic shock and tissue hypoperfusion with metabolic acidosis culminating in multiple organ failure.

Spread of infection to contiguous areas, or hematogenous spread, may rarely add to the gravity of the illness. Empyema is the commonest of these complications. It may be tucked away posteriorly in the paravertebral gutter and can be missed on a chest X-ray. It is clearly demonstrated on a computed tomography (CT) of the chest. It may be responsible for the sepsis syndrome after the consolidation in the lung has resolved clinically and radiologically.

Acute purulent pericarditis is now a very rare complication. It is lethal, if undiagnosed and not promptly treated. As little as 300 mL of pus in the pericardium can cause death from cardiac tamponade in a child. The diagnosis should be suspected when there is a sudden clinical deterioration in a patient with acute pneumonia, particularly in the presence of shock with a raised central venous pressure.

Acute pyogenic meningitis may be the presenting feature of an underlying lobar pneumonia. Neck stiffness and a positive Kernig's sign may however be present in acute lobar pneumonia even without acute meningitis. This is more frequently observed with upper lobe pneumonia in young adults. A lumbar puncture is always mandatory as it is the only certain way of distinguishing meningism from meningitis.

Fig. 1: *Legionella pneumonia*—This patient presented with high-grade fever , chest pain and cough. Chest X-ray showed diffuse fluffy opacities seen in both lung fields suggestive of legionella pneumonia. Legionella antigen was detected on urine examination

Fig. 2: *Mycoplasma pneumonia*. A 47-year-old male patient presented with fever and cough, white blood cells (WBC) count was normal. Anti-mycoplasma titers were very high. Chest X-ray demonstrates streaky and conglomerated opacities in both lower zones, more so on the left side representing *Mycoplasma pneumoniae*

Box 4: Complications of acute life-threatening community-acquired pneumonia

- Acute respiratory failure
- Acute lung injury (ARDS)
- Sepsis syndrome or MODS
- Acute circulatory failure
- Spread of infection to contiguous areas or hematogenous spread, e.g. empyema, acute meningitis, cerebral abscess, acute pericarditis
- Acute left ventricular failure/acute myocarditis
- Acute abdominal distension, acute dilatation of the stomach, ileus
- Femoral vein thrombosis

Abbreviations: ARDS, acute respiratory distress syndrome; MODS, multiple organ dysfunction syndrome.

A sharp deterioration in the clinical state with confusion, delirium and severe prostration may also occur when infection from the lungs spreads hematogenously to produce one or more cerebral abscesses. Localizing signs may be present. A CT Scan is invaluable in confirming the clinical diagnosis.

Acute left ventricular failure is a rare complication in patients with pre-existing left ventricular disease. Acute myocarditis can and does however occur in some patients with acute influenza. It is characterized by tachycardia, hypotension, cardiac dilatation and a diastolic gallop. It may progress to an increasingly severe low output state and death from cardiogenic shock.

In the older age group, patients with acute pneumonia may present with marked abdominal distension. Acute dilatation of the stomach is particularly dangerous, as it compounds respiratory difficulties. Ileus may also occur due to toxemia.

Femoral vein thrombosis is occasionally observed in patients critically ill with pneumonia. Sudden death in acute pneumonia could well be related to pulmonary embolism.

DIFFERENTIAL DIAGNOSIS[12]

A large pulmonary infarct is an important differential diagnosis of acute lobar pneumonia. The distinction at times in difficult. Acute extrinsic allergic alveolitis may present with bilateral upper lobe shadows, whilst acute cryptogenic fibrosing alveolitis may produce bilateral lower lobe shadows with increasing hypoxia. Acute eosinophilic pneumonia should be suspected on the fairly typical radiological features (peripheral shadows in both lung fields). Acute consolidation due to a vasculitis (e.g. Wegener's) may be indistinguishable from consolidation due to an infection. Finally an acute life-threatening pneumonia may occur as a presenting feature of bronchial obstruction produced by a tumor or a foreign body. Aspiration of betel nut (supari) can cause a life-threatening acute necrotizing pneumonia.

Investigations[1]

The diagnosis is made on the basis of clinical features and an X-ray of the chest, which shows one or more areas of consolidation.

Radiological Abnormalities[1]

Generally speaking, it is impossible to determine the etiology from the nature of the radiological shadowing. Homogenous shadows, lobar or segmental in distribution, are more often seen in bacterial pneumonias. Diffuse patchy shadows occur more frequently in atypical pneumonias (e.g. mycoplasmal or viral pneumonias). The latter however also can produce homogenous shadows indistinguishable from bacterial pneumonia. The development of ARDS is recognized by bilateral fluffy shadows, with increasing hypoxia.

Hilar adenopathy is often observed particularly in children and young adults with tuberculous pneumonia. Rarely, it may also occur with mycoplasmal infection.

Pleural effusion is common and when present, a diagnostic tap is helpful in determining the causative organism responsible for pneumonia.

Microbiological Tests[1]

The nature of the infecting organism can only be determined by specific microbiological tests. Sputum samples should be quickly collected whenever possible, but antibiotic therapy should be started without awaiting results. Blood cultures are also sent prior to starting treatment. A positive blood culture is rare in our set-up, but when present, identifies the pathogen with certainty.

Sputum examination in our opinion has a low sensitivity but a high specificity, if positive. A Gram stain and a culture should be done. It is important to first ascertain the adequacy of the sample. If under low power, the sputum sample shows more than 25 neutrophils and less than 10 epithelial cells, it signifies a satisfactory sample, which is worth staining and worth culturing. Such a specimen is minimally contaminated by oropharyngeal flora. The presence of just one kind of organism in large numbers on Gram stain of a suitable sputum specimen is very significant. This finding provides a good guide for initial antibiotic therapy.

Positive sputum cultures should not be viewed as sacrosanct in arriving at an etiological diagnosis. The culture may not necessarily reflect the etiology of infection deep within the lung. Washing or diluting the sputum may help by encouraging only bacteria present in large numbers to grow on culture. We feel that if repeated cultures grow the same organism, the results are generally significant. Sputum cultures are generally negative, or may only grow commensals if the patient has received an antibiotic before admission to the ICU. Most patients have received one or more courses of antibiotics in the community before their eventual hospitalization.

If pleural fluid is present, it should be aspirated, and sent to the laboratory for Gram stain and culture. Organisms seen on Gram stain, or grown on culture of the pleural fluid point to the etiological agent responsible for pneumonia.

A positive diagnosis of pneumococcal pneumonia can be made more frequently by testing for pneumococcal polysaccharide capsular antigen in sputum, blood, urine and pleural fluid, by counter immunoelectrophoresis, co-agglutination and latex agglutination.

The diagnosis of acute viral, mycoplasmal, other atypical pneumonias and Legionella infection is made by serological methods which identify antibodies in the blood at the start of the illness, and again 10–14 days later. The presence of legionella antigen in the urine allows an early diagnosis. There generally has to be a fourfold rise of the antibody titer against a particular organism for the test to be considered as positive. This is obviously of no use in the management of life-threatening infections by these agents. Specific IgM antibody detection can however aid early diagnosis of Legionella or mycoplasmal infection. It is unfortunate that these tests are unavailable except in a few microbiological laboratories in this country. The cost of some of these specialized serological tests is also high and a deterrent to routine use of these tests.

In patients who are seriously ill, who have not responded to initial therapy, and in whom an etiological diagnosis is therefore important for management, secretions from the lower respiratory tract should be obtained through fiberoptic bronchoscopy using protected brushes,[13] and through bronchoalveolar lavage.[13] Material obtained by these methods should be appropriately stained and cultured, and subjected, if necessary to special tests stated above.

A CT- guided biopsy of the area of lung consolidation may also be necessary to arrive at a diagnosis. In difficult cases, one may have to resort to open lung biopsy. This is particularly necessary in life-threatening acute respiratory infections which have not responded to an empiric regime of antibiotics. Through open lung biopsy, we have stumbled occosionally on bizarre manifestations of acute pulmonary tuberculosis and acute vasculitis, conditions which require a different approach in management.

The diagnostic value of the various investigations done for CAP is listed in Table 1.

General Investigations

Leukocytosis greater than 15,000/mm^3 is generally present in bacterial infections. In patients with atypical pneumonias due to viral or mycoplasmal infections, the white blood cell count is usually normal. Severe leukocytosis (WBC >30,000/mm^3) or marked leukopenia (WBC <4,000/mm^3) is a poor prognostic sign.

The PaO_2 is often low and in severe cases may be less than 50 mm Hg, even when the patient is receiving oxygen at a flow rate of 6–10 L/minute. Hypocapnia is usual and this results in respiratory alkalosis. In critically ill patients, overall alveolar hypoventilation ultimately prevails, and the $PaCO_2$ shows a progressive rise. A sudden deterioration in the clinical state is characterized by increasing hypoxia, hypercapnia, and a combination of respiratory-cum-metabolic acidosis.

Abnormal liver functions are frequently present, particularly a mildly raised serum transaminase and slightly elevated serum bilirubin. Hypokalemia and hypoalbuminemia

Table 1: Diagnostic value of investigations in community-acquired pneumonia

Tests	*Remarks*
Microbiological Sputum Gram stain/culture	• Check if sample satisfactory • Collect sputum prior to starting antibiotics • Oropharyngeal contamination may be present • Low specificity (10%), high sensitivity (70–80%), if positive • Washing/diluting sample helpful
Blood culture	• Should be done prior to starting antibiotics • Positive cultures rare in our set-up, but when present, identifies the pathogen
Pleural fluid Gram stain/culture	• If positive, useful in establishing etiological agent
Serological *Antigen detection:* Pneumococcal (blood, urine) Legionella (urine) Cold agglutinins	 • Mainly useful for pneumococcal infection • Accurate means of diagnosing Legionella infection • Positive in over 50% of patients with mycoplasmal pneumonia
Antibody detection: Anti-mycoplasma Anti-chlamydia Anti-influenza	 • Helps in diagnosis of mycoplasma, chlamydia, and viral pneumonia
Invasive tests: Examination of secretions obtained from protected brush biopsies, bronchoalveolar lavage (BAL), or CT guided or transbronchial biopsy of lesion Open lung biopsy	• Should be done in serious illness not responding to initial empiric antibiotic therapy • Helps in etiological diagnosis • Helps in diagnosis in the above situation if BAL, protected brush smears and CT guided biopsies are negative

Abbreviation: CT, computed tomography.

may be observed. Inappropriate secretion of the antidiuretic hormone may cause well-marked hyponatremia. This is more commonly observed in Legionella infections, but can also occur with other pneumonias.

A raised blood urea, proteinuria and hematuria may also occur. Investigations in critically ill patients should include an assessment of the function of various organ systems.

MANAGEMENT

Use of Antibiotics (See Table 1 of Chapter 46)[1,14]

Antibiotics must be started promptly, empirically, and by the parental route in all hospitalized patients with CAP. If possible sputum and blood culture should be sent off prior to initiating therapy. The *pneumococcus* must always be covered as must *H. influenzae* and atypical bacteria. Antibiotic choice must be governed by knowledge of local epidemiology and resistance patterns. More epidemiological studies from different parts of the country will help physicians to empirically but accurately choose their initial antibiotic regime. The following are the author's antibiotic recommendations based on the results of an epidemiological study from Mumbai.[4]

- *If the patient is ill but not in the ICU* We would recommend co-amoxyclav or ceftriaxone in full intravenous doses plus either a quinolone or a macrolide intravenously. This combination would effectively cover the *pneumococcus*, *H. influenzae*, *M. catarrhalis*, *mycoplasma*, *chlamydiae* and *legionella*.
- *If the patient fails to respond or is ill enough to be in the ICU* We would in addition add on an antibiotic with Gram-negative (specifically anti-pseudomonal) cover. In the Mumbai series, though Gram-negatives were rarely responsible for CAP (5% overall), there numbers rose in ICU patients (*Pseudomonas*, 2 out of 19, *Klebsiella*, 2 out of 19). An anti-pseudomonal antibiotic like ceftazidime or ticarcillin should be considered in this critically ill group of patients, where failing to cover a Gram-negative pathogen could make the difference between life and death.
- *Specific situations* If staphylococcal infection is strongly suspected on clinical or radiological grounds, intravenous cloxacillin can be added. If there is a strong suspicion of methicillin-resistant *Staphylococcus aureus* (MRSA),[15] vancomycin should be added. If the history suggests aspiration is a possibility, metronidazole should be used.

If over 48 hours, the patient has not improved, and if sputum is unavailable for examination, or is non-contributory to the diagnosis, it is important to make an exact etiological diagnosis.[13] Examination of bronchoalveolar lavage material, or of material obtained by protected brush biopsy through a fiberoptic bronchoscope may help. In desperate situations, a CT-guided biopsy or an open lung biopsy may be necessary. It is important to be bold and establish an early diagnosis in patients who are critically ill and who do not respond to a wide cover of multiple antibiotics. Yet boldness must be tempered with good sense. The decision as to whether a patient will stand an invasive diagnostic procedure, and whether he is likely to benefit from it or not, is a matter of judgment based on experience and expertise.

Management in the ICU[16]

The patient in the ICU should be carefully monitored with regard to his vital signs and his oxygen saturation. An

increasing respiratory rate, a falling blood pressure, and increasing hypoxia in spite of oxygen therapy, are warning signs of impending cardiorespiratory failure. We use ventilatory support if the respiratory rate is greater than 36–40/minute, if there are signs of respiratory muscle fatigue, if the PaO_2 is less than 55 mm Hg on oxygen, or if the $PaCO_2$ is greater than 50 mm Hg. We also use ventilator support in the presence of circulatory failure as evinced by hypotension, metabolic acidosis and other features of a low output state. Nearly 58–85% of patients with severe CAP require ventilatory assistance. There may be special ventilatory needs in severe CAP, particularly if extensive unilateral involvement is present. Patient positioning may be a simple and effective way of improving oxygenation if unilateral lobar pneumonia is present. By positioning the pneumonic lung up and the non-involved lung down, gravity can increase perfusion to the dependent non-involved lung, optimizing matching between ventilation and perfusion and thus improving oxygenation.[17] We generally initiate ventilator support in the volume control mode. If however peak inflation pressures are high, we prefer the pressure control mode using a pressure control limit of not greater than 30 cm H_2O. Positive end expiratory pressure (PEEP) is adjusted to optimize oxygenation. Sedation and rarely induced muscle paralysis may be necessary for efficient ventilator support.

Noninvasive ventilation has been tried but with limited success in this critically ill group of patients but if the patient continues to deteriorate despite a short trial, intubation and mechanical ventilation should not be delayed. Patients may require ventilatory support for several weeks.

Fluid and electrolyte balance should be carefully maintained, and support to multiple organ systems is often necessary in fulminant infections. Inotropic support and/or vasopressor support need to be used in patients who are hypotensive.

CHAPTER 35

Massive Hemoptysis

INTRODUCTION

Hemoptysis is the expectoration of blood, the source of bleeding being below the vocal cords, either from the tracheobronchial tree or the lungs. In most cases, hemoptysis though frightening to the patient is self-limiting, and requires no treatment other than sedation and rest. In a few instances, hemoptysis may be massive and life-threatening, and requires intensive care and emergency management. There is no generally accepted definition as to what constitutes massive hemoptysis. Various reports in literature use different criteria—hemoptysis varying in range from 100 mL/24 hours to 1,000 mL over a period of several days.[1-3] Most critical care units would consider the loss of 600 mL or more of coughed blood in 24 hours to constitute massive hemoptysis. From the practical point of view, hemoptysis should be considered massive when it is life-threatening. This can be due to exsanguination, or to the risk of asphyxiation following aspiration or retention of blood within the lungs. Thus, the risk of death from hemoptysis has been shown to be related to the amount of blood expectorated, the rate of bleeding, the quantity of blood retained within the lungs, and the underlying pulmonary reserve, regardless of the etiology of bleeding.[2-4] The rate of bleeding is of crucial importance. Crocco and coworkers,[5] in a classic study in 1968 showed that hemoptysis of 600 mL blood in less than 4 hours was associated with a mortality of 71%, compared to 22%, if the same blood loss was within 4–16 hours and 5% if this loss occurred from 16 to 48 hours.

BLOOD SUPPLY TO THE LUNGS

The lungs have two relatively independent sources of blood supply: (1) the pulmonary circulation and (2) the bronchial circulation, so that bleeding with resultant hemoptysis can occur from either of these two vascular beds, or from both.

The pulmonary circulation arising from the right ventricle and the pulmonary artery is a low pressure, high-volume conduit which arborizes into fine capillaries around the alveoli, mediating gas exchange.

The bronchial circulation is a part of the systemic vascular bed and serves as a nutritional source for the structural elements of the lung. There are usually one or two bronchial arteries per lung, arising from the aorta and less commonly from the intercostal arteries. In a small percentage of individuals, the anterior spinal artery originates from the bronchial artery. The bronchial circulation has a systemic blood pressure, and factors which regulate and control systemic arterial flow and pressure, will equally influence blood flow and blood pressure within the bronchial vessels. The bronchial vessels anastomose freely with each other in the peribronchial space, and also penetrate the bronchial wall to form an extensive submucous plexus.

Beyond the terminal bronchioles, the bronchial vessels anastomose quite extensively with the precapillary pulmonary arterioles and the pulmonary veins. This anastomosis is often exaggerated in some lung pathologies, as for example in bronchiectasis, and plays an important role in severe bleeding that occasionally occurs in diseased lungs. The bronchial arteries also become hyperplastic and tortuous in many conditions causing hemoptysis. As these arteries are associated with the airways and are under systemic pressure, they have a propensity to bleed profusely in diseases involving the airways. Generally speaking, bleeding (and hemoptysis) due to erosion or rupture of bronchial vessels is brisker and more profuse, compared to bleeding due to erosion or rupture of pulmonary vessels.

Box 1: Important causes of life-threatening hemoptysis

- Tuberculosis can cause massive hemoptysis due to several mechanisms—
  - Bronchial ulceration with necrosis and rupture of underlying bronchial vessels, or rupture of pulmonary vessels due to alveolar necrosis in tuberculous pneumonia
  - Rupture of aneurysmal portion of a branch of the pulmonary artery (Rasmussen's aneurysm) in cavitative tuberculosis
  - Erosion of bronchial arteries by pressure of a calcified hilar lymph node on a bronchus
  - Due to bronchiectasis occurring as a sequel to tuberculosis
  - Formation of a mycetoma in chronic tuberculous cavities
- Bronchiectasis
- Lung abscess
- Mitral stenosis
- Mycetomas
- Cystic fibrosis and in severe pneumonia as in human immunodeficiency virus (HIV) infection
- Bronchogenic carcinoma or other tumors
- *Iatrogenic hemoptysis:* Following bronchoscopy, Swan-Ganz catheterization or transthoracic needle biopsy, tracheo-arterial fistula and malposition of chest tube
- *Intra-alveolar hemorrhage:* Autoimmune disorders, pulmonary vasculitis, Wegener's granulomatosis, Goodpasture's syndrome, bleeding disorders
- *Vascular anomalies:* Arteriovenous malformations
- Trauma to the chest
- Cryptogenic hemoptysis

This chapter now considers the common causes, clinical features, approach to diagnosis and management of life-threatening hemoptysis.

IMPORTANT CAUSES OF LIFE-THREATENING HEMOPTYSIS (BOX 1)[4,6]

Tuberculosis

Tuberculosis still remains the most important and most frequent cause of massive hemoptysis in India and other developing countries. Hemoptysis may occur in active tuberculous infection of the lung, or may be a sequel to burnt-out disease. Most patients with active tuberculosis, who have severe hemoptysis, have cavitative lung disease with acid-fast bacilli present in the sputum. There are several mechanisms of massive hemoptysis in tuberculosis. These include—

- Bronchiolar ulceration with necrosis and rupture of the underlying bronchial vessels in tuberculous pneumonia. Rupture of pulmonary capillaries due to alveolar necrosis may also be an associated feature.
- Rupture of an aneurysmal portion of a branch of the pulmonary artery in cavitative tuberculosis. Rupture of a Rasmussen aneurysm[7] is a well-accepted cause of massive hemoptysis in either active tuberculosis, or in patients with prior infection. Pulmonary arteries traversing thick-walled cavities develop aneurysmal dilatations due to local inflammation of the vessel wall. These aneurysms herniate and project into the cavity lumen. Sudden transient increase in pulmonary artery pressure, or continued inflammation of the vessel wall can cause rupture of the aneurysm with profuse hemorrhage and hemoptysis.
- A healed calcified lymph node at or near the hilum can press on a bronchus, and erode through a bronchial vessel into the lumen of the airway, resulting in massive hemoptysis. The patient may cough up this calcified node in the form of a broncholith. This may immediately precede hemoptysis, or occur during a bout of hemoptysis.
- Massive hemoptysis can occur due to bronchiectasis which often occurs as a sequel to tuberculosis. Bleeding occurs due to erosion of tortuous, enlarged bronchial vessels, and a profuse anastomosis between the bronchial and pulmonary circulation.
- Chronic tuberculous cavities often predispose to the formation of aspergillomas. The latter can cause profuse bleeding.

Bronchiectasis

Bronchiectasis is often associated with bronchial artery hypertrophy, expansion of the peribronchial and submucosal bronchial arterial network, and increased anastomosis between the bronchial and pulmonary circulations. Massive bleeding can originate from hypertrophied bronchial arteries (under high systemic pressure), or from the submucosal vascular plexus in the bronchiectatic segments.

Mitral Stenosis

Before the era of valvulotomy and mitral valve replacement, massive hemoptysis occurred in 9–18% of patients with mitral stenosis.[5] Severe hemoptysis is generally due to rupture of engorged, tortuous, dilated varicose bronchial veins that result as a consequence of an elevated left atrial pressure and passive pulmonary hypertension. In these patients, massive hemoptysis may be precipitated by respiratory infection, by a bout of coughing, or by an increase in intravascular volume, as in pregnancy.

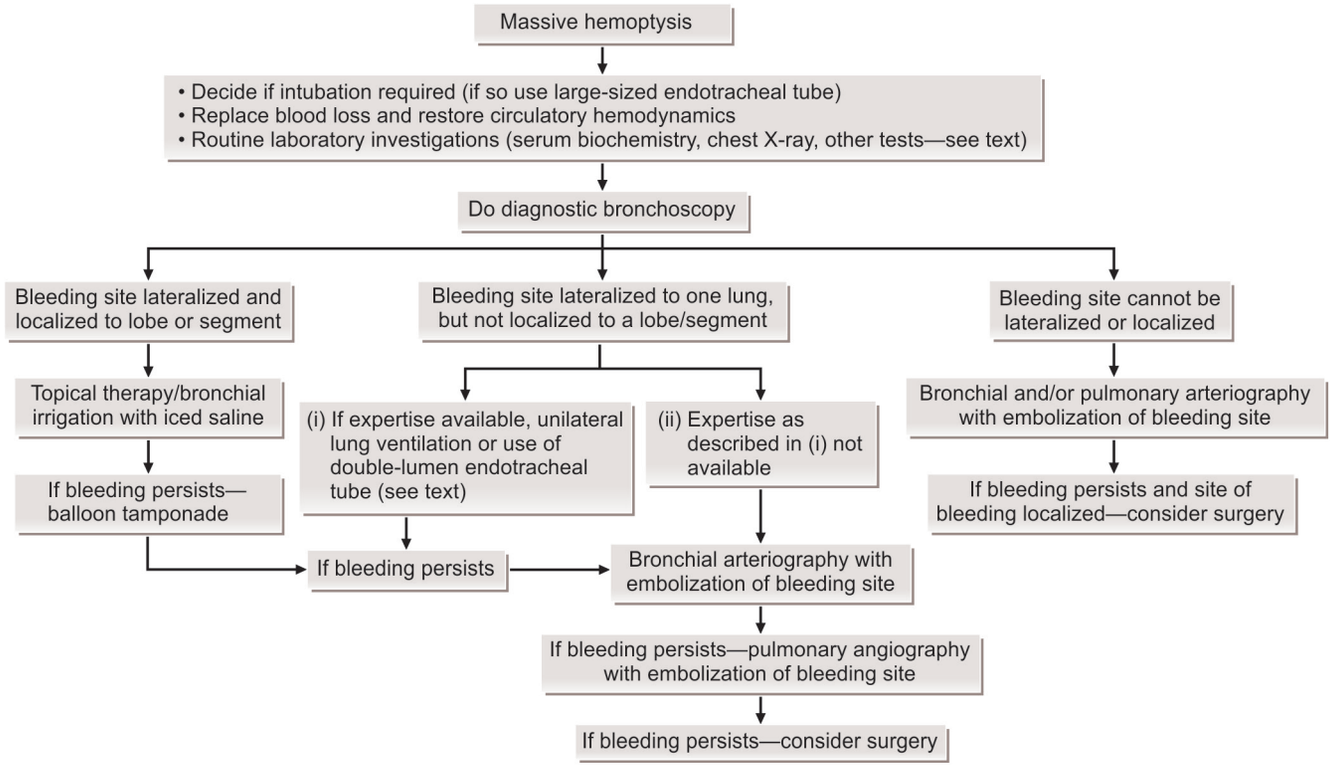
Lung Abscess

Masssive bleeding occurs in 20–50% of lung abscess patients with hemoptysis. It is related to necrotizing inflammation of the lung parenchyma eroding bronchial and pulmonary vessels.

Mycetomas

Mycetomas are fungal balls occurring in patients with pre-existing cavitary lung disease. They are most frequently seen in tuberculous cavities, but have been reported in cavitary disease secondary to sarcoidosis, lung abscess, cavitary carcinoma, bronchiectasis, bullous emphysema and

Flowchart 1: Algorithm for the management of massive hemoptysis



Massive hemoptysis
• Decide if intubation required (if so use large-sized endotracheal tube)
• Replace blood loss and restore circulatory hemodynamics
• Routine laboratory investigations (serum biochemistry, chest X-ray, other tests—see text)
Do diagnostic bronchoscopy
Bleeding site lateralized and localized to lobe or segment
Bleeding site lateralized to one lung, but not localized to a lobe/segment
Bleeding site cannot be lateralized or localized
Topical therapy/bronchial irrigation with iced saline
If bleeding persists—balloon tamponade
(i) If expertise available, unilateral lung ventilation or use of double-lumen endotracheal tube (see text)
(ii) Expertise as described in (i) not available
Bronchial and/or pulmonary arteriography with embolization of bleeding site
If bleeding persists and site of bleeding localized—consider surgery
If bleeding persists
Bronchial arteriography with embolization of bleeding site
If bleeding persists—pulmonary angiography with embolization of bleeding site
If bleeding persists—consider surgery

pulmonary infarction. The most frequent mycetoma is an aspergilloma. The cause of massive bleeding in a mycetoma is disputed. Vascular injury by aspergillus-associated endotoxin, aspergillus-related proteolytic activity and a Type III related hypersensitivity reaction have all been postulated.[8]

Bronchogenic Carcinoma and Other Tumors

These rarely cause massive or life-threatening hemoptysis.

Iatrogenic Hemoptysis

This is a potential complication of bronchoscopy, transthoracic needle biopsy, or the use of a Swan-Ganz catheter.

Rupture of the pulmonary artery is the most catastrophic complication following the use of the Swan-Ganz catheter; it carries a mortality of 50% due to massive pulmonary hemorrhage.[9] This complication is more frequently observed in patients with pulmonary hypertension.

Intra-alveolar Hemorrhage

Intra-alveolar hemorrhage is observed in leptospiral and dengue infections, in pulmonary vasculitis, autoimmune diseases, Goodpasture's syndrome, Wegener's granulomatosis, bleeding disorders, acute infections and in other idiopathic systemic disorders. Whatever the etiology, the presenting features are hemoptysis, alveolar infiltrates on chest X-ray, dyspnea and hypoxemia. The degree of hemoptysis need not always be a guide to the severity of intra-alveolar hemorrhage.

Vascular Anomalies

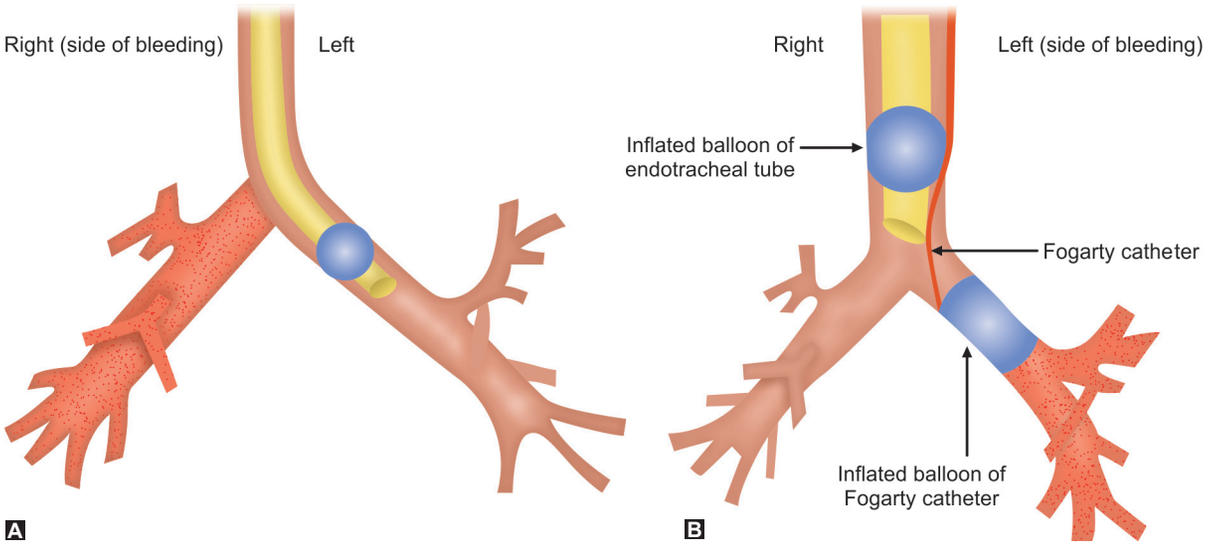
Arteriovenous malformations may rarely cause massive fatal hemoptysis.

Cryptogenic Hemoptysis

About 15% of patients with massive hemoptysis even after extensive investigation have no detectable cause of their hemoptysis, and are labeled as cryptogenic hemoptysis. Patients with massive cryptogenic bleeds generally stop bleeding spontaneously, and require only supportive care. A periodic follow-up is mandatory in these patients.

CLINICAL FEATURES

The clinical features of massive hemoptysis are related to: (1) aspiration of blood into the lungs which can cause hypoxemic respiratory failure due to interference with gas exchange; (2) effects of blood loss. Lethal hemoptysis more often than not kills because of aspiration of blood into the lungs, the patient literally drowning in his own blood, rather than dying because of blood loss.



Figs 1A and B: Unilateral lung ventilation using endotracheal balloon tamponade. (A) In bleeding from the right lung, an endotracheal tube advanced into the left main bronchus permits selective ventilation of the left lung and prevents spill-over of blood from the right into the left lung. (B) In bleeding from the left lung, a Fogarty balloon catheter is passed on the outside of the endotracheal tube to a point below its lower end. After guiding the Fogarty catheter into the left main bronchus, the balloon is inflated. The right lung is thus ventilated by the endotracheal tube, and bleeding from the left side is prevented from spilling into the right lung

Source: Modified from Winter SM, Ingbar DI. Massive hemoptysis: pathogenesis and management. J Intensive Care Med. 1988;3:171-88.

Clinical examination may occasionally reveal focal signs pointing to the site of the bleed. Auscultation of the heart, specifically for the tell-tale murmur of mitral valve disease should always be done.

DIAGNOSIS AND MANAGEMENT[10] (FIG. 1)

The immediate diagnostic step in a patient admitted to the ICU for massive hemoptysis is to determine whether the source of bleeding is from the upper gastrointestinal (GI) tract or from the respiratory tract. A thorough history, clinical examination and examination of the material coughed up, generally suffice. The blood in hemoptysis is bright red, frothy and alkaline. Once the intensity of hemoptysis lessens, the patient often continues to cough up sputum mixed with blood or coughs up blobs of bright red blood. In some instances, both bronchoscopy and an upper GI scopy are necessary to ascertain the source of the bleed. It is to be remembered that in severe hemoptysis, a patient may swallow large quantities of blood. Hematemesis (if he vomits) and melena may then follow. Similarly, a patient with severe hematemesis may aspirate blood into the lungs, and this may result in cough with expectoration of blood. Blood in the mouth can also come from the sinuses, the nasal passage and the upper airway, i.e. the pharynx and from above the vocal cords. Upper airway bleeding can be easily missed if not carefully sought.

The next step in diagnosis is to determine whether the bleeding is from the right or left lung—i.e. to lateralize the bleed and also if possible to determine the lobe or the segment of a lobe from which the blood arises. Diagnostic steps may also reveal the etiology of the bleed. A baseline history, physical examination and a chest X-ray are mandatory. Focal signs over a lobe or a lung may well lateralize the bleed; similarly a chest X-ray may point to the lung or even the lobe involved. However, in our experience, in a truly massive hemoptysis it is frequently impossible to localize the lung or the lobe from which bleeding has occurred either on clinical examination or on a chest X-ray. This is because aspiration of blood into both lungs can result in diffuse or false localizing signs, and similarly an X-ray of the chest may show shadows related to aspiration of blood, rather than to the pathology causing the bleed.

Routine use of computed tomography (CT) chest in massive hemoptysis is usually unrewarding. Aspirated blood often obscures the underlying lesion, or may result in a misleading mass-like effect. CT of the chest may detect arteriovenous aneurysms, cavitative lung disease not apparent on a plain X-ray of the chest, and bronchiectasis. Haponik et al.[11] noted that a CT of the chest did not obviate the need for bronchoscopy in any patient. They also noted that an X-ray chest and bronchoscopy provided all the information necessary for diagnosis and management in 94% of patients.[11]

Immediate priorities The immediate priorities in the management of a truly massive hemoptysis are to maintain and protect a clear airway and to stabilize the hemodynamic state. These priorities should be established even before initiating diagnostic steps to determine the cause and site of the bleed. It should be decided whether the patient needs to be intubated for protection of the airway, proper suctioning, for maintaining adequate oxygenation and gas exchange, and for protection against sudden cardiorespiratory arrest.

If intubation is decided upon, a large-sized (No. 8) endotracheal tube should be used. This facilitates easy suction and permits bronchoscopic evaluation through the large endotracheal tube.

Resuscitation A volume load with either colloids or crystalloids may be immediately necessary to restore blood volume, and arrangements to replace the lost hemoglobin with whole blood or packed cells should be made.

Once the airway has been established and hemodynamic stabilization is achieved, diagnostic and therapeutic procedures should be promptly carried out, even if the bleeding has lessened, as recurrence of brisk bleeding is both possible and unpredictable.

If the bleeding is not massive and life-threatening, a detailed history and physical examination can precede more considered diagnostic procedures, including bronchoscopy. Routine laboratory investigations include a chest X-ray, urine examination, blood count, packed cell volume (PCV), blood urea nitrogen, serum creatinine, platelet count, bleeding time, coagulation profile, blood grouping and cross-matching, arterial pH and arterial blood gas analysis. Sputum should be examined for acid-fast bacilli, other bacteria, and should be cultured. Sputum should also be sent for fungal stains and cultures in appropriate clinical conditions. Sputum cytology is important if there is suspicion of a carcinoma. Other special tests may need to be performed depending on the clinical situation. Tests for autoimmune diseases, and for the detection of antiglomerular basement membrane antibodies, are necessary in patients with hemoptysis and intra-alveolar hemorrhage. The presence of massive intra-alveolar hemorrhage should also prompt tests for leptospiral infection (CPK level in blood and serology).

Vital signs should be closely monitored in the ICU, and the patient should be sufficiently sedated with morphine, 5–7.5 mg subcutaneously or 2 mg intravenously, or with buprenorphine 0.2 mg intravenously, to allay anxiety, restlessness, and to prevent unnecessary coughing. However, the patient should not be oversedated, and the cough reflex should not be unduly depressed; this can lead to accumulation of blood within the lungs, with serious impairment of gas exchange.

Localization of the Site of Bleeding and Therapeutic Measures to Stop Bleeding

Bronchoscopy[12,13]

Early bronchoscopy is advocated preferably during active bleeding, with three specific objectives—(1) to determine from which lung the bleeding occurs, (2) to determine the site (i.e. the lobe or segment) of the bleed, and if possible, (3) to determine the cause or pathology. In patients with lateralized or localized bleeding detected on bronchoscopy, the following therapeutic bronchoscopic procedures may help to stop the bleeding—

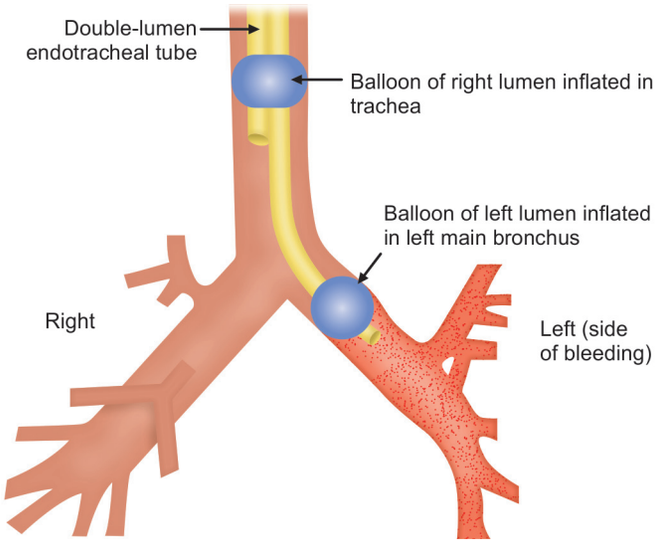
- *Topical therapy* Topical thrombin and fibrinogen-thrombin solutions have been successfully used to stop bleeding in massive hemoptysis.[14] The bleeding may stop permanently or temporarily. This procedure allows time for further evaluation and future planned elective therapy if necessary. Topical epinephrine (1:20,000) has been used to treat hemoptysis secondary to transbronchial biopsy, but its efficacy in massive hemoptysis has not been proven. It would be perfectly justifiable to apply epinephrine over visibly bleeding lesions.
- *Bronchial irrigation* Conlan et al.[15,16] in a study in South Africa used endobronchial irrigation and lavage with iced saline to arrest bleeding in 23 patients with massive hemoptysis. 50 mL aliquots of iced saline arrested the bleeding in all patients, and the average volume of irrigation fluid required per patient was 500 mL.[16] The iced saline presumably acts by inducing localized vasoconstriction with stoppage of bleeding.

Balloon Tamponade

Endobronchial balloon tamponade has successfully arrested bleeding in massive hemoptysis for prolonged periods of time. A fiberoptic bronchoscope is used to guide a 4 Fr 100 cm long Fogarty balloon catheter, which is then inflated in a segmental or subsegmental bronchus leading to the site of bleeding. The balloon is kept inflated for 24–48 hours. If bleeding has stopped on deflating the balloon, and no further bleeding occurs after 6–8 hours of further observation, the balloon can be removed. Balloon tamponade is helpful in preserving gas exchange in the non-bleeding lung in patients with massive hemoptysis. This technique can also be used as a stop-gap measure to support the patient before arteriographic embolization or surgical resection. Balloon tamponade in the manner described above, can however produce ischemic mucosal injury and pneumonia in the obstructed segment.

Unilateral Lung Ventilation

If bronchoscopy can only lateralize the lung from which bleeding occurs without exactly localizing the bleeding segment or lobe, a modified balloon tamponade technique may be employed. The patient is first intubated with a large bore endotracheal tube. The bleeding site is lateralized by a flexible or rigid bronchoscope. If the right lung is bleeding, the endotracheal tube is advanced into the left main bronchus, permitting ventilation of the left lung only, and preventing aspiration of blood from the bleeding right lung into the left side (Fig. 1A). If the left lung is bleeding, a Fogarty balloon catheter is passed on the outside of the endotracheal tube, to a point below the lower end of the endotracheal tube. Through a fiberoptic bronchoscope passed via the endotracheal tube, the tip of the Fogarty balloon catheter is now guided into the left main bronchus, and the balloon is then inflated. The fiberoptic bronchoscope is now removed. The endotracheal tube now serves to ventilate the right lung, and blood from the bleeding left lung is prevented from being aspirated into the right lung (Fig. 1B). Selective intubation of the right lung carries the danger of occluding the right upper lobe bronchus orifice.



Double-lumen endotracheal tube
Balloon of right lumen inflated in trachea
Balloon of left lumen inflated in left main bronchus
Right
Left (side of bleeding)

Fig. 2: Schematic representation of proper placement of a left-sided double lumen endotracheal tube. The inflated ballon in the trachea allows ventilation of the right lung. The inflated balloon in the left main bronchus prevents spill-over from left into right side

Unilateral ventilation is often unsuccessful in maintaining satisfactory gas exchange, particularly if aspiration of blood has already occurred into the non-bleeding lung.

Double-Lumen Endotracheal Tubes

In very selected situations, separation of the two lungs can be achieved by double lumen endotracheal tubes (Fig. 2). These tubes are often extremely difficult to place, and need an experienced and skilled anesthetist. There is danger of the tube getting blocked by secretions and clotted blood. It is often impossible to pass a fiberoptic bronchoscope through the small lumen to verify the position of the tube. If successfully placed, both lungs can be ventilated independently, and aspiration of blood from one lung to the other is prevented. The patient often needs to be paralyzed to allow efficient ventilation. Other complications include dislodgment of the tube, and tracheobronchial rupture from use of too large a tube, or overinflation of the balloon.

Positioning of the patient A patient with massive hemoptysis should be positioned with the bleeding lung down so as to confine the blood to that lung and prevent aspiration into the other. Once an airway is established, patient position is controversial. Blood could clot in the dependent lung and in the airways of that lung causing a permanent atelectasis. If bleeding is from the pulmonary circulation, placing the bleeding lobe or lung higher would, through gravity, perhaps lessen bleeding by creating zone I conditions in which alveolar pressure is higher than the pulmonary artery pressure.

In very brisk bleeds, a bronchoscopic evaluation often fails to lateralize the side of the bleed. This happens when the briskness of bleeding outstrips or is faster than what can be removed by suction, so that vision through the bronchoscope is obscured. A rigid bronchoscope may then be of greater value, as more efficient suction is possible through it. Even so, bronchoscopy at times fails to be of diagnostic help, and is unable to lateralize and localize the site of bleed.

Arteriography and Embolotherapy[17-19]

We have no experience with either unilateral ventilation or double lumen endotracheal tubes in the management of massive hemoptysis. Therefore, if bronchoscopic examination allows identification of the site of the bleed, and if the bleed cannot be controlled by topical methods used via the bronchoscope, we go immediately for arteriography. Arteriography is also promptly done if bronchoscopy fails to lateralize the bleed and localize its site. Initially bronchial arteriography is done. It should be noted that non-bronchial systemic collateral vessels from the axillary, subclavian and internal mammary arteries can also feed into diseased areas of the lung, and be responsible for massive hemoptysis. Once the bleeding site is identified by arteriography, embolotherapy is performed at the same sitting. The bleeding should stop; if it persists the pulmonary arteries are examined angiographically, and if a bleeding site is determined, embolotherapy is performed to stop the bleed. Successful long-term control of bleeding after embolization ranges 70–88%, with follow-up periods ranging 1–60 months.

Successful embolization depends on the interventional radiologist's experience and expertise. Technical failure occurs in 4–13% of attempted embolizations because of failure to cannulate the artery. If the anterior spinal artery branch arises from a bleeding bronchial artery, embolization should be avoided as it could otherwise cause spinal cord injury and paralysis. When the position of the tip of the catheter is unstable, reflux of embolic material into the aorta has resulted in systemic embolization, with dangerous complications due to embolic infarction of other organ systems.

Recurrent hemoptysis generally indicates incomplete embolization due to incomplete evaluation of systemic collaterals seen frequently in patients with mycetoma and in tuberculous disease. Recurrent hemoptysis could also be due to bleeding from the pulmonary vessels.

Surgery

Surgery is indicated in the following situations—

- In uncontrolled massive hemoptysis when the site of bleeding has been lateralized, and preferably localized to a segment or lobe.
- When embolization is not available or feasible, or when the patient continues to bleed in spite of embolization. The site of bleeding needs to be established by diagnostic bronchoscopy.
- When bleeding from a known site within a lung is associated with persistent hemodynamic instability and respiratory compromise.

- As definitive therapy in patients whose hemoptysis has stopped or has markedly reduced, and who are hemodynamically stable.

We would prefer to avoid immediate definitive surgery in patients whose bleeding has ceased spontaneously, or following bronchoscopic procedures, except under exceptional circumstances. Elective surgery is perhaps best planned at a later date when the patient's condition has improved significantly.

Surgery is contraindicated under the following circumstances—

- In the presence of well-marked arterial hypoxemia and carbon dioxide retention.
- In patients with poor pulmonary reserve, with dyspnea at rest, or on slight exertion.
- In bilateral lung disease.
- Inability to lateralize and localize the site of bleeding.
- In patients with diffuse disease as in multiple arteriovenous aneurysms or malformations, cystic fibrosis and non-localized bronchiectasis.
- In patients with pulmonary hypertension—a mean pulmonary artery pressure greater than 30 mm Hg is a contraindication to surgical resection.

If surgery is decided upon, a few basic investigations need to be done to assess the risk and fitness for surgery. Bedside spirometry to measure the FVC and FEV_1, and in doubtful cases quantitative ventilation-perfusion scanning may be used to predict the cardiac output and the ventilation directed toward the portion of lung that is to be resected. The postoperative FEV_1 can be predicted from the above information. A predicted postoperative FEV_1 of less than 800 mL contraindicates surgery because of the high risk of persistent severe postoperative respiratory failure.

Postoperative complications are common and include the necessity for prolonged ventilatory support, bronchopleural fistula, infection and recurrent pulmonary hemorrhage. The overall mortality ranges from 10% to 50%. Active bleeding at the time of surgery is associated with a greater degree of morbidity and mortality, probably related to an increased risk of aspiration. As far as possible, surgery, if decided upon, should be done in between episodes of bleeding in massive hemoptysis, as this significantly reduces morbidity and mortality.

Better techniques in bronchial vessel embolization and in other non-surgical bronchoscopic therapeutic procedures have reduced the need for emergency surgery in the management of massive hemoptysis.

MANAGEMENT OF SEVERE IATROGENIC HEMOPTYSIS

Massive Hemoptysis Due to Tracheoarterial Fistula[10]

This is generally fatal, if the tracheostomy tube erodes the inominate artery. The following steps should be tried—

- Overinflate the cuff in the hope that tamponade is achieved over the bleeding site.
- Apply downward and forward pressure on top of the tracheostomy tube, tamponading the potential bleeding point at the stoma.
- If bleeding slows or stops, an endotracheal tube should be placed distal to the tip of the tracheostomy tube. Ideally a surgeon should be present when the tube is removed.
- If bleeding restarts the surgeon can attempt a finger tamponade of the inominate vessel against the sternum.
- A definitive repair in the theater should be undertaken by the surgeon as soon as possible.

Iatrogenic Rupture of the Pulmonary Artery during a Swan-Ganz Catheterization[20]

A balloon tamponade of the ruptured vessel with the Swan-Ganz catheter is helpful. The balloon is first deflated; the catheter is withdrawn 5 cm and the balloon inflated with 2 mL air. It is then allowed to float back into the bleeding vessel so as to occlude it. The patient should be immediately intubated in the main stem bronchus opposite to the involved lung, to minimize aspiration. More often than not death occurs from bleeding before this can be accomplished.

If bleeding is reduced or arrested an urgent angiography is performed to detect the site of tear. Embolization of the affected vessel is performed if a tear or pseudoaneurysm is present.

MANAGEMENT OF SEVERE INTRA-ALVEOLAR HEMORRHAGE

Selective arterial embolization is obviously not possible. For immunologically mediated disease, corticosteroids, cytotoxic agents, plasmapheresis are available options.

To start with methylprednisolone is given in a dose of 1 g intravenous (IV) daily for 3 days followed by oral prednisolone 1 mg/kg per day for a week, the dose being gradually tapered down to a maintenance dose of 10 mg/day. Corticosteroids are often combined with cytotoxic drug therapy in the management of vasculitides and immunological lung disorders.

Recombinant factor VIIa has been used successfully for treatment of diffuse alveolar hemorrhage due to disseminated aspergillosis, bone marrow transplantation, small vessel vasculitis and cystic fibrosis.[21,22]

CHAPTER 36

Diseases of the Pleura in the Critically Ill

PNEUMOTHORAX IN THE INTENSIVE CARE UNIT

The most important cause of pneumothorax in the intensive care unit (ICU) is iatrogenic, related to invasive procedures or to barotraumas. Patients with secondary pneumothorax due to pre-existing lung disease may also be admitted or transferred to the ICU because of increasing respiratory distress and hypoxemia. Tension pneumothorax always necessitates intensive care; its early diagnosis and prompt treatment make the difference between life and death. Patients with trauma to the chest often receive critical care as besides suffering a pneumothorax they may have an injury to the chest wall, lung or mediastinal structures.

Iatrogenic Pneumothorax

Insertion of a Central Venous Catheter

The most common cause of iatrogenic pneumothorax in the ICU is following insertion of a central venous catheter in the subclavian or the internal jugular vein. The pleural complications following insertion of a central venous catheter have been discussed earlier in the Section Procedures and Monitoring in the Intensive Care Unit. Most pneumothoraces occur at the time of the procedure due to direct lung puncture, but delayed pneumothoraces are not uncommon. Therefore, a radiographic examination of the chest should be done not only soon after the procedure but also 12–24 hours later. If a small pneumothorax is diagnosed and the patient is asymptomatic and not on mechanical ventilator support, the catheter need not be removed, provided repeated radiography of the chest shows that the leak has not increased. If however the patient is being mechanically ventilated, or the pneumothorax is large, or the patient is symptomatic, or shows gas exchange abnormalities, the central line should be promptly removed and a tube thoracotomy performed as soon as possible.

Barotrauma

An important cause of pneumothorax in the ICU is barotrauma caused by mechanical ventilator support. Barotrauma occurs in 3–10% of patients on mechanical ventilation and includes interstitial emphysema, pneumothorax, pneumomediastinum, pneumoperitoneum and subcutaneous (surgical) emphysema. The most frequent and most clinically important of all these is pneumothorax[1] which occurs in 1–15% of all patients on mechanical ventilation. The number of ventilator days, aggressive ventilator strategies, the degree of positive end-expiratory pressure (PEEP) used, and underlying disease [chronic obstructive pulmonary disease (COPD), acute respiratory distress syndrome (ARDS), necrotizing pneumonia] all influence the incidence of pneumothorax.[2] When pneumothorax occurs during mechanical ventilation more than 30% develop tension pneumothorax.[2]

The early sign of barotrauma during mechanical ventilation is interstitial emphysema, manifest as linear air streaks within the interstitium and by a perivascular air halo. Subpleural air cysts may also be present and warn of impending pneumothorax. The latter may however occur without any radiological evidence of interstitial emphysema or subpleural cysts. Ultrasonography has been shown to help in the bedside diagnosis of pneumothorax. The absence of lung sliding on an ultrasonographic examination of the chest is believed to denote a pneumothorax[3] although false-positive signs may occur in patients with emphysematous bullae or in patients with pleural adhesions.

Whenever radiographic evidence of barotrauma is detected, without the occurrence of a pneumothorax, ventilatory settings must be suitably modified (lowered PEEP, lower tidal volumes) and increased sedation considered. A close clinical and radiological follow-up is necessary in anticipation of a pneumothorax.

Tension Pneumothorax

Tension pneumothorax in the ICU is most frequently observed when pneumothorax results in patients on mechanical ventilation. It may however also occur in secondary pneumothorax or in a primary pneumothorax. It is characterized by air entering the pleural space during inspiration, but because of a check-valve mechanism at the site of rupture, little or no air can gain egress back into the lung and hence to the outside during expiration. The intrapleural pressure continues to increase and causes rapid cardiorespiratory collapse.

The patient is tachypneic, breathless, cold, clammy, extremely distressed and gasping for air. The markedly increased intrapleural pressure together with the marked mediastinal shift to the opposite side hinders venous return. Hence, there is marked tachycardia and hypotension. The total collapse of the lung, together with the preservation of a fair degree of blood flow through it leads to a large right to left shunt within the collapsed lung so that there is increasing hypoxia, cyanosis and increasing respiration failure. The markedly increased intrapleural pressure on the affected side is transmitted to an extent to the contralateral pleural space so that the lung function of the contralateral side is also adversely affected. Ultimately, if the tension pneumothorax is not promptly relieved, there is well-nigh stoppage of venous return because of a tamponade-like effect on the heart. A cardiac arrest often associated with an electromechanical dissociation on the electrocardiogram (ECG) is the end result.

Diagnosis[4]

Tension pneumothorax is a dire emergency and diagnosis should be clinical, at the bedside. Tachypnea, tachycardia, and respiratory distress with absent breath sounds on the affected side are observed. A hyper-resonant note on the affected side may be missed if the tension within the pleural space is marked. The heart and mediastinum are shifted to the opposite side.

Tension pneumothorax in a patient on mechanical ventilator is characterized by the sudden appearance of respiratory distress, apprehension, tachycardia, tachypnea, hypotension, cyanosis or a sharp fall in O_2 saturation. The patient clashes continuously with the ventilator, is restless, cold, clammy and there is a marked increase in both peak pressure and pause pressure, decreasing compliance and increasing auto PEEP. Difficulty in bagging the patient with an Ambu bag or providing adequate tidal volumes is also noted. Breath sounds are absent on the ipsilateral side. It should be noted that at times breath sounds heard on the normal side may be transmitted to the affected side, particularly in patients on ventilator support (see Chapter Procedures in the Intensive Care Unit).

The diagnosis in comatose patients or in patients who already are critically ill (before the event) may be delayed. Sudden unexplained hypoxia and tachypnea in these patients should always arouse suspicion of a possible tension pneumothorax.

Treatment[4]

Treatment should not be delayed and should not await radiographic confirmation if the clinical features described above are present. This is particularly crucial in patients receiving mechanical ventilation, as death due to quickly mounting intrapleural tension can otherwise result in minutes. If a chest tube is not immediately available, a large bore needle is pushed into the pleural space through the second intercostal space in the midclavicular line. A rush of air is noted on entering the pleural space. A large intercostal drainage chest tube can then be placed and connected to a drainage system to drain the large air leak that is invariably present if the patient is on mechanical ventilator support (see Chapter Procedures in the Intensive Care Unit).

Once intrapleural tension falls, there is a rapid relief in symptoms and signs. The tachycardia subsides, the blood pressure rises and oxygen saturation and PaO_2 increase very significantly. If the patient is on the machine, the peak and plateau pressures fall and the compliance improves. Ventilator settings may need modification to allow good gas exchange and at the same time minimize the air leak into the pleura. The sooner the ventilator is removed the quicker the healing of the tear in the pleura.

Secondary Pneumothorax

Secondary pneumothorax must be drained through intercostal tube drainage even if the pneumothorax is small. Aspiration should be considered only in asymptomatic small pneumothoraces. Air leak may often persist in a secondary pneumothorax so that the lung may take more than 7 days to expand even with adequate drainage. Surgical intervention may be necessary if the lung fails to expand; chemical pleurodesis is an alternative approach.

Bronchopleural Fistula[5]

A bronchopleural fistula is characterized by a communication between the bronchial tree and the intrapleural space. A bronchopleural fistula is diagnosed when there is a failure of the lung to expand in spite of adequate chest tube drainage of the pneumothorax. This is observed in some patients who suffer a pneumothorax during ventilator support, in a few patients following trauma to the chest, or following diagnostic and therapeutic procedures such as thoracic surgery.

In a critical care unit, the most common cause of a bronchopleural fistula is barotrauma during mechanical

Box 1: Management of pneumothorax with a bronchopleural fistula

- Drain pneumothorax with a large-bore drain: avoid suction or use very soft suction—else air leak will increase
- Reduce "steal flow" (which is the difference between inspired volume and expired volume) by keeping the diseased lung in dependent position
- Monitor "steal flow"
- If on ventilator support—
  - Reduce tidal volume, go off positive end expiratory pressure
  - Reduce inspiratory time and if possible the tidal volume
  - If possible, allow spontaneous respiration, using bilevel positive airway pressure (BiPAP) or continuous positive airway pressure (CPAP)
- If air leak is not reduced over time, attempt to seal site of leak with a fibrin seal through a bronchoscope
- If the above measures fail—
  - Surgery, if patient's condition allows
  - Double lumen intubation for single lung or differential ventilation

ventilation causing a large communication between a fair-sized bronchus and the pleural space. This occurs particularly in the presence of serious underlying parenchymal lung disease—for example, ARDS or necrotizing pneumonia.

For all practical purposes, if in a patient with pneumothorax, there is a continuous air leak for more than 24–48 hours in spite of adequate chest tube drainage, a bronchopleural fistula exists. If a patient is on ventilator support, a persistent large air leak results in failure of lung re-expansion, loss of delivered tidal volume, inability to use PEEP and alveolar hypoventilation which results in hypercapnia.

Management[5]

The management of a bronchopleural fistula is summarized in Box 1.

PLEURAL EFFUSIONS IN THE CRITICAL CARE UNIT

It is not the purpose of this section to elaborate on the subject of pleural effusion. Relevant points in relation to pleural effusion in the critical care unit need to be kept in mind.

- There needs to be a collection of near 350–500 mL of pleural fluid before it can be clinically detected. The most constantly present physical finding over pleural fluid is diminished or absent breath sounds. A stony dull note is present if there is at least 500 mL of pleural fluid.
- In the ICU, the best way to detect a suspected pleural effusion is through ultrasonography of the chest.
- Pleural effusions are caused not just by diseases within the lungs; they can be due to systemic causes and to diseases of the heart, liver and kidneys.
- The only way to distinguish between a pleural transudate and exudate is by doing a diagnostic tap and examining the pleural fluid. Light's criteria enable one to make this differentiation.
- Pleural exudates as defined by Light's criteria have one or more of the following criteria—
  - The total protein in the pleural fluid divided by the total serum protein is more than 0.5.
  - The lactate dehydrogenase (LDH) of the pleural fluid divided by the LDH in the serum is more than 0.6.
  - The LDH of the pleural fluid is greater than two-thirds of the upper limits of the normal LDH in the blood.
- Pleural transudates have none of the above features. In addition, pleural exudates have high cell counts.
- One must be wary of the fact that a pleural transudate—say due to heart failure, may occasionally show a higher protein content than expected if the patient has been diuresed significantly by a diuretic, like furosemide.
- The intensivist needs to know the common causes of pleural effusion encountered in the ICU.
- In most medical ICUs, transudates are more common than exudates. The important causes of transudates are—
  - Congestive cardiac failure; this is the most common cause of bilateral pleural transudates.
  - Hypoalbuminemia from any cause can also result in bilateral transudates. Renal disease and cirrhosis of the liver are two other important causes of pleural transudate.
  - Atelectasis may also be associated with a small pleural effusion which on examination is a transudate.
  - Ascitis due to hepatic dysfunction can track into mainly the right chest through pores present on the right dome of the diaphragm leading to a pleural transudate. At times, the presentation is with more fluid in the chest and much less in the abdomen.
- There are many causes of pleural exudates encountered in medical and surgical ICUs. The presence of an exudate should prompt a careful physical examination not just confined to the lungs but to all other organ systems. Special relevant investigations may be necessary to make a complete diagnosis.
  - The most important and frequent cause of a pleural exudate is pneumonia—either community acquired, nosocomial, or aspiration.
  - Other important causes are pulmonary embolism (the pleural fluid is often hemorrhagic), pancreatitis, postmyocardial infarction, esophageal rupture, pleural effusion secondary to a subdiaphragmatic pathology—as for example, a liver abscess or a subphrenic abscess. Mitotic lesions involving the lung or pleura may present with a pleural effusion which on examination is an exudate.

The important causes of exudates and transudates constituting a pleural effusion are listed in Box 2 and Box 3, respectively.

At times, the pleural fluid is blood stained as in pulmonary infarction, malignancy involving the lungs, pleura, and rarely in tuberculosis.

Box 2: Causes of pleural exudates

- Infections—
  - Tuberculosis
  - Other infections
  - Bacterial
  - Viral
  - Nocardial
  - Fungal
  - Parasitic
- Malignancies—
  - Pleural metastasis
  - Lymphoma
  - Pleural mesothelioma
- Vascular—
  - Pulmonary embolism
  - Vasculitides
- Gastrointestinal (GI) diseases—
  - Pancreatitis
  - Pancreatic pseudocyst
  - Perforation of the esophagus
  - Intrahepatic or subphrenic abscess
- Inflammatory (noninfectious)—
  - Asbestosis
  - Radiation
  - Uremic
  - Post-thoracotomy
  - Post-transplant
- Connective tissue diseases
- Iatrogenic, traumatic (including hemothorax)
- Miscellaneous—
  - Lymphangioleiomyomatosis
  - Meig's syndrome
  - Yellow nail syndrome
  - Chylothorax

Box 3: Causes of pleural transudate

- *Common causes*—
  - Congestive heart failure
  - Cirrhosis of liver
  - Nephrotic syndrome
  - Hypoalbuminemia from any cause
  - Continuous peritoneal dialysis
- *Uncommon causes*—
  - Superior vena caval obstruction
  - Constrictive pericarditis
  - Hypothyroidism
  - Atelectasis
  - Urinothorax
  - Budd-Chiari syndrome

A hemothorax generally results following blunt and penetrating chest trauma, invasive procedures, malignancy, hemorrhagic disorders and the use of anticoagulation.

The presence of chyle (rarely seen in the ICU) is suggested by the presence of milky pleural fluid, the presence of chylomicrons and triglycerides more than 110 mg/dL.

A diagnostic pleural tap if performed under ultrasound guidance with meticulous attention to technique should not cause complications. Pneumothorax has however been reported in 4–30% of cases.[6] Liver or splenic puncture may occur if the patient is not sitting upright but is recumbent during the procedure. Recumbency leads to the migration of the abdominal viscera upward. The upward displacement of abdominal viscera is however easily detected by ultrasonography, so that this complication of accidental splenic or liver puncture should be prevented if the diagnostic tap is done under ultrasonic guidance. A relative contraindication for a diagnostic tap is the presence of a bleeding disorder.

A diagnostic pleural tap of a small pleural effusion when the patient is on mechanical ventilator support risks a pneumothorax. The tap should always be done under ultrasound guidance and the ventilator turned off very briefly just before the needle enters the pleural space. It can be restarted the moment the needle is withdrawn.

THERAPEUTIC THORACOCENTESIS

The primary indication for a therapeutic thoracocentesis is the relief of dyspnea. The major relative contraindication of thoracocentesis is a bleeding diathesis or anticoagulation. The danger of a pneumothorax is significant if therapeutic thoracocentesis is attempted in patients on mechanical ventilator support.

It is best not to remove more than a liter and a half at one time. The occurrence during the procedure of cough, breathlessness, tightness in the chest is an indication to stop the paracentesis. A precipitous drop in pleural pressure to less than –20 cm H_2O can cause problems. This is almost always avoided if the fluid removed is not in excess of a liter or so at one time.

Complications of therapeutic paracentesis are pneumothorax, bleeding, particularly if the patient has a bleeding tendency and the introduction of secondary infection, if an aseptic technique is not followed.

There are three complications which are unique to thoracic paracentesis. They are hypoxemia, unilateral pulmonary edema and hypovolemia. Hypoxemia occurs because of worsening ventilation perfusion ratios despite relief of dyspnea. It is related to occult or clinical pulmonary edema in the ipsilateral lung. Ipsilateral acute pulmonary edema occurs as a complication when the collapsed lung (particularly if it has remained collapsed for weeks or months) quickly expands following rapid removal of pleural fluid. The increased negative pressure within the pleural space causes transudation of fluid into the alveoli resulting in pulmonary edema. This negative pressure pulmonary edema causes breathlessness, which may manifest during the withdrawal of fluid, or minutes or even hours after withdrawal. A slower removal of fluid restricted generally to about a liter at a time generally prevents these complications.

The reason for the relief of dyspnea following thoracic paracentesis is debatable. It cannot be explained solely by an increase in PaO_2 as this increase is modest. In fact in some patients there is an initial fall in PaO_2 which subsequently rises. It also cannot be easily explained by an increase in the lung volume, as immediate changes in lung volume are modest and variable. Perhaps relief of dyspnea following thoracocentesis may be the result of decreased stimulation of lung, or chest wall receptors, or of both.[7-9]

CHAPTER 37

Negative Pressure Pulmonary Edema

INTRODUCTION

Negative pressure pulmonary edema (NPPE), also called post-obstructive pulmonary edema (POPE), is a dangerous and potentially fatal condition, which is of particular relevance both in anesthesiology and critical care. It typically occurs perioperatively[1,2] following removal of the endotracheal tube. Very occasionally the patient has severe laryngeal spasm with resulting acute severe obstruction to the airway. The markedly increased negative intrapleural pressure and intra-alveolar pressure caused during breathing attempts against a closed glottis leads to transudation of fluid into the interstitium and alveoli of the lung with sometimes florid pulmonary edema.[3,4]

The NPPE that results from acute upper airways obstruction is termed NPPE type I. The incidence of NPPE I has been reported to be 0.05–0.1% of all anesthetic practices, though it is suggested that it perhaps occurs more frequently than is generally documented. NPPE I develops immediately or soon after the onset of acute upper airways obstruction.

Other causes of acute upper airways obstruction causing low pressure pulmonary edema include surgical manipulation of the upper airway,[5] strangulation, hanging, foreign bodies, upper airway tumors, croup, epiglottitis, migration of a Foley's catheter balloon into the larynx when the Foley's catheter is used to tamponade the nose in epistaxis. NPPE can also occur in near drowning accidents (due to intense laryngospasm), and following a blocked endotracheal or tracheostomy tube.[6]

Type II NPPE is believed to result following relief of upper airways obstruction caused by big tonsils, hypertrophic adenoids or a redundant uvula.

In adults, the most frequent and important cause of NPPE is postoperative laryngospasm.

PATHOPHYSIOLOGY[3,4,7,8]

The highly negative intrapleural pressure (as much as –40 to –100 cm H_2O compared to –3 to 10 cm H_2O) causes a dramatic increase in systemic venous return to the heart, associated with a fall in cardiac output due to reduced pulmonary venous drainage into the left atrium. The conjunction of increased capillary pressure with a markedly negative intra-alveolar pressure leads to fluid moving out from the vascular system first into the interstitial tissue spaces and then into the alveoli, resulting in pulmonary edema. Pulmonary edema persists even after the airway obstruction is relieved.

Pathophysiology of NPPE II

The pathophysiology of NPPE II is not quite clear. It is proposed that chronic upper airways obstruction leads to a modest level of positive end-expiratory pressure (PEEP) and increased lung volumes. Relief of obstruction removes PEEP, returning both lung volumes and pressures at end-expiration to normal. It is postulated that altered permeability and some degree of occult interstitial edema do not resolve immediately and that the removal of PEEP leads to interstitial fluid transudation and pulmonary edema. The explanation given above is rather feeble and unsatisfactory. NPPE II is not considered further in this section.

CLINICAL FEATURES OF NPPE I[9]

The symptoms of NPPE usually develop immediately after extubation though at times the onset may be delayed for

a few hours or even later.[10] The importance of close peri-operative and post-operative vigilance and care cannot be over-emphasized.

The onset of pulmonary edema is characterized by tachypnea, tachycardia, restlessness and respiratory distress. The oxygen saturation shows a sharp drop. Manifestations of acute upper airways obstruction include stridor, use of accessory muscles of respiration, retraction of suprasternal, supraclavicular areas and of the intercostal spaces during inspiration. Auscultation reveals crackles and wheezes. In severe cases pink frothy sputum literally wells out of the mouth. Arterial blood gases show a low PaO_2 (<60 mm Hg on room air); hypercapnia may be present. pH is often less than 7.3 both because of hypercapnia and at times due to lactic acid acidosis.

X-ray of the chest show frank pulmonary edema. There is comparatively little data with regard to the distribution of post-extubation pulmonary edema. High resolution computed tomography (HRCT) studies suggest there is a striking preferential central and non-dependent distribution of ground glass attenuation (edema) which parallels the pleural and interstitial pressure gradients.[11]

DIFFERENTIAL DIAGNOSIS

The diagnosis is promptly suggested by the history and the presence of laryngeal spasm. Symptoms usually occur immediately or within 1 hour of extubation, but occasionally may be further delayed. The major differential diagnosis particularly in elderly patients is acute left ventricular failure. It is possible that the stress of acute upper airways obstruction could decompensate a heart with underlying valvular, hypertensive or coronary artery disease. Acute respiratory distress syndrome (ARDS) does not enter into the differential diagnosis unless there is evidence of sepsis or prolonged surgery associated with multiple blood transfusions. Fluid overload during surgery should always be a consideration but none of these entities is associated with the features of an upper airway obstruction.

MANAGEMENT

Management consists of—

- Relief of hypoxia with oxygen through a high flow mask.
- Control of the airway is imperative if it continues to be obstructed. This would involve reinsertion of the endotracheal tube or performing a tracheostomy in the presence of a severe unrelenting laryngospasm. Attempts at reintubation by inexperienced anesthesiologists or intensivists can do more harm.
- Hypoxia and pulmonary edema causing acute respiratory failure (ARF) need ventilator support. In the milder cases noninvasive ventilator support using continuous positive airway pressure (CPAP) or biphasic positive airway pressure (BIPAP) may suffice. In the more severe cases invasive ventilator support is mandatory either after reintubation or following a tracheostomy. PEEP should be used; the value titrated to improve oxygenation without causing cardiovascular compromise. The fraction of inspired oxygen (FiO_2) should be increased (if necessary even to 100%) to ensure adequate relief of hypoxia.
- Intravenous frusemide is given in titrated doses or as a continuous IV infusion so that a urine output of 100 mL/hour (in adults) is maintained.
- Hypotension may need appropriate treatment with vasopressors and inotropes.

Very rarely NPPE may evolve into ARDS and multiple organ failure.[12]

Mechanical Ventilation in the Critically Ill

- Mechanical Ventilation in the Critically Ill
- Weaning from Ventilator Support

CHAPTER 38

Mechanical Ventilation in the Critically Ill

INTRODUCTION

Mechanical ventilation as a therapeutic intervention was first widely used during the poliomyelitis epidemic in Europe and the United States in the 1940s and 1950s. Since then there have been great advances in technology, so that negative-pressure ventilators that were used originally in the 1940s and 1950s have been replaced by increasingly sophisticated positive pressure machines.

The purpose of mechanical ventilation is to provide ventilatory support partially or fully by an external device to patients who cannot maintain an adequate gas exchange, as for example in acute respiratory failure. Ventilator support also reduces the oxygen cost of breathing. Mechanical ventilator support, however, has its own hazards; these include ventilator-induced lung injury, barotrauma, adverse hemodynamic changes and the potential for serious nosocomial infection.

Ventilator support to any critically ill individual requires expertise and round-the-clock supervision and care. Life in many such patients is totally dependent on the efficient working of a machine. A mechanical failure, accidental disconnection of the machine from the patient, or a sudden obstruction of the airway, are all potential disasters which can lead to sudden death or brain damage from protracted hypoxia. A patient on mechanical ventilator support must therefore never be left unattended even for a minute. Thus, the optimal and safe use of mechanical ventilation is only possible in intensive care units (ICUs). Though the standard of critical care (which includes ventilator support) has improved and continues to improve significantly at least in the large metropolitan cities of India, care provided in large public and district hospitals in India and many other developing countries leaves much to be desired. In fact, critical care units in the poor countries of the world are often mere apologies of what they ought to be, or are nonexistent. In the absence of a full-fledged ICU, the next best option is to use ventilator support in a patient who needs it, in a special or even a general ward, provided that the medical registrar and nurses are well-trained in ventilator management. We managed several decades back, to do this at one of the large public teaching hospitals in Mumbai, and salvaged a number of very ill patients who would otherwise have died. The need for all medical registrars (at least in the large hospitals of India and other developing countries) to be familiar with the use of mechanical ventilators is thus imperative. It is the duty of the medical and administrative staff of such hospitals to provide basic facilities, and train a team of doctors and nurses who can manage critically ill patients on ventilator support, even in the absence of well-equipped ICUs.

This chapter to start with briefly tabulates the physiological effects of mechanical ventilation. It then proceeds to discuss the indications and criteria for ventilator support, types of ventilators for intermittent positive-pressure ventilation (IPPV), and the management of ventilatory support. This is followed by a description of the different modes of ventilator support, and the use of positive end-expiratory pressure (PEEP) as an adjunct. Then comes a section on the complications of mechanical ventilation. The chapter ends with a discussion on noninvasive ventilator support and of respiratory monitoring during mechanical ventilation.

9

INDICATIONS FOR MECHANICAL VENTILATION (BOX 1)

In many ICUs, particularly in the smaller cities of India, there is yet a certain hesitation and trepidation observed regarding the use of mechanical ventilation in patients who need ventilator support. In other words, mechanical ventilation is started much later than it should have been in the natural history of a disease requiring ventilatory support. The other equally common misconception and error is to be in a tearing hurry to remove ventilator support in a critically ill patient. Such a premature withdrawal of ventilator support is love's labor's lost—the patient regresses from near recovery to a critical state, which again necessitates the use of the ventilator. Indications for mechanical ventilation are discussed below.

Established Acute Respiratory Failure

Early ventilator support is now initiated by all good units in patients with acute respiratory failure.[1] The criteria and timing for initiating support depend on the etiological agent producing acute respiratory failure, and above all, on the rate at which respiratory function is observed to deteriorate. Different diseases producing acute respiratory failure present their own special problems with regard to initiating mechanical ventilation, technicalities in maintaining ventilation, and difficulties in weaning the patient from ventilator support. It is therefore best from the practical point of view to consider the indications in acute respiratory failure, with reference to the different groups of diseases frequently encountered in the ICU.

Box 1: Indications for mechanical ventilation

A. Established acute respiratory failure—
   - Primary ventilatory failure where lungs are normal to start with, e.g. poisonings that depress the CNS, CNS and neuromuscular disorders (poliomyelitis, infective polyneuritis, myasthenia), snake bite, severe tetanus
   - Hypoventilating comatose patients
   - Acute pulmonary disease, e.g. fulminant pneumonia, acute lung injury (ARDS)
   - Fulminant pulmonary edema
   - Major or massive pulmonary embolism
   - Major or massive atelectasis
   - Patients with COPD in acute crisis, unresponsive to conventional therapy
   - Patients with acute severe asthma unresponsive to conventional therapy
   - Patients with severe respiratory muscle fatigue

B. Incipient respiratory failure—
   - Patients with excessive ventilatory demands
   - Obese patients who have undergone upper abdominal surgery, or poor risk surgical patients
   - Patients with acute/fulminant parenchymal lung disease with rapidly progressive impairment of pulmonary function and reserve
   - Respiratory muscle fatigue in critical illnesses

C. Low-output states—shock of any etiology

D. Purposeful hyperventilation—
   - To decrease intracranial tension in patients with head injury associated with increased intracranial tension
   - To reduce cerebral edema after CPR or massive CVA

Abbreviations: CNS, central nervous system; CPR, cardiopulmonary resuscitation; CVA, cerebrovascular accident; COPD, chronic obstructive pulmonary disease.

Ventilator Support in Primary Ventilatory Failure

The most common indication for mechanical ventilation is acute primary failure of ventilation. Ventilatory failure occurs commonly in poisonings that depress the central nervous system (CNS), in acute inflammatory and other diseases involving the CNS, in some patients with head injury, increased intracranial tension, poliomyelitis, acute infective polyneuritis and myasthenia gravis. Severe tetanus is an important cause of ventilatory failure in India. Neuromuscular paralysis following a krait or cobra bite is particularly common in South India. The lungs are normal to start with, but changes within the lungs (chiefly increasing widespread atelectasis), almost always occur if treatment is delayed. In many patients with neuromuscular disease, deterioration can occur suddenly, almost precipitously, with disastrous consequences. It is therefore wise to start early ventilatory support in these patients.

Ventilator Support in a Hypoventilating Comatose Patient

Deep coma is an indication for securing the airways with an endotracheal tube or a tracheostomy. Hypoventilation in such patients may be due to depressed respiratory drive or secretions causing obstructed airways or patchy atelectasis. Hypoxia and hypercapnia resulting from hypoventilation may further impair the conscious state, which in turn may further depress ventilation. Unless the patient is clearly hyperventilating, a deeply comatose patient is safer on mechanical ventilation.

Ventilator Support in Acute Pulmonary Disease

These patients are hypoxic due to hypoxemic acute respiratory failure. Typical examples are in acute lung injury (ALI), acute respiratory disorder syndrome (ARDS),[2] and fulminant pneumonia. Patients with acute pulmonary disease are difficult to ventilate. They have a strong respiratory drive, are often severely hypoxic, and fight the ventilator. An inability to maintain a PaO_2 of above 55 mm Hg while on oxygen at a flow rate of 6–8 L/minute, is an indication for initiating ventilator support. Other criteria for starting mechanical ventilation in these patients are dealt with later.

Ventilator Support in Fulminant Pulmonary Edema

Acute pulmonary edema, if fulminant, literally chokes the patient at the level of the alveoli. Mechanical ventilation is life-saving not only because it allows the maintenance of an adequate PaO_2, but perhaps also because the high inflation

pressures used to ventilate the lungs reduces the transudation of fluid from the alveolar capillaries into the alveoli. Ventilator support buys time during which diuretics like furosemide have a chance to act, and other corrective measures to treat the underlying cause of acute pulmonary edema may be profitably undertaken.

Ventilator Support in Acute Thromboembolic Lung Disease

Ventilator support is indicated if the PaO_2 is below 60 mm Hg on supplemental oxygen, particularly in the presence of shock.

Ventilator Support in Acute on Chronic Respiratory Failure in Patients with Chronic Airways Obstruction[3]

Many patients in this group are used to a low PaO_2 below 65 mm Hg, and a high $PaCO_2$ above 50–60 mm Hg. Ventilator support should not be used unless all other modalities of treatment have been of no avail, clinical deterioration is evident, and there is a further deterioration in the arterial blood gases and arterial pH. In such patients ventilatory support is fraught with difficulty, and requires experience and expertise.

Ventilator Support in Acute Severe Asthma[4]

Acute severe asthma is probably one of the most difficult problems for effective mechanical ventilation. Yet, ventilator support is life-saving in those cases of acute severe asthma not responding to corticosteroids, nebulized bronchodilators and other medical therapy.

Ventilator Support in Patients with Severe Muscle Fatigue

Severe muscle fatigue (involving the muscles of respiration), is an increasingly recognized and important cause of hypoventilation and respiratory failure. Muscle fatigue can occur in patients with primary neuromuscular disease involving the respiratory muscles. It occurs much more frequently in lung disease and in any condition (not necessarily involving the lungs), where ventilatory demands are excessive. The timing of initiating ventilator support in these patients is a matter of fine judgment. Altered blood gases or feeble ventilatory efforts are of course an immediate indication. Irregular breathing patterns, or the presence of a respiratory paradox in which the abdominal muscles move inward rather than outward during inspiration, point to excessive muscle fatigue. Respiratory alternans is characterized by alternate excursions involving the diaphragm and the intercostals, and is also a pointer to muscle fatigue. Another important pointer to impending disaster is the presence of apneic spells which are often forerunners of prolonged respiratory arrest. It is better to ventilate such patients even if the arterial blood gases are not significantly distorted, rather than wait for disaster to occur.

Factors, which precipitate and contribute to respiratory muscle fatigue are hypoperfusion of the muscles, hypermetabolic states leading to an increased work load on the muscles of respiration, hypoxia, electrolyte and acid-base disturbances, poor nutrition as in alcoholics, or those with chronic liver or renal disease, and in old, feeble, debilitated patients.

Incipient Respiratory Failure

Mechanical ventilation is increasingly being used in patients in whom some degree of respiratory failure is anticipated. Perhaps the most important group comprises patients who have to meet increased ventilatory demands, and who therefore sooner or later show evidence of respiratory muscle fatigue. This is typically seen in acute severe asthma, but can occur in numerous medical and surgical problems. It is difficult for a seriously ill patient to sustain a ventilatory rate of greater than 35–40/minute or a minute ventilation (V_E) greater than 10–12 L/minute for any prolonged period of time without increasing muscle fatigue and the danger of impending sudden respiratory failure.

There is a special category of surgical patients who frequently require ventilator support for impending or insidious respiratory failure. These are obese individuals who have undergone upper abdominal surgery. This often leads to fixed or splinted domes of the diaphragm resulting in a loss of volume in both lower lobes. These patients are markedly tachypneic, particularly in the presence of fever and infection; their V_E is often as high as 12–15 L/minute, and their respiratory rates between 35/minute and 45/minute. They maintain their arterial blood gases within the normal range for some length of time, but not uncommonly these patients go into sudden respiratory failure, deteriorate sharply, and pose problems in emergency intubation and ventilation. A quick anticipation of worsening problems calls for early intubation and ventilator support before such a disaster occurs.

Other susceptible patients in whom hypoventilation is a likely sequel include poor-risk surgical patients whose recovery from surgery or trauma is hindered by obesity, chronic lung disease, old age, debility and electrolyte imbalance. In all these patients, postoperative ventilatory support is merely an extension of surgical care in the operation theater. They may require mechanical ventilation for a period varying from a few hours to a few days, and are weaned off ventilator support when they can maintain adequate gas exchange on spontaneous breathing.

Similarly, in acute or fulminant parenchymal lung disease where the tempo of impairment of respiratory reserve and respiratory function is very rapid, it is best to anticipate events in advance to allow for elective intubation and ventilatory support.

Low-Output States and Septic Shock

Ventilator support is now always indicated in low cardiac output states as in cardiogenic shock, or for that matter in shock from any etiology. It is often used in septic shock, at times quite early in the natural history, when the march of events signifies a rapidly evolving dangerous clinical state. In shock from any

cause, and in low-output states of any etiology (for example, in advanced liver cell failure or multiorgan failure), tissue perfusion is inadequate in relation to tissue oxygen needs. Also, a low cardiac output is generally associated with a low PvO_2, which in turn is responsible for a low PaO_2. Shock of any etiology, which results in a low pulmonary artery pressure and diminished perfusion of the lungs leads to an increase both in the dead space (V_D)/tidal volume (V_T) ratio, as well as to a ventilation/perfusion imbalance. Ventilator support helps in two ways—

1. With an increase in FiO_2 (if needs be to 70–80%), the PaO_2 increases, and therefore both the arterial oxygenation and the arterial oxygen content rise.
2. The muscles of respiration are rested once the ventilator takes over the function of ventilation.

This prevents incipient respiratory failure from progressing to frank ventilatory failure, and even ventilatory arrest. In patients who breathe excessively, the oxygen cost of breathing is considerably increased. At rest, the normal work of breathing accounts for 2–3% of total oxygen consumption. This can increase in acute respiratory failure to as high as 35–40%. In low-output states, resting the overworked respiratory muscles through mechanical ventilation sharply reduces the oxygen cost of breathing and allows more oxygen to be diverted to vital organs starved of their oxygen supply. However, in critically ill patients, it is equally important to control fever, shivering, constant movement and restlessness, as these can all contribute to increased oxygen consumption, and thereby reduce the already meager available oxygen supply to the vital organs.

Mechanical Ventilation for the Specific Purpose of Hyperventilation

A comparatively rare indication for mechanical ventilation is to hyperventilate patients with head injury, when associated with increased intracranial pressure. Hyperventilating these patients reduces the $PaCO_2$, which leads to reduction in the cerebral blood flow, and hence in the intracranial pressure. Hyperventilation is generally combined with sedation and muscle paralysis to prevent coughing and clashing with the ventilator, as these could lead to a rise in intracranial pressure. Clinicians often prefer to manage unconscious neurological and neurosurgical patients with increased intracranial pressure, with controlled mechanical hyperventilation. The same approach is sometimes used to counter cerebral edema following resuscitation after a cardiopulmonary arrest or in patients with cerebral edema consequent to a massive cerebrovascular accident. However, the efficacy of hyperventilation in all the above-mentioned situations is temporary (generally not exceeding 48 hours) and debatable.

OBJECTIVE CRITERIA FOR INITIATING VENTILATOR SUPPORT IN ADULTS

The criteria enumerated in Box 2 are mere guidelines, and not sacrosanct rules. It is crucial to take the clinical picture, the evolution of the disease in a given patient, and the trend and rate of change in the parameters outlined below, into consideration. The parameters given in Box 2 apply to patients in ventilatory failure, and to respiratory failure occurring with acute lung disease; they are not applicable to patients with chronic obstructive airways disease. These patients even under normal or basal conditions may have a PaO_2 of 60 mm Hg, and a $PaCO_2$ between 55 mm Hg and 60 mm Hg. They are used to hypoxia and hypercapnia, and tolerate both rather well.

Box 2: Criteria for initiating ventilator support in adults

- Respiratory rate >35/min
- VC <10–15 mL/kg
- MV >10–12 L/min over a prolonged period
- Maximum inspiratory force <20 cm H_2O
- PaO_2 <60 mm Hg on nasal oxygen at 6–8 L/min and/or $PaCO_2$ >55 mm Hg
- Alveolar-arterial oxygen gradient >300–350 mm Hg on FiO_2 of 1
- V_D/V_T >0.6
- Visible excessive work of breathing in critically ill or debilitated patients
- Clinical evidence of respiratory muscle fatigue—
  - Poor chest excursions
  - Tachypnea
  - Respiratory muscle paradox, respiratory alternans
  - Apneic spells

Abbreviations: VC, vital capacity; MV, minute ventilation; V_D, dead space; V_T, tidal volume.

Types of Ventilators for Intermittent Positive Pressure Ventilation[5]

Ventilators in ICUs are either volume-cycled or pressure-cycled or time-cycled.

A volume-cycled, i.e. a volume-targeted ventilator, delivers a preset volume and continues to do so regardless of a change in the patient's airway resistance or lung compliance.

A pressure-cycled, i.e. a pressure-targeted ventilator, cycles to expiration after a specified preset pressure has been attained. Thus, gas flows into the lungs until a preset pressure limit is reached. The volume delivered will therefore change if the airway resistance and/or the lung compliance change.

In a time-cycled ventilator, the inspiratory phase ends when a predetermined time has elapsed. This time remains fixed, and is controlled by a timing mechanism within the ventilator, which is unaffected by conditions in the patient's lungs.

Volume-targeted ventilatory support is more flexible, easier to learn, and easier to manage than pressure-targeted or time-cycled ventilator support. All modern ventilators are capable of delivering adequate V_E and of varying the oxygen concentration (FiO_2) from 25% to 100%.

Most modern ventilators incorporate within a single unit, mechanisms that allow either volume-targeted or pressure-

Table 1: Comparison between volume-controlled (volume-targeted) and pressure-controlled (pressure-targeted) ventilation

Parameters	*Volume-targeted*	*Pressure-targeted*
Rate	Set or variable	Set or variable
Tidal volume (V_T)	Set	Variable
Peak airway pressure	Variable	Set
Peak alveolar pressure	Variable	Set
Peak flow	Set	Variable
I:E ratio	Variable	Set

Abbreviation: I:E, inspiration-expiration.

targeted ventilatory support, the use of PEEP, and the choice of several modes of ventilator support, detailed later. Adjustment of V_E, respiratory rates, flow rates, inspiratory-expiratory ratios are also possible. The ventilator is fitted with a series of alarms for better patient care, and can be fitted with modules that can monitor and display lung mechanics (compliance, airway resistance, wave-forms, flow-volume loops) and the end-tidal PCO_2.

From the clinical viewpoint, neither volume-targeted nor pressure-targeted ventilation offer a distinct advantage with regard to gas exchange, hemodynamic stability and pulmonary mechanics.

The major advantage of volume-targeted ventilator support is its ease of application, and the provision of a fixed V_T in spite of changing airway resistance or pulmonary compliance. The main advantage of pressure-cycled or pressure-targeted ventilation is that gas is delivered at a fixed preset pressure; if there is increased impedance to ventilation (either due to increased airways resistance or to a lowered pulmonary compliance), the V_T delivered falls. Overstretching of the alveoli with resulting volutrauma, barotraumas and biotrauma is thus prevented. Pressure-control ventilation may also be able to provide the high inspiratory flow demands of some critically ill patients.

For comparison between volume-controlled (volume-targeted) and pressure-controlled (pressure-targeted) ventilation see Table 1.

Management of Mechanical Ventilation

Initiating Ventilation—Basics of Initial Ventilator Set-up

There are a number of ventilator modes available to help ventilate a patient. We generally initiate ventilator support with volume-controlled or volume-targeted ventilation using the assist-control mode. In assist-control ventilation, the patient triggers the inspiration by a spontaneous effort which is enhanced by the ventilator. In this mode, if for some reason the patient fails to trigger the machine, the machine takes over, initiates inspiration and takes over full ventilatory support. Most patients with different respiratory problems can be adequately ventilated by the volume-targeted, assist control mode.

Tidal volume[6] The tidal volume for an individual patient should be set between 5 mL/kg and 10 mL/kg of body weight. Selection of V_T in a given patient is influenced by the nature of the disease, the approximate V_E requirement, pulmonary compliance, airway resistance, airway pressure, PaO_2 and $PaCO_2$.

Very low tidal volumes result in atelectasis, hypoventilation and hypoxemia. On the other hand, very high V_{Ts} can cause respiratory alkalosis, decrease cardiac output by reducing venous return and predispose to barotrauma, volutrauma and biotrauma. There is definite evidence that overstretch of alveolar walls through very large tidal volumes can induce lung injury.

In patients with normal lungs to start with (as in neuromuscular disease causing respiratory failure, CNS disease, coma, poisoning, and immediate postoperative conditions), the V_T is set at 10 mL/kg. In patients whose lungs are stiff because of abnormal respiratory mechanics (as in ALI, pneumonia) V_{Ts} are set at 5–7 mL/kg. A convenient algorithm is to start with 10 mL/kg, stabilize the patient and then progressively reduce the V_T to 5–7 mL/kg so that the plateau pressure does not exceed 30 cm H_2O.

Respiratory rate The rate is generally set between 10 and 14 breaths/minute, if the patient is clinically stable. Higher rates may be required (20–25/minute) in patients with stiff lungs [e.g. acute respiratory distress syndrome (ARDS)], so as to match the machine to the spontaneous breathing pattern of the patient. Lower rates may be necessary in chronic obstructive pulmonary disease (COPD) patients where V_E needs to be restricted. If the respiratory rate is too high, respiratory alkalosis, auto-PEEP and barotrauma can result. If too low, hypoventilation, hypoxemia and patient discomfort are observed.

Minute ventilation Minute ventilation is set according to the approximate ventilatory requirements of a patient and to start with is set at 5–10 L/minute. The V_E decided upon is also influenced by the nature of the disease and the altered respiratory mechanics for which ventilatory support is offered.

Inspiration-expiration ratio The I:E ratio to start with is set at 1:2 or 1:3 to allow sufficient time for expiration.

Oxygen concentration If the patient is hypoxic, the FiO_2 to start with should be 1.0. After 15–20 minutes, this is gradually reduced to a level, which allows a PaO_2 above or equal to 60 mm Hg, and O_2 saturation greater than or equal to 90%.

Inspiratory flow rate The inspiratory flow rate is usually set at 40–60 L/minute in volume-targeted ventilation. This can be increased to 60–100 L/minute in patients with high inspiratory flow demands. However, higher inspiratory flow rates would cause an increase in the peak inspiratory pressure. Lower flow rates can be used to decrease peak inspiratory pressure in patients who to start with have high peak inspiratory pressures (as in ARDS). Lowering inspiratory flow rates would increase inspiratory time, but decrease expiratory time—this could lead to air trapping, auto-PEEP, patient discomfort and barotrauma.

9

Box 3: Common problems encountered during initiation of ventilator support

A. Difficulty in synchronizing patient's respiration with the ventilator—
   - Reassure patient and use tranquillizers (diazepam 5–10 mg IV)
   - Use adequate alveolar minute ventilation to maintain $PaCO_2$ at 35–40 mm Hg
   - Use high FiO_2 temporarily to ensure there is no hypoxia
   - Increase V_T and RR beyond patient's spontaneous rate. Once patient is taken over by machine, setting gradually lowered to desired values
   - Recognize and treat other factors contributing to 'clash' between machine and patient
   - If in spite of above measures asynchrony between patient and machine persists (as in patients with severe parenchymal disease producing stiff lungs), sedate and depress respiration by 2–4 mg IV morphine, or IV diazepam or IV midazolam, IV fentanyl or IV propofol or induce neuromuscular paralysis

B. Other problems—
   - Malposition of endotracheal tube
   - Aspiration of stomach contents
   - Hypotension

Abbreviations: IV, intravenous; RR, respiratory rate, V_T, tidal volume.

Positive End-Expiratory Pressure[7]

Positive-end expiratory pressure (PEEP) may need to be used if the O_2 saturation is less than 90% on an FiO_2 greater than 0.5 (see subsequent section on PEEP).

It needs to be stressed that the V_T, respiratory rate, V_E, I:E ratio and inspiratory flow rates are so adjusted as to enable good exchange of gases and yet maintain plateau pressure less than or equal to 30 cm H_2O. This lung protection strategy minimizes the risk of barotrauma and volutrauma.

All alarms on the ventilator provided both for patient safety and as indicators of proper functioning of the ventilator should be activated—in particular, the high pressure, low pressure alarm and the apnea alarm.

PROBLEMS AT INITIATION OF VENTILATOR SUPPORT (BOX 3)[8]

The major and the most common problem is difficulty in synchronizing the patient's respiration with the ventilator. In an unconscious or apneic patient this presents no difficulty.

The problem is also easily surmountable in patients with respiratory failure due to poisoning, neuromuscular disease, or other CNS problems. The following points are helpful in management—

- Allay anxiety and fright in the patient by explaining the situation in a gentle and confident manner, and by the use of a tranquillizer. Diazepam, 5–10 mg intravenously is of great help.
- The most common cause of difficulty in synchronizing is inadequate alveolar V_E. The V_E selected should result in a $PaCO_2$ between 35 mm Hg and 40 mm Hg. Ordinarily a V_T of 10 mL/kg with a respiratory rate of 12–15/minute is adequate. However, many patients with lung disease require higher V_E than that stated above.
- If the patient continuously clashes with what appear to be reasonable ventilator settings, it is advisable to proceed as follows—
  - Use a high FiO_2 temporarily to ensure that there is no hypoxia—this can be easily checked by noting the oxygen saturation on the pulse oximeter.
  - If a very strong respiratory drive is responsible for asynchrony between the patient and the machine, the V_T is increased, and the respiratory rate increased to well beyond the patient's spontaneous rate. Once the patient is taken over by the machine, the settings are gradually lowered and modified to the desired values. Generally, if alveolar ventilation is adequate, and if other causes contributing to restlessness and increased respiratory drive are looked into and taken care of, the patient does not fight the machine and is relaxed. The only way to determine whether the alveolar ventilation is adequate is by monitoring the $PaCO_2$. A $PaCO_2$ above 45 mm Hg denotes alveolar hypoventilation; that below 35 mm Hg, alveolar hyperventilation. Hyperventilation in the initial stages reduces the respiratory drive and helps the machine to take over. Once this is achieved V_E is adjusted so that the $PaCO_2$ is maintained around 35 mm Hg, and preferably not below 30 mm Hg.
  - In tachypneic patients with a strong respiratory drive, the patient's inspiratory flow rate is generally higher than the usual 40–60 L/minute set on the machine. Increasing the inspiratory flow rate appropriately, or decreasing the I:E ratio, prevents clashing and allows smoother ventilatory support in these patients.
  - Manual control of ventilation by using 100% oxygen for 5 minutes is a useful method for abolishing the patient's respiratory effort, by ensuring oxygenation, and proper alveolar ventilation.
  - Besides a strong respiratory drive chiefly related to altered mechanics of the lungs, there are other contributory factors, which increase the degree of clash between the machine and the patient. These may be present at the very outset, or may evolve during the critical care of a patient. They are briefly discussed later, and should be recognized and treated for more efficient ventilator support.
- Asynchrony between the machine and the patient may persist, however, in spite of appropriate ventilator settings, the use of corrective measures, and despite all attempts to match the machine to the patient. This generally happens in patients with severe parenchymal lung disease producing very stiff lungs, tachypnea and severe hypoxia. In many of these patients the spontaneous respiratory rate is greater than 40/minute. It is unwise to even attempt to

match the machine to this spontaneous respiratory rate. What is more, these patients are critically ill, often with multiorgan failure and cardiovascular instability. It is important that the respiratory muscles are rested in such circumstances. Effective ventilation can be achieved only by depressing respiration, or by inducing neuromuscular paralysis. The respiration can be depressed by the use of 2–4 mg morphine, or 0.2–0.4 mg buprenorphine intravenously, repeated as and when necessary. An alternative is to use 10 mg intravenous diazepam or 2–4 mg midazolam intravenously or an intravenous combination of midazolam and fentanyl, titrated to produce the desired effect. The main disadvantage of morphine is hypotension, which should be countered by vasopressors or by a volume load. In patients where morphine or a morphine derivative or diazepam or midazolam or fentanyl, is unsuitable or ineffective, particularly in ventilating patients with severe lung injury, it is necessary to use intravenous pancuronium or an intravenous bolus dose of vecuronium 0.08–0.1 mg/kg. After an intravenous bolus dose, vecuronium is given as a 0.8–1.2-μg/kg per minute continuous infusion, to induce neuromuscular paralysis and thereby abolish or sharply reduce spontaneous ventilatory support. Pancuronium is given as an intravenous bolus dose of 0.06–0.1 mg/kg and repeated as and when necessary to allow smooth takeover by the machine. It is unwise and often unnecessary to produce total paralysis with curare-like drugs.

Other important problems occurring within the first few minutes or hours of initiating ventilator support are—

- Malposition of the airways.
- Aspiration of stomach contents.
- Hypotension. These are dealt with at length under complications of ventilator support.

OBJECTIVES OF VENTILATOR SUPPORT

- Regulate gas exchange.
- Overcome mechanical problems.
- Increase lung volumes—in conditions in which the functional residual capacity (FRC) is reduced.

Regulate Gas Exchange

Oxygenation

- Most patients requiring ventilator support have uneven ventilation and disturbed ventilation-perfusion ratios. Only a small minority on ventilator support can be adequately oxygenated with room air or 20% oxygen; most require an increased concentration of oxygen in the inspired air.
  It is best to use an inspired oxygen concentration (FiO_2) sufficient to maintain O_2 saturation greater than or equal to 90% and a PaO_2 above or equal to 60 mm Hg. In severe lung disease, high oxygen concentrations are necessary; oxygen concentrations greater than 70% for a prolonged period are a hazard as they contribute to lung injury. In very severe lung injury, an FiO_2 of 100% may be necessary to prevent death from hypoxia. If this is indeed so, 100% oxygen should be used, notwithstanding the fear of oxygen toxicity.
- Use of PEEP. PEEP is indicated when the PaO_2 is below 60 mm Hg despite inspired oxygen concentrations exceeding 50%.

Carbon Dioxide Elimination and Regulation

The physiological dead space in patients with lung disease is often increased. The increase in dead space in relation to V_T may in fact be so large, that in some patients on ventilators 50–70% or even more of the V_T becomes dead space ventilation. It is therefore important to note the following points—

- It is impossible to predict the ventilation requirements of patients on ventilatory support as most patients have an increase in physiological dead space. Their ventilation requirements are invariably in considerable excess of that predicted by standard nomograms.
- The only certain way to ensure adequate ventilation is to measure the $PaCO_2$ and to adjust volume exchange so that the $PaCO_2$ is close to normal.
- It needs to be re-stressed that a disturbance in gas exchange may be as much due to a fault in the pulmonary circulation as to a fall in alveolar ventilation.
- Ventilator support can also be manipulated so as to purposely induce hyperventilation (with a low $PaCO_2$) in patients with raised intracranial pressure, or to purposely settle for hypoventilation (permissive hypercapnia) in certain clinical situations (ARDS and airways obstruction).

Overcome Mechanical Problems

Mechanical ventilation is of use to rest fatigued respiratory muscles, to overcome the abnormal mechanics of the thoracic cage in flail chest and to prevent or treat atelectasis.

Increase in Lung Volumes in Patients with a Low Functional Residual Capacity

Use of PEEP improves ventilation-perfusion ratios and reduces the right to left shunt within the lungs.

Summary of Ventilatory Patterns in Different Groups of Respiratory Diseases Requiring Ventilator Support

- In patients with normal lungs: V_T of 10 mL/ kg with respiratory rates between 10/minute and 14/minute, a flow rate of 40–60 L/minute, and an I:E ratio of 1:2 to 1:3 are recommended.
- Patients with trauma to the chest wall causing a flail chest, and often hematoma or injury to the lung.[9] These patients may need controlled ventilation for which sedation or neuromuscular paralysis becomes necessary. V_T of 10 mL/kg, with a respiratory rate between 12/minute and 14/minute are recommended. The V_E is adjusted to maintain a $PaCO_2$ between 30 mm Hg and 40 mm Hg.

- Acute hypoxemic respiratory failure due to severe lung disease, e.g. ALI, ARDS, pneumonia.[10] The principle is to avoid as far as possible high inflation pressure and to use small V_T of 5–7 mL/kg. In mild to moderately severe cases, smaller V_T of 6–8 mL/kg with a higher respiratory rate of 20–25/minute are used to match the patient's breathing pattern. The inspiratory flow rates are adjusted to between 40 L/minute and 60 L/minute. An increased FiO_2 and the use of PEEP are necessary. If adequate or efficient ventilation is not possible, particularly so in severely hypoxic, tachypneic, critically ill individuals, heavy sedation or even muscle paralysis with controlled ventilation becomes necessary, the principle again being not to exceed a plateau pressure of 30 cm H_2O as far as possible, even if this entails a rise in $PaCO_2$ (permissive hypercapnia). If pressure-controlled or pressure-targeted ventilator support is given to these patients, the peak inspiratory pressure should as far as possible not exceed 30 cm H_2O. PEEP is used in all patients. Inverse ratio ventilator support is occasionally tried when gas exchange remains unsatisfactory with the usual volume-targeted or pressure-targeted ventilatory support. The inverse ratio in our opinion should not be increased to higher than 1:1.
- Acute on chronic respiratory failure in patients with chronic airways obstruction. Small V_T of 6 mL/kg with a respiratory rate and V_E enough to allow a $PaCO_2$ between 45 mm Hg and 55 mm Hg are adequate. These patients are used to a high $PaCO_2$ and it is unwise to aim at a $PaCO_2$ of 40 mm Hg, as their $PaCO_2$ even under ordinary conditions is significantly elevated. Sedation or at times induced paralysis is often necessary for ventilator support to be effectively maintained. Moderately low inspiratory flow rates (50 L/minute), an I:E ratio of 1:3, and avoidance of high inflation pressure by using a low V_T is recommended. Hypoxia is countered by an appropriate increase in the FiO_2.
- Acute severe asthma. These patients also require low V_T (350–400 mL), and comparatively low V_E (often <5 L/minute) to prevent hyperinflation of the lungs. A rise in $PaCO_2$ does not matter as long as hypoxia is relieved by an appropriate increase in the FiO_2. Ventilation in these patients can at times prove extremely difficult.

Lung protection strategies (outlined in the Chapter Acute Lung Injury and Acute Respiratory Distress Syndrome) should always be kept in mind in the management of mechanical ventilator support. It is constant practice that allows the clinician to adjust ventilatory requirements to the need of each individual patient so as to allow adequate gas exchange and yet prevent as far as possible the hazards of mechanical ventilator support.

Three more points need to be stressed—

1. Hypovolemia contributes to poor gas exchange and accentuates or precipitates hypotension in patients on mechanical ventilation. It is therefore important to ensure normal circulatory volume, good pump function, a normal blood pressure and an adequate hemoglobin concentration.

Box 4: Conventional modes of ventilator support

- Controlled mode ventilation (CMV)
- Assist/Control mode (A/C)
- Pressure-controlled ventilation (PCV)
- Synchronized intermittent mandatory ventilation (SIMV)
- Pressure-support ventilation (PSV)
- Continuous positive airways pressure (CPAP)
- Inverse ratio ventilation (VC IRV) and (PC IRV)

2. Humidification of inspired gas, aseptic suction of secretions through the tracheobronchial tree at frequent intervals, and good chest physiotherapy are all vitally important. Good physiotherapy often spells the difference between life and death in critically ill patients on ventilator support.
3. Efficiently carried out mechanical ventilation can only ensure a satisfactory gas exchange. More often than not, a critically ill patient on ventilator support in the ICU has numerous other complications that pose potential hazards to life. Circulatory failure, renal dysfunction, bleeding, acid-base disturbances, overwhelming sepsis, and in our country, a poor nutritional state, singly or in combination with other factors, can be dangerous enough to cause death. Therefore, to concentrate solely on the correct and efficient working of a machine and on a single aspect of deranged physiology, constitutes bad medicine. An overall perspective should never be lost sight of in the management of a critically ill patient.

Modes of Invasive Ventilator Support[11]

The most common modes in use are volume-controlled ventilatory (VCV) mode,[11] pressure-controlled ventilatory (PCV) mode, synchronized intermittent mandatory ventilatory (SIMV) support, and pressure-support ventilation (PSV). These modes and the use of PEEP are considered to start with in this section, followed by a brief explanation of the more recent modes (Box 4).

It is very important for the clinician or the intensivist to be thoroughly familiar with the basic modes of ventilator support before attempting familiarity with the numerous other modes that modern ventilators are able to provide.

VOLUME-TARGETED SUPPORT

Controlled Mode Ventilation

In Controlled Mode Ventilation (CMV), the ventilator completely controls the patient's ventilation, delivering a set V_T (or a preset peak pressure) at a set frequency. It is indicated in individuals who are apneic, or in those with respiratory muscle paralysis. It is also indicated in patients who are heavily sedated or those paralyzed with neuromuscular agents so that ventilatory support is mandatory—a classic example of this situation is fulminant tetanus. Patients receiving CMV cannot increase their V_E voluntarily; their ventilator needs should

therefore be closely monitored, and changing needs should be met by suitable adjustments on the machine.

Assist/Control (A/C) Mode

This is the most commonly used mode. The machine delivers a preset volume (or pressure) in response to a patient-initiated breath. To prevent the patient from being totally dependent on triggered breaths, a back-up minimum respiratory rate is set. The requisite V_E can then be provided even if for some reason or the other the patient fails to trigger the machine. The main advantage of this mode is that the patient can increase his V_E by increasing his respiratory rate. The disadvantages include the production of respiratory alkalosis and of dynamic hyperinflation (particularly in COPD patients), if the machine is triggered too frequently, and the possibility of asynchrony between the ventilator and the patient. Initial ventilator settings are a V_E of 8–10 L/minute, respiratory rate at 10–14/minute, a sensitivity of –2 cm usually. If the patient triggers the machine too frequently, the sensitivity is set at –2 to –6 cm and the patient is sedated to reduce his respiratory drive. Most ventilators allow adjustment of the inspiratory flow rate or the I:E ratio, the inspiratory rise time, end-inspiratory pause time and the flow pattern during inspiration.

Pressure-Controlled Ventilation (PCV)[12]

In this mode, the maximum peak pressure is preset, so that the ventilator increases the pressure to this preset level with each inspiratory breath. The V_T obtained depends on the preset pressure (the higher the preset pressure, the higher the V_T), the stiffness of the lungs (greater the stiffness, the lower the V_T for a preset pressure) and resistance to airflow (the greater the resistance, the lower the V_T). The adjustable parameters are preset pressures delivered by the ventilator and the inspiratory time. The flow pattern is decelerating, in that the flow is high to start with, but decreases as the preset pressure is about to be reached.

Synchronized Intermittent Mandatory Ventilation[13]

In this mode, the ventilator delivers synchronized breaths at a set rate at either a preset V_T or a preset pressure, in addition to allowing the patient to breathe spontaneously.

The V_T and rate are determined by the patient. If for any reason, the patient does not breathe for a predetermined period, a machine breath is delivered. SIMV can be used with pressure support for spontaneous breaths. PEEP can be introduced in this mode, in which case the machine breaths will be combined with PEEP and the spontaneous ones with continuous positive airways pressure (CPAP). The advantages claimed for the SIMV mode are as follows—

- Decreased asynchrony with the machine and less sedation requirements.
- Less chances of hyperventilation as compared to the A/C mode.
- Greater patient comfort.

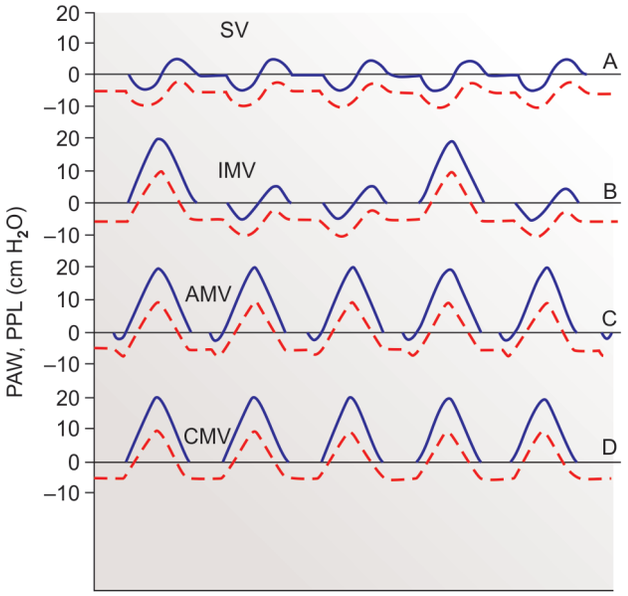

Fig. 1: Wave forms created by different modes of mechanical ventilation with positive pressure (B to D) compared with spontaneous ventilation (SV) (A). IMV, intermittent mechanical (mandatory) ventilation; AMV, assisted mechanical ventilation (or assist/control mode); CMV, controlled mechanical ventilation. Solid line, airway (PAW) or alveolar pressure; dashed line, pleural pressure (PPL)

Source: Luce JM, Tyler ML, Picrson DJ. Intensive Respiratory Care. Philadelphia: WB Saunders; 1984.

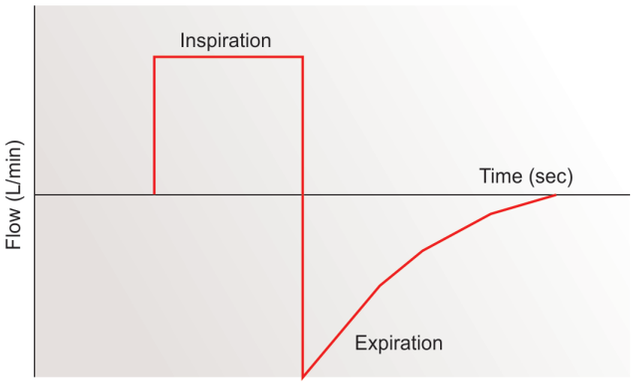

Fig. 2: A flow versus time curve for a mechanically volume targeted breath

- Continued use of respiratory muscles, which is believed to prevent respiratory muscle dysfunction.
- Reduced mean airway pressure even with the simultaneous use of PEEP, because many respiratory cycles are related to spontaneous breaths. This minimizes the cardiovascular effects of mechanical ventilation and is less likely to cause a fall in cardiac output or in arterial blood pressure.

In our opinion, the advantages ascribed to SIMV with or without PEEP are theoretical, and except in occasional instances, most patients are more comfortably and more satisfactorily ventilated with the A/C mode of ventilator support. In fact, the more ill the patient, greater the necessity to rest the respiratory muscles rather than exercise them.

9

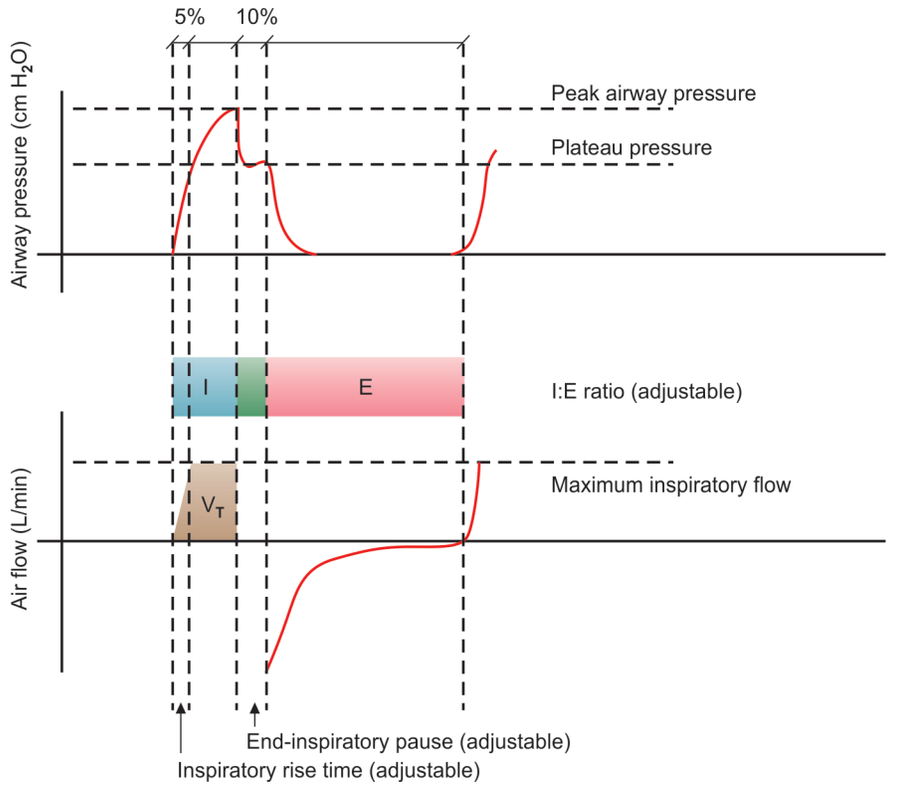

Fig. 3: Volume-targeted ventilation. Tidal volume is preset and the machine delivers the preset tidal volume regardless of change in compliance or airway resistance. Pressure rises during inspiration to peak inspiratory pressure (PIP). With a breath hold, the plateau pressure can be measured. Pressures fall back to baseline during expiration

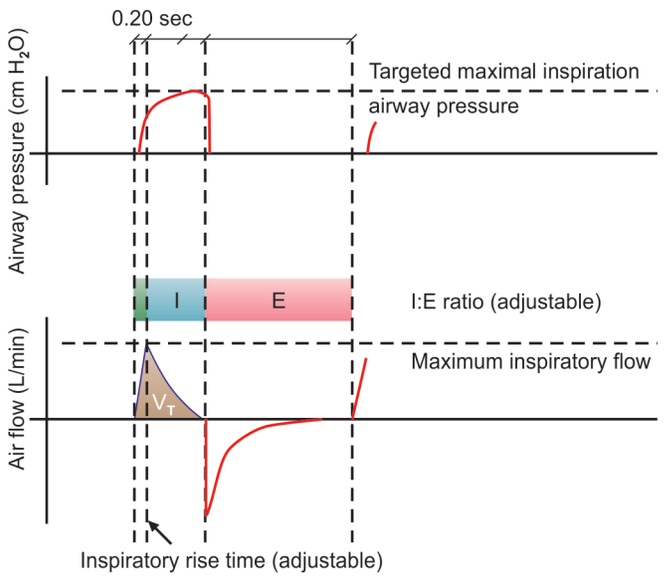

Fig. 4: Pressure targeted ventilation. The maximum inspiratory pressure is preset and the tidal volume will depend upon lung compliance and airway resistance. I:E ratio and the inspiratory rise time is adjustable

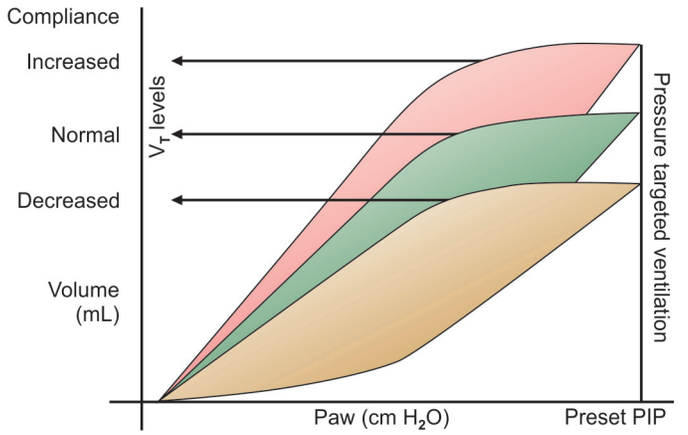

Fig. 5: Changes in the lung compliance in a patient receiving pressure targeted ventilation where the peak inspiratory pressure PIP is constant and the V, keeps changing. As dynamic compliance varies, so does the tidal volume

The VO_2 by overworked respiratory muscles can be as high as 15–40% of the total oxygen consumption and this is certainly undesirable. The SIMV mode cannot also respond to changes in the patient's condition, and therefore needs close monitoring.

The chief uses of this mode are stated below—

- In patients who develop hypotension while on the A/C mode or CMV mode with PEEP. The use of SIMV in such patients is associated with a lower mean airway pressure and this may restore cardiovascular instability.
- In patients on the A/C mode who develop respiratory alkalosis. This can be countered by either sedation or by changing to the SIMV mode.

- To prevent auto-PEEP in certain situations.
- In patients with respiratory failure and a bronchopleural fistula. In this situation, one would desire the lowest mean airway pressure that does not adversely affect ventilation and gas exchange, yet allows the bronchopleural fistula to heal and get sealed. Low V_T with increased respiratory rates to allow for adequate V_E, the avoidance of PEEP, and the use of the SIMV mode may be ideally suited to these patients. This should be combined with the lowest effective chest drainage tube suction.
- For weaning purposes (see Chapter Weaning from Ventilator Support).

Initial Setting

Settings to deliver a V_E of 6–10 L/minute or a preset pressure (sufficient to allow a V_E of 6–10 L/minute) with 10–12 mandatory breaths.

Pressure Support Ventilation[14]

In this mode a patient's inspiratory effort triggers a response from the ventilator. The ventilator delivers a preset positive pressure to the airways, reducing the work of breathing and helping in patient comfort. Once the predefined percentage of the maximal inspiratory flow is reached, the ventilator stops inspiration and opens the expiratory valve. The respiratory rate and inspiratory flow rate are determined by the patient. This mode cannot be used in an apneic patient or in one who lacks an adequate spontaneous respiratory drive. It is chiefly used in selected COPD patients and as a weaning procedure.

Initial Setting

Set a pressure of 10–12 cm of H_2O, ensuring a V_T of 7–10 mL/kg. The pressure support is gradually decreased to 5–7 cm H_2O provided an adequate V_T is maintained. Once this occurs, the patient can be weaned and allowed to breathe spontaneously.

Continuous Positive Airways Pressure

Continuous positive airways pressure (CPAP) is a mode of spontaneous breathing in which the airway pressure is maintained at levels greater than the ambient pressure throughout the entire respiratory cycle. A PEEP may be added as an adjunct to CPAP. All modern volume ventilators incorporate CPAP as a ventilatory mode. The ventilator does not provide any machine-generated breaths, but its humidification and alarm systems are available for use. Special CPAP systems without a ventilator are also available.

Inverse Ratio Ventilation

Inverse ratio ventilation can be volume-targeted or pressure targeted. Whereas the normal I:E ratio is 1:3 or 1:2, in inverse ratio ventilation the I:E ratio is 1:1 or even less. Ordinarily, one hesitates to go beyond 1:1. This is used in patients with ALI, ARDS, pneumonia, atelectasis, who show refractory hypoxemia (O_2 saturation <90% on an FiO_2 ≥60% on A/C mode in spite of suitable PEEP). In volume-controlled inverse ratio ventilation (VC-IRV), the inverse ratio of I:E is achieved by lowering inspiratory flow rate (and thereby lengthening inspiration) or by introducing a suitable end-inspiratory pause. The V_T is lowered sufficiently so as not to exceed a plateau pressure of 30 cm H_2O. In pressure-controlled IRV (PC-IRV), the I:E ratio is set to the desired level. The peak pressure should preferably not exceed 30 cm H_2O, or at most 35 cm H_2O. PEEP is used with both VC-IRV and PC-IRV.

The advantages attributed to IRV are better relief of hypoxemia and promotion of lung protection strategy that reduces the risk of both barotrauma and volutrauma.

Permissive Hypercapnia[15]

The principle behind this approach is to protect the lung from both volutrauma and barotrauma when using either volume targeted or pressure-targeted ventilatory support. Small tidal volume (5–7 mL/kg) are used in certain groups of patients in volume-targeted ventilatory support, so that plateau pressures do not exceed 30 cm H_2O. When pressure-targeted ventilator support is used, peak pressure is generally set to not more than 30 cm H_2O. This lung protection strategy can lead to hypoventilation and thereby hypercapnia. The hypercapnia is generally well tolerated by the patient and is permissible as an offshoot of the lung protection strategy stated above.

Use of Positive End-Expiratory Pressure[7]

The use of PEEP is a valuable adjunct to every mode of volume-targeted ventilatory support, pressure-targeted ventilator support, pressure-support ventilation and to the SIMV support.

The effects of PEEP and its complications are listed in Box 5.

Indications for Use of Positive End-Expiratory Pressure[7]

Positive end-expiratory pressure is indicated in patients with severe hypoxic respiratory failure who have poorly compliant lungs and a large degree of ventilation-perfusion mismatch so that hypoxia persists despite using an FiO_2 of 50–60% or more to ventilate the lungs. It is invariably indicated in patients with ALI, severe pneumonia, in patients with pulmonary edema who require ventilatory support and in hypoxemic respiratory failure due to flail chest and marked obesity. All these patients have a reduced FRC leading to alveolar and small airways collapse thereby causing a ventilation-perfusion mismatch with a right to left shunt within the lungs. In these patients, PEEP increases the FRC, opens up collapsed alveoli, particularly in the dependent lung regions, prevents derecruitment of opened alveoli during expiration, redistributes fluid within the alveoli and is believed to protect surfactant. The overall effect is to improve the ventilation-

Box 5: Physiological effects and complications of PEEP

Effects of PEEP

- *On lungs—*
  - Opening up of fluid-filled atelectatic alveoli, with increase in FRC and TLC
  - Decrease in shunt causing increase in PaO_2
  - Increase in V/Q units
  - Increase in dead space and V_D:V_T ratio
  - Increase in compliance up to a point; later fall in compliance
- On heart—
  - Decrease in cardiac output; this can decrease shunt, and thereby increase PaO_2. Thus rise in PaO_2 may also result from a fall in cardiac output, and not necessarily from improvement in lung function

Complications of PEEP

- Barotrauma—pneumothorax, pneumomediastinum, interstitial emphysema
- Fall in PaO_2 due to over distension of compliant alveoli, and increase in V/Q abnormalities
- Increase in intracranial pressure
- Water retention

Abbreviations: FRC, functional residual capacity; TLC, total lung capacity; V/Q, ventilation/perfusion; V_D, dead space; V_T, tidal volume.

Box 6: Practical guidelines for the use of PEEP

- PEEP only helps to counter hypoxia in acute hypoxemic respiratory failure due to lung injury; it does not alter the natural history of acute lung pathologies requiring ventilator support
- PEEP should not be used as a preventive measure, except after open heart surgery to prevent mediastinal bleeding, or to open up atelectatic segments chiefly present in the lower lobes
- It is not necessarily indicated if conventional ventilator support with FiO_2 of 50–60% maintains PaO_2 >60–65 mm Hg
- Start with PEEP levels of +5 cm H_2O, gauge effect, and then increase; do not exceed as far as possible levels of +15 cm H_2O in Indian patients as barotrauma invariably results
- Use the lowest PEEP that allows a PaO_2 of 60 mm Hg on FiO_2 <0.6; ascertain that the rise in PaO_2 following the use of PEEP is not associated with a fall in CO as this will lead to poor oxygen transport and poor tissue oxygenation
- If hypotension or decrease in CO is associated with use of PEEP, the PEEP level should be reduced, or even discontinued. The BP and CO are raised with volume load and/or inotropic support, and PEEP may then be better tolerated
- PEEP may rarely cause a fall in PaO_2—it then needs to be reduced, or even discontinued
- PEEP should be gradually tapered off, before discontinuing ventilator support

Abbreviations: PEEP, positive end-expiratory pressure; CO, cardiac output; BP, blood pressure.

perfusion mismatch, reduce the absolute right to left shunt (also termed the true venous admixture) within the lungs, thereby increasing PaO_2, O_2 saturation, so that need for high FiO_2 is reduced. The danger of oxygen toxicity caused by prolonged use of high FiO_2 in these patients is thus obviated. The prevention of derecruitment or collapse of alveoli during expiration with PEEP allows breathing to occur in the favorable range of the pressure volume curve, reducing the work of breathing. At one time PEEP was strictly contraindicated in patients with respiratory failure due to severe asthma or following an acute exacerbation of COPD requiring ventilator support. Many of these patients have dynamic hyperinflation of the lungs. The FRC is high and the alveolar pressure at the end of expiration exceeds atmospheric pressure, resulting in auto-PEEP or intrinsic PEEP. Also, because of dynamic hyperinflation this auto-PEEP progressively increases. A high auto-PEEP increases the inspiratory work of breathing and ultimately leads to respiratory muscle fatigue that can progress to respiratory arrest. The principle of ventilatory support is to use small tidal volumes with an I:E ratio of 1:3 and a rate preferably not more than 12–14/minute to help reduce dynamic hyperinflation. The application of extrinsic PEEP is also indicated in patients with severe airways obstruction who are on ventilatory support and develop a high auto-PEEP. The proper application of external PEEP will then counter the effect of auto-PEEP on the work of breathing, chiefly in relation to inspiratory effort. It is important however to set the level of extrinsic PEEP below that of the auto-PEEP observed in the patient.

In the past the main focus of attention in the use of PEEP was to improve oxygenation by reducing ventilation-perfusion mismatch and right to left shunt within the lungs. An equally important concept on the use of PEEP today is that it prevents the concertina-like opening and closing of alveoli during inspiration and expiration, keeps the alveoli open all through the respiratory cycle, thereby reducing the shear forces acting on the alveoli and hence reducing ventilator-induced injury (Box 6).

Selection of the Degree of Positive End-Expiratory Pressure Used

A variety of methods have been used to determine the optimal level of PEEP. In busy ICUs, the simplest, safest and the most practical method is to use the lowest level of PEEP, which maintains the PaO_2 equal to or above 60 mm Hg, on an FiO_2 equal to or less than 0.6. Other methods of selecting an optimum level of PEEP are described below.

Optimal Oxygenation

It is wrong to aim at an ever increasing PaO_2 by increasing the levels of PEEP. A high PEEP can cause an increasing rise in the PaO_2 and yet can result in a sharp drop in the cardiac output. This fall in cardiac output further reduces oxygen transport to the tissues, in spite of the increase in the PaO_2; this can have disastrous consequences.

Maximal Oxygen Transport

Adjusting the PEEP so as to obtain maximal oxygen transport (i.e. the product of arterial oxygen content and the cardiac output), takes the PaO_2, the hemoglobin and the cardiac output into consideration. Nevertheless, frequent measurements of cardiac output often pose problems in critically ill individuals.

Best Compliance

With the use of PEEP, the reduced FRC increases, and the compliance increases up to a point. If static compliance is measured with a graded increase in PEEP, a level of PEEP which produces an optimal increase in the compliance can be arrived at. Further increase in PEEP beyond this point now leads to a fall in static compliance pointing to overdistension of the alveoli. An optimal compliance produced by a particular level of PEEP in any particular patient, is generally associated with an optimal rise in the PaO_2.

Lowest Q_S/Q_T

As long as the level of PEEP does not significantly reduce the cardiac output, the optimal level of PEEP correlates with the lowest level of Q_S/Q_T. Many workers aim at reducing the shunt fraction to 15%, or aim at a PaO_2/FiO_2 ratio of 300 or more.

Lowest V_D/V_T and the Lowest $PaCO_2$-$PETCO_2$

The lowest V_D/V_T ratio and the lowest $PaCO_2$-$PETCO_2$ gradient are other parameters used by some workers to arrive at an optimal PEEP setting.

Complications of Positive End-Expiratory Pressure [7,16]

The three major complications are barotrauma, a fall in cardiac output, and at times a fall instead of the expected rise in PaO_2. PEEP used over a number of days, can result in an increase in intracranial tension, and to an increase in water retention, and a decrease in renal and portal blood flow.

Barotrauma

The risk of barotrauma depends on the end-inspiratory airway pressure and regional over inflation of parts of the lung. End-inspiratory pressure is a function of the V_T, the FRC, the inspiratory flow rate, the total compliance of the lungs, and the level of PEEP used. High V_T, high inspiratory flow rates and high levels of PEEP, in association with a reduced FRC and compliance, potentiate the risk of barotrauma. Even in severely diseased lungs, there are some regional areas which are more compliant than others. With high levels of PEEP, these alveoli get enlarged and overdistended, and have a lower recoil pressure than the smaller, poorly compliant alveoli. High alveolar pressure in such distended alveoli predisposes to rupture. On the other hand, the smaller, poorly compliant alveoli have a larger recoil pressure, and can therefore withstand high alveolar pressure and are less liable to rupture. Alveolar rupture can lead to interstitial emphysema, pneumothorax, mediastinal emphysema, and surgical emphysema of the soft tissues which may involve the neck, face and trunk. Pneumothorax on high levels of PEEP is a disaster which often leads to death.

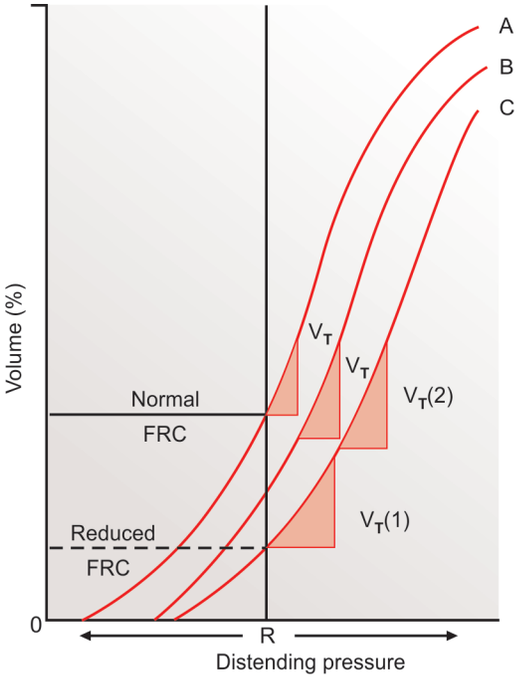

Fig. 6: Effect of positive end-expiratory pressure on functional residual capacity (FRC) in patients with reduced compliance, e.g. acute lung injury. Curve A represents a normal pressure-volume curve, wherein a relatively small distending pressure is required to achieve a given tidal volume (V_T). Curve C represents a pressure-volume curve in a patient with reduced compliance (as in acute lung injury) with decreased FRC. This is a more flattened curve and requires a greater distending pressure to achieve the same V_T(1). With the addition of PEEP, the FRC may be improved along the same abnormal compliance curve (2), or would shift to curve B, so that lesser distending pressure is required to achieve the same V_T but the absolute value of the distending pressure is still greater than that required for curve A

Fall in Cardiac Output

High levels of inflation pressure and PEEP are transmitted to the pleural space. The rise in the intrapleural and intrathoracic pressure leads to a fall in the venous return to the right heart, and a poor filling of the left heart due to a decrease in the transmural pressure across the left ventricular wall. Overinflation of the alveoli also increases the pulmonary vascular resistance with right heart strain, which further reduces the cardiac output. Also, right ventricular strain produces a shift of the interventricular septum to the left, thereby distorting and diminishing the size of the left ventricular cavity, and further impairing left ventricular filling and cardiac output. A sharp fall in the cardiac output leads to hypotension, poor oxygen transport, and inadequate tissue perfusion. A volume load together with dopamine support may be necessary in some patients to restore the cardiac output and oxygen transport to desired levels.

Table 2: Open lung procedure

Open lung and determine the opening pressure	Use Pressure Control Mode; rate 15/min I:E 1:1, PEEP 10–15 cm H_2O Raise PIP stepwise to 40–60 cm H_2O to open the lung. Allow 10–15 breaths for each stepwise increase in PIP Open lung—signified by a sharp sustained jump of PaO_2, PaO_2/FiO_2 and disproportionate increase in tidal volume. Note PIP for opening lung
Determine closing pressure	Lower PIP stepwise 2 cm at a time (allowing a few breaths at each reduction) till alveoli again start to close. This is signified by a sharp fall in PaO_2 and in tidal volume
Reopen lung	Reopen lung as described above
Now set PIP to just above closing pressure so that lung which has been opened is kept open	Stepwise reduce PIP to a level just above closing pressure to keep lung open. Check PaO_2, PaO_2/FiO_2 and tidal volume. Adjust respiratory rate for adequate ventilation

Abbreviations: PEEP, positive end-expiratory pressure; PIP, peak inflation pressure.

Fall in PaO_2

A paradoxical fall in the PaO_2 is sometimes observed with PEEP. This occurs when there are regional areas of normally compliant or over-compliant lung in patients with hypoxemic respiratory failure due to parenchymal lung disease. Overdistension of compliant alveoli leads to a decrease in the blood flow to these alveoli, and a shift of blood flow to the nonventilated, noncompliant areas of the lung. This causes a further increase in the shunt and a fall in the PaO_2. Ventilatory settings and PEEP levels should be adjusted to allow less distension of the compliant alveoli, and better distribution of inspired gas to the poorly compliant portions of the lungs.

Open Lung Concept[17]

The "Open lung concept" is being used in some critical care units in ALI and ARDS and in postoperative atelectasis (see Chapter Acute Lung Injury and Acute Respiratory Distress Syndrome). The principle behind this concept is to "open" the lung and keep it "open" with the least changes in pressure so as to minimize alveolar shear forces. This serves to improve gas exchange and serves as a lung protection mechanism by avoiding the concertina-like opening of the alveoli during inspiration and their collapse and closure during expiration. Sequential settings in a patient with ARDS on whom the open lung concept is used are given below.

- *Use pressure control* and set upper pressure limit to 50 cm H_2O. Set PEEP at 10–15 cm H_2O. Set pressure control level above PEEP to a value, which gives a V_T of 10–15 mL/ kg. Set respiratory rate at 15/minute. Inspiratory time 50% or I:E 1:1.
- *Determine opening pressure* Raise peak inspiratory pressure stepwise by 2 cm H_2O at a time, allowing 10–15 breaths at each stepwise increase, till the lung is fully "open". This generally requires a rise in the peak inspiratory pressure to 40–60 cm H_2O. The features that signify a fully "open" lung are a sudden and sustained jump of the PaO_2, so that the PaO_2/FiO_2 is greater than 400, and also the sharp disproportionate increase in V_T in relation to the stepwise increase in peak pressure.
- *Determine closing pressure of the lung* Decrease peak inspiratory pressure stepwise by 2 cm H_2O, allowing a few breaths for each setting to enable a stabilized reading. The closing pressure is that pressure at which the alveoli collapse or close. This is signified by an abrupt fall in the high PaO_2 and a sharp decline in V_T.
- *Reopen the lung fully* by repeating the steps outlined above.
- *Keep the lung open* Slowly, stepwise, reduce the peak inspiratory pressure once more to a level which is 1–2 cm above the closing pressure. Now the lung has been opened and is being kept open. The V_T should remain stable and the arterial blood gases good and constant.

Positive end-expiratory pressure is generally set at 10–15 cm H_2O. Some units prefer to set PEEP at higher levels of 15–25 cm H_2O. It is however not known if this high PEEP is necessary. Therefore, the same procedure as described above to determine ideal peak inspiratory pressure is now performed to find the lowest level of PEEP. After once again opening the lung, the peak inspiratory pressure and the PEEP are adjusted to just above closing pressure, so that the lungs remain open.

Avoid unnecessary ventilatory disconnects, or changes in ventilator settings. If ventilator disconnects occur or there is a change in lung condition to suggest further atelectasis, the whole procedure described above to reopen the lung and keep it open is repeated. Table 2 describes the stepwise open lung procedure.

NEWER MODES OF VENTILATOR SUPPORT

The conventional modes that provide ventilator support have been described above. They deliver a fixed, uniform, predetermined degree of assist without taking into account the variability of the breathing pattern present in different individuals in different situations and at different times in the same patient. Therefore, ideal synchrony between the patient and the ventilator is often absent. Asynchrony between the patient and ventilator can result in an increase in the workload. New technologies have therefore been developed that allow the ventilator to provide assistance in proportion to the patient's demand, which may vary from breath to breath. These newer modes of ventilator support are briefly considered below.

Airway Pressure Release Ventilation[18]

This ventilatory mode comprises CPAP that is intermittently released to allow a brief expiratory interval. The advantage is a lower mean alveolar pressure as compared to that during positive pressure ventilation. It has been used in patients with ARDS, and postoperatively in some patients, and has been found to be effective in providing adequate oxygenation.

Proportional Assist Ventilator

The ventilator in proportional assist ventilator (PAV) has the ability to sense every inspiratory effort breath-by-breath and adjust ventilator support accordingly. It does this by delivering positive pressure throughout inspiration in proportion to inspiratory airflow and volume generated by the patient. In conventional ventilatory modes, peak inspiratory pressure and V_T are relatively constant. In PAV, there is a direct constant relationship between the inspiratory effort of the patient and the peak inspiratory pressure generated by the ventilator from breath to breath. The V_T and peak inspiratory pressure are thus dependent variables. The PAV mode necessitates that the patient is capable of performing a portion of the respiratory work. It demands that the ventilator should be able to determine the elastance and resistance of the respiratory system in spontaneously breathing patients.

Pressure Regulated Volume Control and Volume Support

In the pressure regulated volume control mode a pressure-targeted ventilation is used to achieve a desired V_T. In the volume support mode a pressure support is given by the ventilator to achieve a predesigned V_T. This is done from breath to breath. The major concerns with both these assist modes is that if because of inspiratory respiratory demands (for example, fever or increased metabolism from any cause) there results an increased effort in breathing, the level of assistance offered by the ventilator will paradoxically decrease. Also, the machine delivers a predesigned V_T; however, in spontaneously breathing patients the V_T is not constant and may vary breath to breath.

Neurally-Adjusted Ventilatory Assist[19]

This mode uses the electrical activity of the diaphragm (EAdi) to control the ventilator. It is based on the concept that EAdi (triggered through the phrenic nerve) is representative of the overall neural respiratory effort both in timing and amplitude. In neurally adjusted ventilatory assist (NAVA), positive pressure exerted by the ventilator is in direct proportion to the amplitude of the EAdi, sensed by the ventilator. The patient's respiratory control mechanisms including feedback from various receptors adjust the EAdi; thereby regulating both V_T and the peak inspiratory pressure. NAVA has been tried out in specialized ICUs, and has been shown to enhance ventilator-patient synchrony, provide adequate gas exchange, unload respiratory muscles without alteration in circulatory hemodynamics, both during invasive and noninvasive ventilatory support. We have no experience with either the PAV or the NAVA ventilator modes and would rather wait for more clinical trials to define their optimum use.

Bilevel Positive Airway Pressure

In bilevel positive airway pressure (BiPAP) ventilation, two levels of continuous positive pressure are used, the patient being allowed to spontaneously breathe at both pressure levels. Assistance to spontaneous breathing can be given optimally at the low pressure level, high pressure level or at both levels. The change from low pressure level to high pressure level is co-ordinated by the patient's breathing effort. The BiPAP mode has its chief use in noninvasive ventilator support rather than in the invasive form.

High-Frequency Ventilation[17,20]

Several modes of high-frequency ventilation (HFV) have been employed. The basic feature in common is the use of a V_T which is smaller than the dead space volume. Gas exchange does not occur through convection as in conventional ventilatory modes, but by molecular diffusion, non-convective mixing, and by other mechanisms. The two important modes of HFV are high-frequency oscillatory ventilation and high-frequency jet ventilation. The advantages claimed for HFV include a decreased risk of barotrauma, and efficient gas exchange. This mode is believed to be best suited for healing of bronchopleural fistulae. Controlled trials, however, have shown no distinct benefit with this mode as compared to other conventional modes. The risk of complications is also significant.

Differential Lung Ventilation

Patients in respiratory failure due to severe asymmetrical lung disease may fail to be adequately ventilated by conventional ventilatory modes. In such patients adequate gas exchange can be provided by differential lung ventilation.

Clinical examples include patients with bronchopleural fistula, unilateral trauma, scoliosis or marked asymmetrical degree of parenchymal inflammatory disease in each lung (one lung being grossly affected and the other only slightly so). When there is a large difference in compliance, resistance or both parameters between the two lungs, a larger proportion of each tidal breath (using conventional ventilatory modes), is distributed to the comparatively unaffected lung. This results in a mismatching of ventilation and perfusion, an increase in the shunt, and poor gas exchange.

The initiation of differential lung ventilation requires the patient to be intubated with a double-lumen endotracheal tube (Carlen, Robert-Shaw, Univent, or Bronchocath). Different tidal volumes, flow rates, V_E, and if necessary even PEEP, are set for each lung. Differential lung ventilation can

9

Box 7: Newer modes of ventilatory support

- Airway pressure release ventilation (APRV)
- Proportional assist ventilation (PAV)
- Pressure-regulated volume control (PRVC) and volume support (VS)
- Neurally adjusted ventilatory assist (NAVA)
- High frequency ventilation (HFV)
- Bilevel positive airway pressure (Bi PAP)
- Differential lung ventilation
- Extracorporeal membrane oxygenation (ECMO)

be through two asynchronous ventilators each with its own circuit and its own settings, or through two synchronized ventilators, which deliver tidal breaths to both lungs through two independent circuits. The V_T, FiO_2 and other ventilatory settings for each lung are independently adjustable.

Extracorporeal Membrane Oxygenation[21]

Extracorporeal membrane oxygenation has been dealt with in the Chapter Acute Lung Injury and Acute Respiratory Distress Syndrome to which the reader is referred.

The newer modes of ventilatory support are listed in Box 7.

COMPLICATIONS OF MECHANICAL VENTILATION[22]

Alveolar Hyperventilation

A $PaCO_2$ below 20 mm Hg can be dangerous. Respiratory alkalosis results in cramps, tetany, reduced cerebral blood flow and hypotension. Electrolyte disturbances characterized by a sudden shift of potassium from the extracellular to the cellular compartment can trigger dangerous arrhythmias like ventricular tachycardia, or ventricular fibrillation. Prolonged alveolar hyperventilation makes weaning difficult as the respiratory center gets used to a low arterial CO_2 tension, and cannot tolerate a rise of $PaCO_2$ to even normal levels.

Atelectasis

This may be of two kinds—

1. Segmental, lobar or even massive.
2. Diffuse airspace atelectasis.

Lobar or massive atelectasis is easy to detect clinically as well as on X-ray. It produces distress with a rise in the static compliance (a rise in both peak and plateau pressure is observed). A slipping of the endotracheal tube into the right main bronchus is an important cause of collapse of part or whole of the left lung.

Diffuse airspace atelectasis is characterized by a collapse of very many scattered alveoli in both lungs, so that both the clinical examination, and the chest X-ray are essentially normal. It is at times observed when tidal volumes less than 10 mL/kg are used to ventilate the lungs. The use of tidal volumes of 10 mL/kg is the best prophylactic measure for this complication. Diffuse airspace atelectasis is suspected when there is a fall in the compliance, with an increase in the alveolar-arterial oxygen gradient, and a normal chest X-ray. When due to an increase in the water content of the lungs, the condition can be corrected by the prompt use of a diuretic like furosemide.

Uneven Compliances within Different Areas of the Lung

These produce uneven distribution of inspired gas. When some areas of the lung are normal or over-compliant, while others show a marked decrease in compliance, the problem in mechanical ventilation is immense. Inspired gas overventilates the compliant lung, and often fails to open or ventilate the stiff or noncompliant parts of the lung. Overdistension of the compliant areas leads to increase in the physiological dead space, increasing Zone I conditions especially when large tidal volumes are used. The capillary perfusion in these areas is severely diminished, with blood being shunted to the less compliant, poorly ventilated areas. This produces an increased right-to-left shunt with a fall in the PaO_2. Lower tidal volumes with a judicious adjustment of PEEP are necessary, but the difficulties in providing adequate gas exchange are not always solved.

Auto-Positive End-Expiratory Pressure

An increase in PEEP occasionally occurs in patients on mechanical ventilation (auto-PEEP), even when PEEP is not used as an adjunct to ventilator support. Auto-PEEP (occult PEEP, intrinsic PEEP) is defined as an unintentional PEEP that occurs when a new inspiratory breath is delivered before expiration has ended, in patients on ventilator support. A progressively increasing auto-PEEP results in a dynamic hyperinflation of the lung, which is merely another expression for increasing air-trapping within the lung. Auto-PEEP and dynamic hyperinflation are most commonly seen in patients with COPD, where narrowed obstructed airways lead to prolonged expiration and air trapping. Other factors that predispose to the occurrence of auto-PEEP are—

- V_E equal to or greater than 10 L/minute.
- Patients over 60 years of age.
- Use of a small-sized endotracheal tube.
- Increase in V_T especially in patients with COPD.
- Increase in compliance.
- Increase in respiratory rate with increase in risk of air trapping, particularly when inspiratory time equals expiratory time.
- Reduced inspiratory flow rate with shorter expiratory time.

Measurement of Auto-PEEP

During normal mechanical ventilation, the auto-PEEP present in the patient's lungs at end-expiration is not registered on the ventilator manometer, as in most ventilators pressures during exhalation are measured internally on the inspiratory side of the machine. Also normally, the expiratory valve is open to the

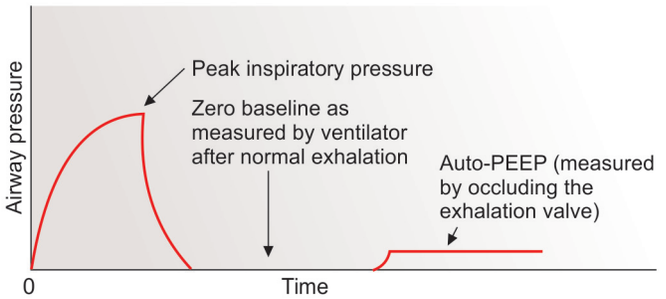

Fig. 7: The airway pressures (peak and plateau) during a positive pressure breath. Pressurizes during inspiration to peak inspiratory pressure (PIP). With a breath hold, the plateau pressure can be measured. Pressures fall back to baseline during expiration

Source: Pilbeam SP. Mechanical Ventilation, Physiological and Clinical Applications. Mosby: Mosby Year Book, MO® Elsevier; 1992.

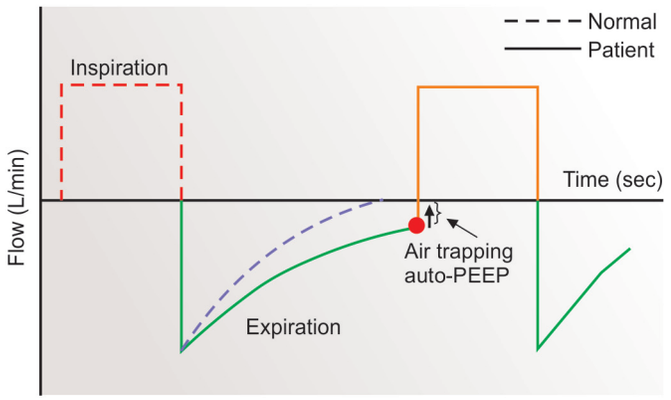

Fig. 8: Air trapping or auto-PEEP. Normally, expiratory flow returns to the baseline prior to the next breath. In the event that the expiratory flow does not return to the baseline and the subsequent inspiration begins below the baseline, auto-PEEP is present

atmosphere during exhalation. Auto-PEEP can be measured by occluding the expiratory limb of the circuit just before the next positive pressure breath. When the exhalation valve is occluded, the manometer measures the pressure in the patient's airway as the pressure equilibrates with the circuit. This method of measuring auto-PEEP requires a quiet patient on controlled ventilation.

Some ventilators like the Siemens Servo 900C and the Ohmeda Advent have end-expiration pause buttons or controls. They are microprocessor ventilators that can time the closing of the exhalation valve. They close this valve just before the next positive breath is due, delay the next breath, and then measure the pressure in the circuit.

Effects of Auto-PEEP

Effects of auto-PEEP are the same as those of PEEP used on purpose as an adjunct to ventilatory support. Deleterious effects include barotrauma, hypotension and a fall in PaO_2.

Methods of Reducing Auto-PEEP

Auto-PEEP can be reduced by the use of—

- Higher inspiratory flow rates, thereby shortening the inspiratory time and allowing longer time for expiration.
- Increased expiratory time by setting a smaller V_T and reduced respiratory rates.
- Low-resistance exhalation valves and large-bore endotracheal tubes to reduce air trapping.
- Low compressible volume ventilator patient circuit.

It must be mentioned that the occurrence of auto-PEEP is not confined to patients on ventilator support. It is frequently observed in spontaneously breathing patients who have severe airways obstruction that leads to air-trapping.

Infection

Nosocomial infection is an important complication and the following preventive measures are enumerated below—

- Cleanliness in the patient's room with scrupulous attention to avoiding cross-infection. Washing hands prior to examining the patient is important.
- Care of the tracheostomy wound—spraying the wound with an antibiotic spray is useful.
- Aseptic suction of secretions through the tracheostomy/endotracheal tube—should be done.
- Meticulous attention to prevention of atelectasis by physiotherapy and postural drainage. Prompt treatment of atelectasis and diffuse airspace collapse is mandatory.
- Frequent sterilization of humidifiers.
- Tracheostomy tubes should be changed every 4–7 days under aseptic conditions.
- Proper nutrition, oxygenation, and perfusion should be well maintained, so as to increase resistance to infection.

In patients on ventilator support, growth of Gram-negative organisms (chiefly pseudomonas strains and klebsiella) is frequently observed on culture of tracheal secretions. A positive culture by itself does not indicate infection, and does not warrant treatment (see Chapter Nosocomial Infections).

Hypotension

This is an important complication of mechanical ventilation. When it occurs soon after initiating ventilation, it is very likely to be related to the effects of the ventilator. In the presence of high inflation pressure, the use of PEEP, or in patients with over-compliant lungs as seen in emphysema, there may be a marked rise in intrapleural pressure. This reduces venous return and cardiac filling and induces a fall in blood pressure. Hypotension is often marked in hypovolemic patients. The treatment in such patients is to reduce inflation pressures, reduce or go off PEEP totally (if this has been used), and give a volume load to expand the circulating volume. Hypotension can also result from barotrauma, for example a pneumothorax induced by ventilator support. This may occur at the time of initiation of ventilator support or at a later period.

When hypotension occurs later during mechanical ventilation (the patient having been hemodynamically stable for several days), the cause is generally unrelated to the ventilator. Severe hypoxia and hypocapnia should be looked for, as they can induce a fall in blood pressure. If the blood gases are normal, hypotension may be due to shock, blood loss, fluid or electrolyte imbalance, sepsis, metabolic acidosis or poor pump function. Only if all these factors have been excluded, should the possibility of a ventilator-induced hypotension be considered.

Barotrauma, Volume Trauma and Biotrauma[23]

Barotrauma and volume trauma (volutrauma) are the most important and dreaded complications of mechanical ventilation. Probably, both high inflation pressure and high tidal volumes, particularly when PEEP is also used, contribute to barotrauma. It is generally the more compliant parts of the lungs, and not the poorly compliant areas, that are susceptible to barotrauma. Barotrauma classically takes the form of pneumothorax—tension pneumothorax occurs when high tidal volumes are used with high inflation pressures. Unless promptly recognized, it causes cardiorespiratory collapse and death. Interstitial emphysema, mediastinal emphysema and surgical emphysema of the soft tissues of the neck, spreading upward to the face and downward to the chest, may occur in the absence of pneumothorax.

A more subtle form of trauma to the alveolar walls can be caused by high tidal volumes (volume trauma or volutrauma). High tidal volumes are as important in producing alveolar damage as high alveolar pressures. The over-stretched alveolar walls are damaged, so that alveoli (even those which were reasonably normal), are now thickened, distorted and poorly compliant, thus adding to the overall stiffness and poor compliance of the lungs, and setting off a vicious cycle, which perpetuates respiratory failure to a point of no return. Over-stretch of alveoli with high tidal volumes is also believed to result in the production of cytokines that further injure the lung and perhaps also increase injury to other organs (biotrauma). The opening and closing of poorly compliant alveoli during inspiration and expiration results in shear forces that induce further lung injury (see Chapter Acute Lung Injury and Acute Lung Injury and Acute Respiratory Distress Syndrome).

Clashing with the Machine

This can occur at any time during mechanical ventilation, though it is most commonly observed during initiation of ventilator support. Clashing or fighting with the machine can be due to several causes, and each should be carefully evaluated prior to taking any decision on the management of the patient.

- Alveolar hypoventilation as stated earlier is an important cause; if present, it should be corrected by incr|easing the V_E.
- Obstructed tracheostomy/endotracheal tube or obstructed airways due to bronchospasm or mucus plugging is an important cause of distress, leading to a clash with the machine. A rise in peak pressure, with a fall in the dynamic compliance and a marked difference between the peak and pause pressure should point to the above cause.
- Atelectasis, pneumonia and pneumothorax are very important causes of a clash with the machine. Distress and high peak pressure with a fall in the compliance are observed.
- Blood loss (as in bleeding within the gastrointestinal tract), shock from any cause, electrolyte imbalance, metabolic acidosis, high fever, pain, a distended bladder or colon, or a dilated stomach are other causes that aggravate difficulties in synchronization with the machine.
- A strong respiratory drive due to altered mechanics within diseased lungs may defy all efforts to match the machine to the patient. It is in this group that controlled ventilation after inducing neuromuscular paralysis or after depressing respiration with intravenous diazepam or morphine is mandatory.

Gastrointestinal Complications[24]

Gastric dilatation and paralytic ileus are observed at times, particularly at the start of mechanical ventilation. The cause is obscure. Treatment is through gastric aspiration via a nasogastric tube, stopping all oral feeds and using intravenous fluids till such time as gut motility returns. The maintenance of fluid and electrolyte balance in such patients is precarious. Hypokalemia tends to aggravate the ileus, and needs to be carefully corrected by potassium replacement through intravenous infusions. Oral feeds are resumed once the gut motility returns.

Gastrointestinal bleeding occasionally occurs as a complication in patients on ventilator support. This is due to acute erosive gastroduodenitis in critically ill patients, particularly in those receiving corticosteroids. GI bleeding is particularly common with acute on chronic respiratory failure secondary to infection in patients with chronic bronchitis. These patients generally have a well-marked acidosis. Antacids and H_2-receptor antagonists, or sucralfate help stop bleeding. At times, laser therapy or endoscopic cauterization of bleeding points may be necessary. The blood loss should be replaced by transfusions.

Water Retention

Patients on prolonged ventilator support may retain water even in the clinical absence of left heart failure, or of a rise in venous pressure. Increase in the water content of the lungs may cause some degree of pulmonary edema. This produces impaired gas exchange, and fluffy shadows in the lungs on a chest X-ray. The problem is managed by restricting fluids to 1,000 mL in 24 hours, and by the use of diuretics like furosemide (Box 8).

Box 8: Common complications encountered during mechanical ventilation

- Alveolar hyperventilation resulting in $PaCO_2$ <25 mm Hg. This causes respiratory alkalosis (with decreased cerebral blood flow, tetany, hypotension), shift in K^+ from extracellular to cellular compartment causing arrhythmias, difficulties in weaning
- Atelectasis—segmental, lobar or massive, diffuse airspace collapse
- Uneven compliances in different areas of the lung resulting in uneven distribution of inspired gas and difficulty in mechanical ventilation
- Occurrence of auto-PEEP
- Nosocomial infection
- Hypotension—initially ventilator-related due to high inflation pressure; later, usually unrelated to ventilator support
- Barotrauma/Volutrauma/Biotrauma—pneumothorax, pneumomediastinum, interstitial emphysema, damage to alveolar walls
- Clashing with the machine
- GI complications—paralytic ileus, gastric dilatation, GI bleeds
- Water retention

Abbreviation: PEEP, positive end-expiratory pressure.

Box 9: Indications for NIPPV

- Acute exacerbation of COPD
- Mild to moderate cardiogenic or non-cardiogenic pulmonary edema
- Community acquired pneumonia with acute respiratory failure
- AIDS with pneumocystis infection or any other infection
- Hypercapnic respiratory failure due to chronic airways obstruction
- Obesity hypoventilation syndrome

Abbreviations: NIPPV, noninvasive positive pressure ventilation; AIDS, acquired immune deficiency syndrome.

Box 10: Contraindications to NIPPV

- Respiratory arrest or need for immediate intubation
- Inability to protect the airway
- Presence of copious respiratory secretions
- Hemodynamic instability or persistent hypotension
- Persistent arrhythmia
- Inability to cooperate or tolerate either the nasal or facial mask
- Presence of facial injuries

Abbreviation: NIPPV, noninvasive positive pressure ventilation.

NONINVASIVE POSITIVE PRESSURE VENTILATION[25]

A number of critical care units attempt, in suitable patients, to offer ventilatory support through a nasal mask or through a fitting orofacial mask, rather than through an endotracheal tube.

The major advantage of noninvasive positive pressure ventilation (NIPPV) is the reduced incidence of nosocomial pneumonia and of other complications associated with endotracheal intubation. The use of NIPPV has been standard therapy in patients with obstructive sleep apnea and in many patients with central sleep apnea. Other indications for NIPPV in acute respiratory failure are as follows—

- Acute exacerbation of COPD; acute crisis in COPD from other causes.
- In some patients with mild to moderate cardiogenic or noncardiogenic pulmonary edema. The more severe forms need intubation and ventilatory support.
- Community-acquired pneumonia with acute respiratory failure.
- In AIDS with *Pneumocystis* infection or with other forms of disseminated pulmonary infection.
- Hypercapnic respiratory failure due to progressive chronic airways obstruction, or due to the obesity hypoventilation syndrome.
- Postoperative respiratory failure (chiefly due to atelectasis).

It is obvious that if NIPPV fails to effect efficient gas exchange, or cannot be tolerated by the patient, prompt intubation with ventilator support becomes necessary. Indications for NIPPV are listed in Box 9.

Noninvasive positive pressure ventilation is contraindicated under the following conditions (Box 10)—

- In patients with a respiratory arrest or need for immediate intubation.
- Inability to protect the airway.
- In the presence of copious respiratory secretions.
- Hemodynamic instability or persistent hypotension (systolic <90 mm Hg).
- Occurrence of dangerous or persistent arrhythmia.
- Inability to cooperate or tolerate either the nasal or facial mask.
- In the presence of facial injuries.

NIPPV is also occasionally used after extubation in patients with marginal weaning criteria. NIPPV offers a transition from intubation to spontaneous breathing.

Different modes of ventilator support have been used with NIPPV. These include volume assist/control, pressure control, pressure support and the CPAP modes.

The major danger with NIPPV is the risk of aspiration of gastric contents. It is the best not to exceed positive inspiratory peak pressures of 20–25 cm H_2O as gastric dilatation with fear of aspiration can become a major problem. The setting should allow a V_T of 7–10 mL/kg.

9

Bilevel pressure ventilators (BiPAP machine) should generally be used for long-term or chronic application of NIPPV as in patients with obstructive sleep apnea or patients with chronic hypercapnic respiratory failure due to COPD. The expiratory positive airway pressure (EPAP) is set at 3–8 cm H_2O and the inspiratory airway pressure (IPAP) from +10 to +20 cm H_2O to provide effective ventilation. A backup assist rate should be set during sleep.

Respiratory Monitoring during Mechanical Ventilation[8]

Monitoring of respiratory mechanics is only possible during volume-controlled ventilation, a ventilatory mode perhaps most often used in most ICUs at least at the start of invasive ventilatory support. The discussion below is limited to patients on volume-preset ventilation. Determining respiratory mechanics at the start and during mechanical ventilation is an important and necessary aspect of ventilatory management. It is important to note the peak pressures, the pause pressures, the V_{Ts}, the PEEP, both extrinsic and intrinsic (if present), and to determine from these observations the dynamic compliance, static compliance and the resistance of the airway.

Airway Pressure and PEEP Measurement[8]

Measurements are reasonably accurate when the patient is relaxed (preferably sedated) on volume-preset ventilatory support. The inspiratory airway pressure (Paw) has three components–one, to overcome resistance of the airways during inspiration, the second, to overcome elastic recoil of the alveoli and expand them, the third, equal to end-expiratory alveolar pressure (PEEP) if this is present.

Paw = PR + Pstat + PEEP where Pstat = static elastic pressure
PR = resistive pressure component
Paw = $VI \times R + V_T \times E + PEEP$

where VI = inspiratory flow
R = resistance of airways
E = elastance of the airways

The individual components of Paw when separated provide significant diagnostic and therapeutic information. PEEP can be measured by the end-expiratory occlusion method. Most ventilators now provide an expiratory pause switch which allows a direct read-out of the PEEP. An error may creep into the measurement of intrinsic PEEP by this method if there is a leak around the endotracheal tubing or around the endotracheal tube cuff or when there is continuous nebulization with bronchodilators at the time of measurement, so that there is gas flow into the circuit, or if the patient is not completely taken over by the machine, and is not relaxed. Extrinsic PEEP is measured as set by the machine. Once PEEP has been measured the remainder of the airways pressure (ΔP = Ppeak – PEEP) can be apportioned between the pressure needed to overcome airways resistance (Pres) and pressure needed to overcome elastic recoil (Pes). This is done by stopping flow at end-inspiration and allowing the Paw to drop to a plateau level (Pplat).

The difference between the peak pressure and the plateau pressure is a measure of the airway resistance. The greater the difference between the peak pressure and the plateau pressure the greater the airways resistance.

If the inspiratory flow rate (VI) is 60 L/minute or 1 L/second the airways resistance during inspiration (Pres) is between 4 and 10 cm H_2O. A rise in airways resistance denoted by an increase in the difference between peak airway pressure and plateau pressure is observed with bronchospasm, obstruction of the large airways or mucus plugging of the bronchi, bronchioles and small airways. An increase in airways resistance (increased difference between the peak and plateau pressures) also occurs if there is obstruction of the endotracheal tube or tracheostomy tube or the trachea. In patients with bronchospasm the airways resistance may fall after nebulization with a bronchodilator and this is evinced by a narrowing of the gap between the peak pressure and the plateau pressure.

There now remains the need to determine the resistance offered by the elastic recoil of the lungs. This is indirectly determined by computing the compliance of the lung.

Dynamic compliance = Tidal volume/Peak pressure – PEEP (if present)
Static compliance = Tidal volume/Plateau pressure – PEEP (if present)
The normal compliance is about 70 mL/cm H_2O

A reduced static compliance means increased elastic recoil of the lungs, i.e. stiff lungs as in pulmonary fibrosis, pulmonary edema, areas of atelectasis, ALI and consolidation. Static compliance is also reduced when a patient on ventilator support develops a pneumothorax, collapsed lobe or lung or when there is increased stiffness of the chest wall or in the presence of abdominal distension.

A significant fall in compliance (the causes of which are listed above) will cause a sharp rise in both peak and pause pressures, pointing thereby to stiff lungs but no increase in the airways resistance (since there will be no increase in the difference between peak and pause pressure).

An increased compliance is observed in emphysema in which there is a loss of elastic recoil within the lungs. If the cause of ventilatory failure in a patient is undetermined at the time of intubation an assessment of the peak and plateau pressure, and of the compliance will help to determine the nature of the problem. A normal peak and plateau pressure in a patient intubated and ventilated for ventilatory failure should make the physician suspect an impaired central drive to breath or neuromuscular weakness as the underlying cause of ventilatory failure.

CHAPTER 39

Weaning from Ventilator Support

INTRODUCTION

Patients on mechanical ventilation should be weaned from ventilator support and extubated at the appropriate time. An unnecessary delay in weaning increases the patients's risk of nosocomial infection, trauma to the airways, adverse effects of prolonged sedation, and health care costs. Yet premature weaning can lead to reintubation with the enhanced risk of nosocomial pneumonia, increased morbidity and mortality.

There are a number of patients who are electively intubated and mechanically ventilated for brief periods of time for reasons other than respiratory failure. These include those ventilated briefly after major surgery as an extension of intraoperative and postoperative surgical care, or those intubated for airway protection. An abrupt termination of ventilator support and often quick extubation is generally possible in such patients, if the following criteria are satisfied—

- The patient is awake, alert and can breathe well spontaneously. He should have a good "blast" through the endotracheal tube, and if needs be, his tidal volume (V_T) can be checked by connecting a spirometer to the endotracheal tube.
- The clinical reason for ventilatory support no longer exists, or has resolved.
- The airways are free of secretions through proper suction or spontaneous coughing, and the patient is capable of protecting the airways from aspiration.
- The patient's chest X-ray is normal, and shows no atelectasis or pulmonary shadowing.
- In patients ventilated after open heart surgery or following major surgical procedures, the arterial blood gases (ABGs) and arterial pH should be normal or near normal, both during ventilator support, and after discontinuing support.
- The patient should remain under intensive care so that respiratory care can be continued in the form of humidification of inspired gas, nebulization therapy, physiotherapy, and if necessary, reintroduction of ventilator support.

The weaning parameters stated below are generally not required to be followed in these patients. When however postoperative pulmonary complications produce respiratory failure, or the presence of infection, bleeding or other complications lead to an increasingly critical state, the decision to wean is necessarily delayed. Clinical considerations together with the respiratory parameters, discussed below, help to decide the appropriate time to commence weaning from ventilatory support in these patients.

Patients who require ventilator support for long periods of time, extending for weeks or even months, are not easy to wean. Prolonged mechanical ventilation is often necessary in severe or fulminant tetanus, prolonged severe acute respiratory distress syndrome (ARDS), neurological problems such as acute infections, polyneuritis, poliomyelitis and injury to the cervical chord. It is also often necessary in fulminant *Plasmodium falciparum* infections, in other fulminant tropical infections such as leptospirosis, in severe sepsis, septic shock, and in multiorgan failure from any cause. In a number of critically ill patients, elective intubation and ventilatory support is offered at a point in time when ABGs are not markedly deranged. The decision to wean such patients from ventilator support should first and foremost be a clinical one, based on clinical considerations. Parameters for weaning are useful, but they should support or supplement a clinical decision, and never be used as a substitute for it.

Table 1: Wean screen criteria used to identify patients ready for a trial of spontaneous breathing

Criteria	*Description*
Reversal of respiratory failure	Evidence for reversal of underlying cause of respiratory failure
Adequate oxygenation	PaO_2/FiO_2 ratio >150–200 PEEP ≤5–8 cm H_2O FiO_2 ≤40–50% pH ≥7.25
Hemodynamic stability	Absence of myocardial ischemic Absence of clinically significant hypotension No vasopressors; dopamine or dobutamine <5 µg/kg/min
Respiratory drive	Capability to initiate an inspiratory effort

Abbreviations: PaO_2, partial pressure of oxygen in the blood; FiO_2, fraction of inspired oxygen; PEEP, positive end-expiratory pressure.

CLINICAL CONSIDERATIONS TOWARDS THE INITIATION OF WEANING FROM VENTILATOR SUPPORT

As a general principle, mechanical ventilatory support can only be withdrawn when the reasons for initiating it are no longer present. This usually means that the underlying disease, whether it involves the lungs or not, has been cured or has markedly improved.

In 2008, the American College of Chest Physicians (ACCP) recommend (on the basis of a multi-society sponsored task force study) that every patient on ventilator support should be assessed each day with a "wean screen" to determine when the process of weaning should be initiated. The recommended wean screen is given in the Table 1.

We agree with this weaning screen (if one wishes to use this label). The parameters in this screen are invariably screened and carefully noted on an intensive care unit (ICU) round often more than once every day. We however feel that the recommended screen takes notice solely of the relevant parameters in the cardiorespiratory system, ignoring the fact that serious involvement of other organ systems (present in many critically ill individuals) may impinge on the function of the cardiorespiratory system. Ignoring the above fact leads to premature weaning, a relapse into cardiorespiratory dysfunction, necessitating reintubation with a return of ventilator support—procedures, which enhance morbidity, mortality and health costs.

Guidelines are important, and should be understood. Yet they should never be blindly followed; clinical consideration and clinical judgment should never be sacrificed at the altar of recommended guidelines when caring for an individual patient.

Besides cardiorespiratory parameters mentioned in the weaning screen, the following conditions should be carefully assessed before initiating weaning (Box 1).

Box 1: Clinical considerations for weaning patient from ventilator support

- Mechanical ventilator support should be withdrawn only when the underlying disorder (pulmonary or extra pulmonary) is completely resolved, or has improved markedly
- Patient should maintain normal arterial blood gases on FiO_2 of 0.4 (except in patients with COPD whose basal $PaCO_2$ values are raised and PaO_2 is around 60 mm Hg)
- There should be no significant pulmonary infection, pulmonary edema, atelectasis or airways obstruction
- Acid-base and electrolyte disturbances should be corrected prior to weaning
- The patient should generally be alert, cooperative and mentally prepared to be weaned; he must be hemodynamically stable and preferably off inotropic support
- General nutritional state and neuromuscular status must be clinically assessed as to whether patient can cope with work of breathing
- In presence of high fever, seizures, gastric dilatation, paralytic ileus, GI bleeds, hepatic or acute renal failure, weaning should not be attempted
- On T-tube breathing, there should be no significant change in pulse rate, BP, no tachypnea or respiratory distress, should maintain normal blood gases and a tidal volume of 5–7 mL/kg

Abbreviations: FiO_2, fraction of inspired oxygen; COPD, chronic obstructive pulmonary disease; BP, blood pressure; GI, gastrointestinal; PaO_2, partial pressure of oxygen in the blood; $PaCO_2$, partial pressure of carbon dioxide in the blood.

- Blood gases as stated in the screen should be satisfactory before initiating the weaning process. An important exception to this is patients with chronic airways obstruction who are being ventilated for acute on chronic respiratory failure. These patients are used to a partial pressure of oxygen in the blood (PaO_2) of ≤60 mm Hg and to a high partial pressure of carbon dioxide in the blood ($PaCO_2$) even under normal conditions.
- The lungs should be free of infection, major atelectasis or edema, as far as possible. Airways obstruction, either from mucus plugging or bronchospasm should be significantly relieved, as these factors significantly increase the work of breathing.
- Disturbances in acid-base balance should be corrected before weaning is commenced. Metabolic acidosis can increase the work of breathing significantly, while alkalosis can result in mental obtundation, and depress respiration.
- A clinical judgment should be made whether the patient in the immediate future can withstand or cope with the demands imposed by the work of breathing. The general nutritional state and the neuromuscular status should be given careful consideration. Poor nutrition, electrolyte abnormalities, hypomagnesemia, hypokalemia and hypophosphatemia lead to difficulties in weaning.

9

Severely catabolic states like tetanus result in marked weight loss and loss of muscle mass in spite of providing a large caloric and protein intake. High carbohydrate diets lead to an increase in carbon dioxide production with increasing demands on ventilation, particularly in debilitated individuals, or in those with pre-existing lung disease. In such patients, less carbohydrates and more fats should be used for nutrition.

Patients with severe liver cell dysfunction, complications caused by renal failure, chronic alcoholics, and those who have weathered a prolonged critical illness, often pose great difficulties in weaning, chiefly because of their poor nutritional state, and their inability to cope with the work of breathing.

Even when cardiorespiratory parameters are satisfactory, weaning is frequently unsuccessful in the presence of severe multiorgan failure involving other organ systems.

- Ventilator support should be continued and weaning delayed in the presence of high fever, seizures, or when complications such as gastric dilatation, ileus, gastrointestinal bleeding, or acute renal failure exist.
- The patient should be awake, alert and cooperative, though there are exceptions to this consideration. The patient should also be prepared, indoctrinated and motivated to go off the ventilator.

PROCESS OF WEANING

Weaning is established in two stages—

1. To free the patient of mechanical ventilator support so that he or she breathes spontaneously through an artificial airway.
2. Extubation (removal of the artificial airway) of the patient.

Indices to Predict Weaning Outcome

Many respiratory indices have been proposed in order to predict weaning outcomes. These include—

- Assessment of ventilatory parameters (Box 2).
- Oxygenation and $PaCO_2$ levels.
- Respiratory muscle strength.
- Work of breathing.
- Central respiratory drive.
- Pattern of spontaneous breathing in relation to tidal volume (V_T) and respiratory rate (f or RR) or f/V_T.
- Peak expiratory flow rate >60 L/minute.

Yang and Tobin[1] studied the predictive power of several respiratory weaning indices and showed that the rapid shallow breathing index (f/V_T) had the best predictive value. The other indices listed above had relatively poor positive and negative predictive values. The f/V_T screening test has a high sensitivity and is useful to predict success in weaning when the test is positive (f/V_T <105) and failure to wean when the test is negative (f/V_T >105). However, it must be stressed that the f/V_T test though sensitive has a low specificity (i.e. there is a large proportion of weaning failure patients in whom the test is positive).

Box 2: Objective respiratory parameters for weaning

- Ventilatory parameters—
  - RR <30/min
  - V_E <8 L/min, and not >10 L/min
  - V_T of minimum 5–7 mL/kg
  - VC of minimum 800–1000 mL
  - Maximum inspiratory force > – 20 cm H_2O
  - V_D/V_T <0.6
  - Alveolar-arterial oxygen gradient on FiO_2 of 1 <250 mm Hg
- Arterial blood gases—
  - pH 7.35–7.45
  - PaO_2 70–100 mm Hg on FiO_2 of 0.4
  - $PaCO_2$ 35–45 mm Hg

Abbreviations: FiO_2, fraction of inspired oxygen; PaO_2, partial pressure of oxygen in the blood; $PaCO_2$, partial pressure of carbon dioxide in the blood; RR, respiratory rate; V_T, tidal volume; V_E, minute volume; VC, vital capacity; V_D, dead space.

METHODS OF WEANING

- In the past, the following methods were utilized—
  - Weaning through lowering the number of ventilator-assisted breaths in a patient on intermittent mandatory ventilation.
  - Weaning through gradually reducing the level of inspiratory pressure support in a patient on pressure support ventilation.
  - Keeping the patient "on" and "off"; ventilator support, and progressively increasing the "off" periods and reducing the "on" periods so that the patient breathes spontaneous first all through the day and ultimately all through the night.

    It is now accepted that weaning with intermittent mandatory ventilation (IMV), significantly delays removal of ventilator support.[2,3]
- The currently accepted weaning strategy to free the patient from mechanical ventilator support is to allow a daily spontaneous breathing trial through a T-tube during which the patient is observed for signs of respiratory failure (Table 2). If there is neither respiratory or cardiac distress, nor any evidence of respiratory failure over a period of 120 minutes, prompt successful extubation can generally be achieved. If the spontaneous breathing trial is unsuccessful, the patient is put back on the ventilator and the spontaneous breathing trial is repeated each successive day till the test is judged to be successful. The patient is then kept off mechanical ventilator support and in most cases is ready for extubation.

  In a multicenter randomized trial, Esteban and colleagues[3] compared four methods of weaning from mechanical ventilation and noted that patients managed with daily spontaneous breathing trials were extubated three times more quickly as those managed with pressure support.

  Ely and colleagues[4] showed that patients managed with a two-step weaning protocol including a daily wean screen

Table 2: Spontaneous breathing trial failure criteria

Criteria	*Description*
Increased work of breathing	• Respiratory rate >35/min or <8/min for at least 5 minutes • Two or more signs of respiratory distress, including tachycardia, bradycardia, accessory muscle use, abdominal paradox, diaphoresis or marked dyspnea
Inadequate oxygenation	• Saturation level of oxygen in hemoglobin (SaO_2) <88% for at least 5 minutes
Hemodynamic instability	• Acute cardiac dysrhythmia
Neurological instability	• Abrupt change in mental status

followed by a spontaneous breathing trial were extubated 1.5 days earlier than when managed with physician-directed weaning.

Esteban and colleagues[5] subsequently evaluated the effect of the duration of the spontaneous breathing trial in a randomized trial. They found that patients who were extubated after successfully completing a 30-minute trial of spontaneous breathing had similar reintubation rates to those who were not extubated until they completed a 120-minute trial. Even so, most intensivists use a 120-minute trial in patients who fail multiple daily spontaneous breathing trials, before proceeding to extubation.

❑ *Pressure-Support Ventilation (PSV)* This is the most common technique used to withdraw mechanical ventilator support when a patient repeatedly fails to pass the spontaneous breathing trial. During weaning, the patient's pressure support is reduced by 2–4 cm twice or thrice daily. If the patient tolerates and is comfortable with a pressure support of 5–8 cm without positive end-expiratory pressure (PEEP) he or she is given a spontaneous breathing trial for 120 minutes and if this is successful, then the patient is ready to be extubated.

When a patient is on PSV, it is important to ensure that there is neither asynchronous breathing nor an ineffective respiratory effort. High levels of pressure support should be avoided as this can lead to high tidal volumes and alkalosis causing inefficient triggering with ventilator-patient asynchrony. Clinical experience[2,3] suggests that the optimal initial levels of pressure support in PSV should be at a level that provide a respiratory rate of 25–30/minute.

❑ *Role of Noninvasive Ventilator Support* Non-invasive ventilator support has been used in three different scenarios—

1. If after successful extubation in a patient weaned off mechanical ventilation, the patient develops "de novo" respiratory failure after a lapse of time, the intensivist has two options—(A) to reintubate and reintroduce mechanical ventilation, or (B) to use noninvasive ventilator support to help tide over the crisis. Two studies[6,7] that have tried to assess the value of noninvasive ventilation (NIV) in the above setting suggest that the use of NIV is of no help. We feel that each patient should be assessed separately notwithstanding the result of these studies. If NIV is used, it should not be persisted with if there is no clear improvement of respiratory failure after a lapse of 4–6 hours. Reintubation and mechanical ventilator support should not be unduly delayed.
2. Noninvasive ventilation is at times used as a preventive measure in high risk patients who have been weaned and extubated. If the patient is considered to be a high risk for reintubation he or she is put on NIV immediately after the endotracheal tube has been removed. Patients who fall in this category are generally old feeble patients, patients who remain hypercapnic at the end of the weaning test, those who have persistent cardiac problems and those who have presented difficulty in weaning. Of the two studies[8,9] carried out one showed a reduction in extubation rate when NIV was given post-extubation and the other showed in addition a decrease in mortality.
3. Rarely NIV is used as a substitute for invasive mechanical ventilation in some patients with chronic respiratory failure who are difficult to wean and who really do not fully meet the weaning criteria. They refuse a tracheostomy or are at high risk for a tracheostomy. Weaning can be successful through NIV in some patients that fall into this category.[10,11]

Newer Modalities A number of newer weaning modalities have been tried with which we are unfamiliar. The use of closed loop PSV[12,13] is one such modality that provides continuous ventilator assistance to a patient's needs 24 hours a day. The above modality as also others in use are tried in the hope of reducing weaning trials compared to conventional methods.

Tracheostomy Tracheostomy becomes necessary if ventilator support is necessary for over 10–12 days. It has both advantages and disadvantages (see Chapter Airway Management).

Unsuccessful Weaning from the Ventilator

Perhaps the commonest reason is wrong judgment in deciding to wean the patient. This will happen if the intensivist is solely protocol driven and has ignored clinical considerations. Potentially reversible reasons for prolonged ventilator support are (Box 3)—

❑ Inadequate respiratory drive.
❑ Inability of the lungs to carry out gas exchange either because of infection, atelectasis, stiff lungs (very low compliance) or airways obstruction.
❑ Inspiratory muscle fatigue.
❑ Elevated diaphragm from a dilated stomach, marked ileus or a severely distended colon.
❑ Incipient undetected cardiac failure.

Box 3: Reasons for prolonged ventilation—"difficult to wean"

- Inadequate respiratory drive
- Inability of the lungs to carry out gas exchange either because of infection, atelectasis, stiff lungs (very low compliance) or airways obstruction
- Inspiratory muscle fatigue
- Elevated diaphragm from a dilated stomach, marked ileus or a severely distended colon
- Incipient undetected cardiac failure

Box 4: Causes of extubation failure

- Patient unable to protect the airway
- Difficulty in clearing secretions
- Excessive endotracheal secretions
- Mentally obtunded either due to neurological problems or to sedation
- Poor cough reflex
- Respiratory muscle fatigue
- Incipient often undetected cardiac failure
- Associated serious comorbid conditions

Extubation—Removal of the Artificial Airway

In a number of patients, extubation (removal of the artificial airway) is successful if the patients have passed the spontaneous breathing test for a period of 2 hours. This signifies total freedom from ventilator support. Nevertheless, there are situations where the patient may not need ventilatory support but still needs an artificial airway for a further length of time varying from hours to days. This is likely if the patient is unable to protect the airway, has difficulty clearing secretions or is mentally obtunded either due to neurological problems or to sedation. A normal or near normal mental status is important for successful weaning. Salam and colleagues[14] carried out a study on patients who were extubated after passing a spontaneous breathing trial. They found that patients who were unable to complete four simple tasks were more than four times likely to require reintubation as compared to patients who completed the tasks. A poor cough reflex, excessive endotracheal secretions are also features, which should prompt the intensivist to delay extubation even when the patient has passed the spontaneous breathing test.

Sedation, though important in the management of many patients in the ICU who are on ventilator support can result in obtundation so that both disconnecting the ventilator and/or extubation is delayed. Interruption of all sedation at the time a patient is given the spontaneous breathing trial (wake up and breathe) leads to both quicker release from ventilator support and quicker extubation. It has been observed that patients who were made to "wake up and breathe" were discharged earlier from the ICU. There was also a 14% absolute reduction in the risk of death in 1 year when the above policy was followed.[15]

Extubation Failure Extubation failure is defined as the reintroduction of ventilator support within 24–48 hours of extubation. The extubation failure rate is the number of patients requiring the reintroduction of mechanical ventilator support divided by the total number of extubated patients. It is important to realize that extubation failure is associated with a significant increase in patient mortality and morbidity (Box 4).[16-18] The underlying pathology in a patient with extubation failure may well influence outcome. Patients requiring reintubation because of respiratory failure had a mortality of 30% compared to a mortality of 7% in patients reintubated because of upper airways obstruction.

ROLE OF INSPIRATORY MUSCLE FATIGUE IN THE WEANING PROCESS

Inspiratory muscle fatigue is often responsible for a patient failing the spontaneous breathing trial. It is also an important reason for reintubation once the patient has been extubated. Inspiratory muscle fatigue should be suspected if the respiratory rate is >30–35/minute on disconnection from the ventilator, if the respiratory excursions are poor, if there are periods of spontaneous apnea or irregularity in the breathing pattern, or if there is paradoxical breathing. Not uncommonly the only manifestation of inspiratory muscle fatigue is a failed spontaneous breathing test.

We have given an evidence based protocol driven approach to weaning from mechanical ventilator support—both in relation to disconnecting the ventilator and extubation. To summarize, evidence presented in Western literature suggests that if the patient passes the weaning screen, he should be given a daily spontaneous breathing trial through a T-tube for 2 hours. If he passes this trial (in that he shows no respiratory or cardiovascular distress or failure) he is fit to go off ventilator support and in most cases fit to be extubated.

We now need to give a critical appreciation and add a few caveats to the above.

- A protocol driven weaning program if divorced from clinical judgment has a significant chance to fail. The weaning screen (as proposed by the ACCP) which takes into consideration just cardiorespiratory parameters is not sufficient for a correct judgment in the suitability of initiating the weaning process. The overall criticality of the patient in relation to other organ functions and other complications prevailing in a particular critically ill patient must be given due consideration before considering the patient fit for weaning.
- The evidence in relation to the spontaneous 120-minute breathing trial is from Western countries. There is no large prospective trial in India, leave aside a multi-centered

randomized trial. We need to gather our own evidence. There is a difference in ethnicity between the West and India and other South East Asian and African countries. More importantly there is in all probability a difference in the case-mix of patients on mechanical ventilator support in the ICUs of the West and the East. Also the case-mix in tertiary private hospitals in large metropolitan cities of India is different from the comparatively poor patient population in the ICUs of large government and municipal hospitals of these cities. It is important to accept the fact that the standard of intensive care both in relation to intensivists and particularly in relation to the nursing staff varies in the different ICUs in our country and also in other developing countries.

- We have noticed that in our ICU even when a patient has passed the 120-minute spontaneous breathing test, he may fail to breathe well after 6–10 hours, necessitating a return to ventilator support. The more critically ill the patient is or has been, the more frequently is this observed. A premature extubation would have certainly resulted in a reintubation in these patients with the added increase in morbidity and mortality.
- The nutritional state of many patients in our ICUs is often poor. Perhaps a 120-minute spontaneous breathing trial is too short for such patients.
- Evidence notwithstanding, the reintubation rates in the West are significant. Vallverdu et al.[19] in a study of 217 medical and surgical patients noted an overall reintubation rate of 15%, ranging from 36% in neurological patients to 0% in chronic obstructive pulmonary disease (COPD) patients. Data by Esteban and colleagues[5,20] show a reintubation rate of 13–19%. What would be the reintubation rate in our ICUs? We feel for various reasons (some of which are mentioned above) that it would be more than the rates reported in the West.
- The role of protocols in hastening the weaning process has been questioned. Krishnan and colleagues[21] in a prospective controlled trial in a closed medical ICU compared protocol based weaning to usual physician directed weaning and did not observe any improvement in clinical outcomes with protocols.
- The 2-hour spontaneous trial method of weaning invariably fails in patients who have been on ventilator support for several weeks or months. We have successfully managed to wean most of these patients by giving spontaneous breathing trial for progressively longer intervals so that hours off the machine are gradually increased. The patient is then first weaned off support during the day and then slowly weaned off support during the night. Pressure support breathing is of help in these patients. Spontaneous breathing trials should be started when the patient breathes comfortably through a tracheostomy collar or a T-tube with a pressure support of 10–15 cm of H_2O.

CONCLUSION

In conclusion, once the patient is judged (this is a clinical and judgmental decision) to be ready for weaning he should be given a daily spontaneous breathing trial for 120 minutes. On the day, he passes the trial a decision needs to be taken about extubation. Should it be immediate or should one wait for some hours or even a few more days. If the duration of ventilator support has been short (<10 days) and there is nothing to suggest any contraindications to extubation the patient should be extubated promptly but watched closely. In our conditions, the decision to extubate is not to be taken by the nursing staff but by the intensivist. We have seen disasters if this dictum is not followed.

If however there is any risk in prompt extubation (after a successful 120-minute spontaneous breath test), or if for any reason it is felt that though the patient has passed the spontaneous breathing test over 2 hours, he could well show cardiorespiratory distress later (this again is a judgmental decision), it is better to delay extubation than risk the possibility of a reintubation, as the latter in our opinion carries with it greater morbidity and mortality. Also if the airway is in place, the patient can be reintroduced to ventilator support if after a lapse of time he shows evidence of cardiorespiratory distress.

Patients who have received prolonged ventilator support extending for weeks or months need a different approach in weaning—a gradual withdrawal of ventilator support as has been stated in the last caveat.

Fluid and Electrolyte Disturbances in the Critically Ill

- Fluid and Electrolyte Disturbances in the Critically Ill

CHAPTER 40

Fluid and Electrolyte Disturbances in the Critically Ill

INTRODUCTION

Disturbances in fluid and electrolyte balance are frequently observed in critically ill patients under intensive care. They occur in a wide spectrum of diseases, are not confined to any particular field of medicine and are common following burns, trauma and major surgery. An essential prerequisite for the management of fluid and electrolyte disturbances in the critically ill is the knowledge of the basic physiology which regulates fluid and electrolyte balance. The kidneys play a crucial role in this balance and are of paramount importance in maintaining the homeostasis of the milieu interior in relation to water and electrolytes. They conserve sodium and water through several mechanisms: Hormonal mechanisms acting via the kidneys include the effects of the antidiuretic hormone, the renin-angiotensin system, aldosterone and the natriuretic hormone. The reader should refer to a standard textbook for a more detailed analysis on the physiology of this important subject.

APPROACH TO PROBLEMS IN FLUID AND ELECTROLYTE IMBALANCE

The conventional and easy method of evaluating disturbances in fluid and electrolyte balance is the frequent measurement of the concentration of serum electrolytes. It is crucial to remember that intracellular and extracellular electrolytes are normally constant, and that major shifts in and out of compartments can occur in disease with minimal changes in serum electrolytes. Again, it is very rare in clinical practice to have a disturbance confined to sodium balance per se; disturbances in water balance invariably accompany the latter. In fact, changes in plasma sodium concentration often are a pointer to disturbances in water balance. Finally, gross loss of sodium, potassium and water may exist in the body without any alteration in the plasma concentration of these electrolytes; if the fluid and electrolyte losses are in the same proportion as normally exist in extracellular fluid and plasma (i.e. if the fluid loss is isotonic with plasma).

An evaluation of fluid and electrolyte changes in disease demands a consideration of (1) the electrolyte concentration in plasma; (2) the volume of its distribution in the body; (3) the rate and quantity of water and electrolyte loss out of the body (as in vomiting and diarrhea) vis-à-vis the intake of water and electrolytes; (4) the movement of electrolytes and water in and out of each compartment; (5) the possible sequestration of electrolytes and water within the body (as in ascites and intestinal obstruction), which represents a loss of extracellular fluid.

NATURE OF FLUID CHANGES IN THE BODY

These disorders are best categorized as follows—

Disturbances of Volume

If isotonic fluid is lost from, or added to the body fluids, only a change in the volume of the extracellular fluid is observed. A loss of intestinal secretions thus leads to a loss of isotonic fluid and to a depletion of fluid within the extracellular compartment. As sodium, chloride and water that are lost are isotonic with plasma, the plasma concentration of sodium chloride remains unchanged. Fluid will not be transferred from the intracellular to the extracellular compartment as long as the osmolarity of the two remains the same. Addition of isotonic solution to the body fluids will result in a volume excess within the extracellular fluid compartment. However,

the concentrations of sodium and chloride in plasma remain unchanged, and there is no shift of water between the intracellular and extracellular fluid compartments.

Disturbances in Concentration

Disturbances in concentration produce a change in osmotic activity of the extracellular fluid (and the plasma). If water alone is lost from or added to the extracellular fluid, the concentration of osmotically active solutes in this compartment will change. Sodium is the most important osmotically active ion in the extracellular fluid. If the sodium concentration in the extracellular fluid falls, water will pass into the intracellular compartment till the osmolarity of both compartments is again equalized. If sodium concentration in the plasma rises, osmotic activity of the extracellular fluid compartment is increased, and water passes from the intracellular to the extracellular compartment so that osmotic equality between the two compartments is re-established.

Disturbances in Volume and Concentration

Volume and concentration abnormalities may both arise because of disease or from inappropriate parenteral fluid replacement therapy. A classic example is the association of a volume deficit together with a fall in serum sodium concentration that results from a massive loss of gastrointestinal fluid (causing a volume deficit), where fluid replacement is only through water (producing a fall in sodium concentration).

Disturbances in Composition

Concentrations of ions other than sodium can be altered within the extracellular fluid compartment without much change in the effective osmotic activity of the extracellular fluid. This produces a compositional change, which may be comparatively small when it involves an electrolyte like potassium, and yet has disastrous consequences (e.g. a rise in serum K^+ from 4 mEq/L to 8 mEq/L), if not promptly corrected. Compositional changes also involve disturbances in acid-base balance.

A combination of any of the disturbances stated above is often present in a critically ill patient.

This chapter now briefly describes volume changes, and then proceeds to describe disturbances in sodium concentration (hyponatremia and hypernatremia). It then describes compositional abnormalities characterized by changes in plasma potassium, calcium, magnesium and phosphate levels. The compositional changes characterized by acid-base disturbances in critically ill are dealt in the Chapter Acid-Base Disturbances in the Critically Ill.

VOLUME CHANGES

Volume deficit or excess is diagnosed by clinical examination. It is to be stressed that a severe volume deficit may exist with a normal, low or even high serum sodium level.

Volume Deficit

Extracellular fluid volume deficit with a decreased volume within the effective intravascular compartment characteristically occurs in vomiting, diarrhea, intestinal fistulae, nasogastric suction and in fluid loss following burns.

Other important causes include sequestration of fluid in soft tissue injuries and infections, intra-abdominal or retroperitoneal infection, peritonitis, and sequestration of fluid within the gut in ileus or in intestinal obstruction.

Renal salt and water loss can occur because of diuretics, renal disease or to adrenal insufficiency.

In the intensive care unit patient, the causes listed above are generally obvious. Less obvious causes include an unsuspected inadequate fluid intake, or fluid loss through excessive sweating as in high fever, hot humid temperature, and in diseases like tetanus. The extent of volume changes during hemodialysis, hemofiltration, and fluid loss from surgical incisions and wounds may also be underestimated.

Clinical Features

Early features of hypovolemia include tachycardia and postural hypotension (difference of 10–20 mm Hg in systolic arterial blood pressure between the supine and sitting postures). With increasing volume deficit and hypovolemia, there is increasing tachycardia, hypotension, collapsed peripheral and central veins with a lowered central venous pressure, and a lowered pulmonary capillary wedge pressure. The skin is cold and clammy, and the urine output is decreased. The urinary sodium is less than 10 mEq/L except in patients whose hypovolemia is related to salt and water loss via the kidneys (the urinary sodium in these patients is normal or increased).

Mental changes include anxiety, restlessness, followed by apathy, and dullness that may progress to drowsiness and coma. Poor tissue perfusion leads to accumulation of lactic acid with lactic acid acidosis. Multiple organ failure ultimately results from prolonged uncorrected hypovolemic shock.

Management

The first principle is to restore circulating volume through infusion of intravenous (IV) fluids. Once this is satisfactorily achieved, disturbances in electrolytes and acid-base balance if present need to be rectified. This is dealt with at length in the Chapter Acid-Base Disturbances in the Critically Ill.

Volume Excess

In the ICU patient, volume excess is often iatrogenic when the fluid intake has consistently exceeded the output. Excessive IV infusions of saline and blood transfusions are important causes of hypervolemia. Renal insufficiency, congestive heart failure, liver disease and other causes of sodium retention or excessive sodium administration can all produce increase in extracellular fluid content and hypervolemia.

A hypervolemic state is manifested by edema, and still later by ascites and pleural effusion. The neck veins are full, and pulmonary congestion may be obvious on clinical

examination. If cardiac function is normal, the circulation is hyperdynamic with tachycardia, a warm skin, a bounding pulse with an increase in the systolic pressure and the pulse pressure. The CVP is raised beyond 12 mm Hg, and the pulmonary capillary wedge pressure is often above 20 mm Hg in the presence of pulmonary edema.

In cases of moderate volume excess salt restriction, restriction of fluid intake, and the use of furosemide as a diuretic, will correct the problem. Fulminant pulmonary edema secondary to overhydration from overtransfusion of blood or fluids is more appropriately dealt with by phlebotomy in stages, so that the pulmonary capillary wedge pressure is reduced below 15 mm Hg.

It is worth remembering that in certain disease states there may be an increase in the volume in the extracellular compartment, associated with a decrease in the effective circulating blood volume. Advanced congestive heart failure and cirrhosis of the liver are classic examples of salt and water retention producing an increase in the extracellular volume, yet being terminally associated with a failing circulation. Suboptimal filling of the vascular space can occur due to a loss of fluid into other spaces as is seen in hypoalbuminemia, portal hypertension, and increased vascular permeability to solute and water.

HYPONATREMIA[1,2]

Hyponatremia is characterized by serum sodium below 135 mEq/L. Severe hyponatremia (Na <120 mEq/L) is fraught with danger and should be promptly treated. Hyponatremia is common in critical care medicine and is observed in diverse medical and surgical problems.

Hyponatremia *always signifies an excess of water relative to sodium in the extracellular (and intravascular) compartment*. A pseudohyponatremia may be observed in patients with extreme elevation of serum lipids or proteins, which causes an increase in plasma volume with consequent reduction in plasma sodium concentration. However, this increase in volume is in the nonaqueous phase, while the sodium is contained in the aqueous phase of plasma. Therefore, in these patients, hyponatremia is not associated with excess of water relative to sodium.

True hyponatremia (excess water in relation to sodium) can occur with a low, a normal or an expanded extracellular volume. It is important to make this assessment from the clinical background and the etiology responsible for hyponatremia. Hyponatremia may occur acutely, or may be slowly progressive or chronic. Acute hyponatremia from any cause, when marked, is life-threatening, and should be promptly evaluated and treated.

The causes of hyponatremia are considered below—

- *True salt and water depletion*—as in vomiting and diarrhea, particularly when fluid loss is partially replaced by dextrose or hypotonic solutions without adequate replacement of sodium and other electrolytes. The important causes of fluid and electrolyte loss have already been enumerated in the earlier subsection on "volume deficit". Hyponatremia due to loss of both fluid and electrolytes is associated with a contracted or low extracellular volume. The presence of a low intravascular volume is evident on clinical examination. Hyponatremia related to vomiting, diarrhea or loss of intestinal fluid is associated with a low urinary sodium (<20 mEq/L); that associated with sodium loss in the urine through diuresis or an adrenocortical insufficiency is associated with increased urinary sodium (>20 mEq/L).
- *Dilutional hyponatremia secondary to chronic heart failure, chronic liver or renal disease* These patients have an expanded extracellular volume, an increase in the total sodium content of the body, and are often waterlogged. The urinary sodium is less than 20 mEq/L in cardiac failure and in liver cell dysfunction, while it is often more than 20 mEq/L in chronic renal disease.
- *Primary dilutional hyponatremia* is generally evident from the history, e.g. overloading in acute renal failure, excessive infusions of 5% dextrose in postoperative patients, and compulsive water drinking in patients with diabetes insipidus who are on pitressin. Here again hyponatremia is associated with an increase in the intravascular volume and in the volume of the interstitial tissue compartment. In milder cases with this form of hyponatremia, clinical examination may not suggest an expanded extracellular volume, as about 5 liters of excess water need to be retained to produce definite pitting edema in an average-sized adult. The urine osmolality in these patients is decreased, and is always less than 100 mOsm/kg H_2O, with urinary sodium less than 10 mEq/L. The decreased urine osmolality distinguishes the above condition from the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) described below.
- *Syndrome of inappropriate secretion of antidiuretic hormone* In critical care medicine this is perhaps a frequent cause of hyponatremia, generally associated with euvolemia.[3] It is also observed after major surgery probably due to sustained nonosmotic release of vasopressin due to stress. The problem is compounded when the surgeon tries to increase the low urine output by IV infusion of glucose.

The diagnostic features of SIADH are hypo-osmolar hyponatremia, inappropriately concentrated urine (>100 mOsm/kg H_2O), clinical euvolemia and normal thyroid, adrenal, cardiac, hepatic and renal function. The urinary excretion of Na is more than 40 mEq/L in the face of a hypotonic plasma (<290 mOsm/kg). The important causes of SIADH seen in critical care medicine are given in Box 1.

In contrast to SIADH patients who excrete concentrated urine, euvolemic hyponatremic patients may present with maximally dilute urine (<100 mOsm/kg) in patients with psychogenic polydipsia or compulsive water drinking, the large consumption of water being in excess of the kidneys capacity to excrete free water, resulting in a dilutional

Flowchart 1: Algorithm for approach to hyponatremia

Malignancies—
- Pharyngeal
- Genitourinary
- Pancreas
- Lymphomas

Pulmonary disorders—
- Bronchogenic carcinoma/Mesothelioma
- Fulminant pneumonia
- Pneumothorax
- Positive pressure ventilation
- Acute severe asthma

CNS disorders—
- Infections (abscess, meningitis, encephalitis)
- Trauma/intracranial hemorrhage
- Brain tumors
- Multiple sclerosis
- Acute psychosis

Drugs—
- Chlorpropamide
- Carbamazepine
- Clofibrate
- Narcotic-analgesics/NSAID
- Isoproterenol
- Nicotine
- Antimitotic drugs

hyponatremia.[4] Reset osmostatic is a chronic condition where the vasopressin osmoreceptors exhibit a lower threshold to the release of vasopressin. This is seen in quadriplegia, psychosis, tuberculosis and chronic malnutrition.[2]

Finally, adrenalcortial insufficiency and hypothyroidism are occasionally known to cause euvolemic hyponatremia.[2]

Essential hyponatremia (sick cell syndrome) This is observed in terminal stages of cardiac and liver cell failure, as also in the terminal stages of tuberculosis, malignancy, or other chronic illnesses.

It is important not only to diagnose hyponatremia, but also to determine its etiology and to determine from the clinical background whether it is associated with a contracted, increased or normal extracellular volume. The evaluation and approach to a hyponatremic patient is illustrated in Flowchart 1.

Clinical Features

The clinical picture of hyponatremia, when there is both a true salt and water depletion, is invariably dominated by features of fluid loss, which result in a reduced or contracted extracellular and intravascular volume. Dehydration and hypovolemic shock of varying degrees result (see Chapter Hypovolemic and Hemorrhagic Shock).

Salt depletion per se produces thirst, severe cramps in the legs, and later in the thighs and abdomen. Potassium depletion is also invariably present as an associated feature, and features of hypokalemia are therefore also often seen (see subsection on Hypokalemia). Fluid and electrolyte loss is also often associated with acid-base disturbances—metabolic alkalosis in vomiting, and metabolic acidosis in diarrhea. Lactic acid acidosis occurs with increasing impairment of tissue perfusion.

Symptoms due to hyponatremia depend on its severity and the rate at which it evolves. Symptoms generally occur with serum sodium less than 125 mEq/L and are chiefly due to water intoxication with edema of the brain cells. Patients may be lethargic, confused, stuporous or even comatose. In severe or rapidly evolving hyponatremia with serum Na less than 110 mEq/L, seizures and coma occur due to brain edema. The clinical picture at times, particularly in older patients, simulates a brainstem infarction or a subarachnoid hemorrhage with neck stiffness, stiffness of the limbs and coma. In a few cases, the diagnosis becomes first apparent on a cerebrospinal fluid examination, which shows a very low chloride content.

Management[5,6]

Hyponatremia due to Salt and Water Loss

In hyponatremia *due to both salt and water loss* causing a decreased intravascular volume, dehydration and hypovolemia are corrected by infusions of N saline (see Chapter Hypovolemic and Hemorrhagic Shock). As explained earlier, the flow rate is quicker through a large-sized catheter inserted in a peripheral vein. A central venous line helps to monitor the CVP and should be inserted if the patient is in shock. In severe shock, the simultaneous use of colloidal solutions (albumin or haemaccel) should be started to produce a more rapid expansion of the vascular compartment.

The total quantity of IV fluid depends on the degree of shock, the clinical history, an estimation of the rate and volume of fluid loss by carefully maintaining the output chart, and by the response to therapy. Thus, in a patient with a violent gastrointestinal infection, such as cholera, the fluid loss may amount to 500–1,500 mL/hour, and death results if the volume is not adequately replaced. Often in patients with a profuse fluid and electrolyte loss, 10–12 liters may need to be infused in the first 24 hours. The CVP should be maintained between 7 cm and 10 cm H_2O. Rapid infusions in patients with left heart disease or renal insufficiency can however trigger pulmonary edema even with a normal CVP. Clinical auscultation of the lung bases for basal crackles and a chest X-ray for pulmonary congestion aid in diagnosing this complication, and help in controlling the administration of IV fluids.

We invariably go by clinical considerations (this includes CVP monitoring) in adjusting the quantity, quality and rate of IV administration of infusions in hyponatremia associated with fluid and sodium loss. This is notwithstanding the formulae, which are given to help evaluate the degree of salt and water loss in different situations. Hyponatremia due to fluid and sodium loss is generally associated with hypokalemia and often associated with acid-base disturbances, which need to be corrected.

Severe Symptomatic Hyponatremia (Serum Na Less than 115 mEq/L)

Severe symptomatic hyponatremia with serum sodium less than 115 mEq/L deserves urgent correction as the mortality exceeds 50%. Management is guided by the clinical background. It is important to clinically assess whether hyponatremia is associated with a low extracellular volume (ECV), a normal or near normal ECV or an increased ECV.

Severe hyponatremia with a low ECV Hypertonic 3% saline is infused till the serum Na increases to about 125 mEq/L. The amount of sodium needed can be determined by estimating the sodium deficit.

Sodium deficit (mEq) = TBW × [125–serum Na of patient (in mEq/L)]

Where TBW is total body water.

The total body water (TBW) is taken as 60% of body weight, which in a 70 kg male amounts to 42 liters. It is to be noted (for reasons given below), that it is best not to increase serum sodium to more than 125 or at the most 130 mEq/L by the use of hypertonic saline.

Once the sodium deficit is calculated, the volume of 3% hypertonic saline to be infused is easy to determine as 1 mL of 3% hypertonic saline is equivalent to 1 mEq of sodium, 500 mL thereby roughly providing 500 mEq of sodium.

As mentioned earlier, volume replacement with isotonic saline to restore both vascular volume and the volume in the interstitial tissue compartment should be of prime importance in these patients.

Severe hyponatremia with a normal or near normal ECV This is best treated with restriction of water intake to 700 mL and the use of diuresis with furosemide. This is then followed by the use of isotonic saline. In severely symptomatic cases (and this is rare), hypertonic saline as described above may be administered.

Severe hyponatremia with an expanded ECV These patients are best treated with restriction of water intake to 700 mL and the use of furosemide diuresis. Hypertonic saline infusions invariably do harm to these patients. Water excess can be roughly estimated by the following equation—

Water Excess = TBW × (125/current plasma sodium) – 1

Where TBW is total body water.

Dangers of Rapid Correction of Hyponatremia: Osmotic Disequilibrium Syndrome[2,7,8]

Though severely symptomatic hyponatremia carries a mortality of over 50%, rapid correction of hyponatremia can in itself result in the dangerous complication of central pontine myelinolysis, now called the osmotic disequilibrium syndrome. Physiologically, in the presence of hypoosmolarity, water enters the brain cells; edema of the brain cells is responsible for obtundation, coma, seizures, temporal lobe herniation and death. The administration of hypertonic saline leads to withdrawal of this water from the brain cells. If the cellular dehydration is too rapid, it causes central pontine myelinolysis; myelinolysis can also occur in other parts of the brain. The clinical picture is typically characterized by obtundation progressing to coma, pupillary and ocular changes, with a progressive neurological deficient, such as pseudobulbar palsy and spastic quadriparesis. A magnetic resonance imaging of the brain confirms the diagnosis. This complication generally occurs 1–6 days after treatment. It has a poor prognosis and there is no effective treatment. To avoid this complication, the maximum rise in serum Na should not exceed 10 mEq/L in first 24 hours. Patients with acute hyponatremia (<48 hours) can tolerate a faster increase in sodium concentration. The rate of increase is sodium can be targeted at 1.5–2 mEq/hour so as to reach a goal of 120 mEq/L. Alcoholic and malnourished patients are at greater risk of developing central pontine myelinosis so that precautions stated above assume even greater importance.

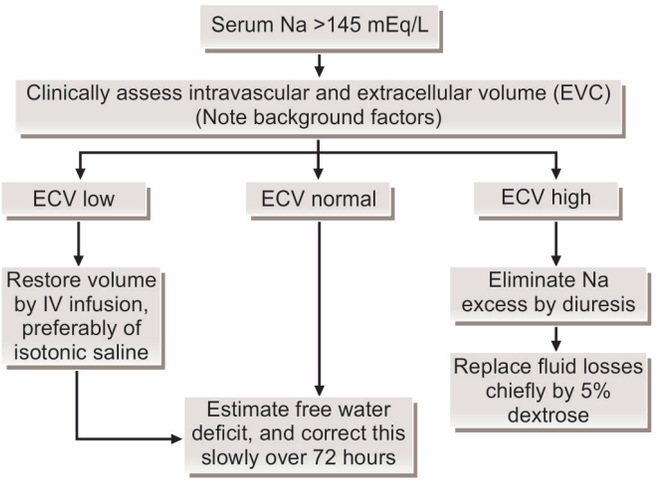
HYPERNATREMIA[2,9-11]

Hypernatremia exists when the serum sodium is in excess of 145 mEq/L. It means that there is an excess of sodium relative to water in the extracellular and vascular compartments. Hypernatremia, as is explained later, is invariably due to a massive depletion of water which relatively exceeds the depletion of sodium. In other words, most patients with hypernatremia are hypovolemic with a contracted extracellular volume. The increased osmolality in the extracellular fluid causes a shift of water from the intracellular to the extracellular compartment. Water loss from plasma is to an extent buffered. Massive loss of water is therefore necessary for significant hypernatremia to occur. The intracellular dehydration caused by hypernatremia chiefly affects the function of the brain cells as will be discussed later.

Hypernatremia observed in the ICU is (1) chiefly due to excessive loss of water relative to sodium; (2) occasionally it is due to very inadequate water intake in comatose or obtunded patients treated at home, or in old patients who are not looked after, or in those in whom thirst is either deficient or unsatisfied; (3) rarely it is iatrogenic and induced by excessive IV infusions of sodium bicarbonate (following cardiac arrest or to correct metabolic acidosis), or IV infusions of hypertonic saline used to correct hyponatremia.

- Water loss—
  - Through the gastrointestinal tract—gastric secretions are hypotonic to plasma; rarely unreplaced losses can lead to a hypernatremic, hypovolemic state.
  - Loss in hot climes can occur from excessive sweating. Large quantities of hypotonic fluid can be lost from the skin and to a lesser degree from the lungs. In burns, involving a large body surface area, hypernatremia is a common complication.
  - Loss of water from the kidneys in quantities sufficient to cause hypernatremia, occurs only in two conditions—uncontrolled diabetes, where water loss can be significantly greater than the sodium loss, and the solute diuresis, observed after IV mannitol and in uremic patients. Tube feeding in unconscious patients with feeds containing a high protein and low water content, can also produce hypernatremia in ICU patients. The products of protein catabolism following the use of such feeds, act as solutes producing a solute diuresis, more water being excreted than sodium.
- Excess of sodium—
  - We have rarely observed hypernatremia due to increased body sodium, because we carefully monitor the use of IV sodium bicarbonate, and use hypertonic saline only for the correction of acute symptomatic hyponatremia. When hypernatremia is due to an overall increase in the sodium content of the body, hypervolemia and an expanded extracellular compartment are always accompanying features.

Flowchart 2: Algorithm for management of hyperantremia



Serum Na >145 mEq/L
Clinically assess intravascular and extracellular volume (EVC) (Note background factors)
ECV low
ECV normal
ECV high
Restore volume by IV infusion, preferably of isotonic saline
Estimate free water deficit, and correct this slowly over 72 hours
Eliminate Na excess by diuresis
Replace fluid losses chiefly by 5% dextrose

Clinical Features

The clinical features produced by hypernatremia involve CNS dysfunction due to intracellular dehydration. To some extent the intracellular dehydration within the brain cells is reduced by a build-up of osmotically active solutes within the cells. Marked hypernatremia however results in a shift of water from the brain cells. This could cause petechial, intracerebral, subarachnoid or subdural bleeds, resulting in neurological deficits, and an obtunded or even comatose state.

A flowchart for the evaluation and management of a hypernatremic patient in the ICU is shown in Flowchart 2.

Management[12]

Hyperosmolar states (exactly like hypo-osmolar states), need gradual correction.

Hypovolemic hypernatremia (the most common form) is treated by first restoring volume by IV infusions, preferably of isotonic saline. It should be noted that hypovolemia though present, is not as marked as in hyponatremic states. This is probably because the hypertonicity within the plasma continues to draw fluid from the intracellular and interstitial tissue compartments, thereby preserving the blood volume to an extent. Once volume replacement is adequate (and this can be roughly gauged clinically), the water deficit relative to sodium is corrected. Hypotonic (e.g. half-strength saline) infusions are often advocated. However, as gradual correction is the aim of treatment, normal saline may be more suitable when plasma Na is more than 165 mEq/L. It is wise to take at least 72 hours to correct the water deficit, only about one-third of the excess of sodium concentration being reduced in the first 8 hours. Over-enthusiastic infusion of hypotonic solutions can lead to a rebound cerebral edema in place of the previous dehydration of nerve cells. Sudden shifts of water also enhance the tendency to cerebral hemorrhage. We have observed one patient who developed central pontine myelinolysis during correction of a hypernatremic state.

It is difficult to determine the exact free water deficit in hypernatremic patients. A method, which gives a rough estimate of free water deficit and which serves as a guide to fluid replacement is illustrated below.

For example, a 70 kg man has serum sodium of 170 mmoL/L, which needs to be lowered to 140 mmoL/L. The TBW is taken as 60% of the body weight, which in a 70 kg individual amounts to 42 liters. To reduce the plasma sodium, this volume needs to be increased to 170/140 × 42. This equals to 51 liters, which means that a positive balance of 9 liters is required. A slow replacement with isotonic saline, or both isotonic and hypotonic saline infusions over 4 days should restore plasma osmolality safely to normal limits. Infusions to correct hypernatremia should be monitored both clinically and by estimating the plasma electrolyte levels.

Hypervolemic hypernatremia is rarely encountered and is due to excessive infusion of sodium containing fluids, chiefly sodium bicarbonate. When due to infusions of sodium bicarbonate, if the bicarbonate solution contains 1 mEq Na/mL, then the excess of sodium due to sodium bicarbonate can be calculated thus—

$$\text{Sodium excess (mEq)} = 0.6 \times \text{wt. (kg)} \times (\text{Patient's serum Na-140})$$

The sodium excess is removed via the urine by diuresis, and the sodium concentration in the urine will give an approximate idea of the volume of urine required to be passed to eliminate the excess sodium. Thus, a sodium excess of 500 mEq with urine sodium of 100 mEq/L, would necessitate urine output of 5 L to excrete the excess sodium.

$$\text{Volume of urine to excrete excess sodium} = \frac{\text{Excess Na (mEq)}}{\text{Urinary Na (mEq / L)}}$$

Volume loss in the urine needs to be replaced mainly by 5% dextrose, else the excretion of hypotonic urine will cause a further rise in serum sodium.

Hyperosmolar nonketotic diabetic states Hyperosmolar hypernatremic nonketotic diabetic coma is dealt with as a separate entity in another chapter.

HYPERKALEMIA[13,14]

Hyperkalemia exists when the serum potassium (K^+) is above 5.5 mEq/L. Hyperkalemia is a dangerous potentially fatal condition. A rise of K^+ above 7 mEq/L is life-threatening and values above 10 mEq/L are incompatible with life.

Hyperkalemia in an ICU setting is due to:

- Release of K^+ from cells following injury: crush injuries, trauma, ischemic injury due to acute severe peripheral vascular disease are all conditions causing hyperkalemia.
- Uncontrolled diabetes even if associated with an overall K^+ deficit in the body may be associated with hyperkalemia due to shift of K^+ from the cells into the interstitial tissue and vascular compartments.
- Metabolic acidosis causes a shift of H^+ ions into cells, and a shift of K^+ ions out of the cells into the interstitial tissue compartment. Respiratory acidosis has little or no effect on serum K^+. Lactic acid acidosis has a lesser effect on cellular shifts in K^+ when compared to the acidosis of renal failure.
- Excessive K^+ intake particularly in patients with mild renal insufficiency can produce a dangerous rise in serum K^+ in critically ill patients. The routine, unchecked use of high concentrations of KCl orally in patients on a small dose of furosemide is dangerous and reprehensible, particularly in elderly patients with impaired renal function.
- Hyperkalemia is frequent when there is reduced renal excretion of K^+. This occurs in an ICU setting chiefly in patients with renal failure. Ordinarily the glomerular filtration rate should be as low as 10 mL/minute, or the urine output less than 1 L/24 hours for the serum K^+ to rise.[13] Acute renal failure, acute or chronic renal failure and the ingestion of a diet rich in K^+ by patients on hemodialysis for chronic renal failure, are perhaps the most frequent causes of hyperkalemia in an ICU setting.

Box 2: Important causes of hyperkalemia in an ICU setting

- Crush injuries, trauma, ischemic injury due to acute, severe peripheral vascular disease
- Uncontrolled diabetes mellitus
- Metabolic acidosis
- Excessive potassium intake, particularly in patients with renal insufficiency, or in those on hemodialysis
- Acute renal failure, or acute or chronic renal failure
- Use of angiotensin converting enzyme inhibitors in the treatment of hypertension, or of potassium-sparing diuretics like aldactone
- Rarer causes—interstitial nephritis, hyporenic hypoaldosteronism, adrenocortical insufficiency

An important cause of moderately severe hyperkalemia in an ICU setting is the use of angiotensin converting enzyme inhibitors in the treatment of hypertension, or the use of potassium-sparing diuretics like aldactone.

Interstitial nephritis and hyporenic hypoaldosteronism are comparatively rare causes, but can produce hyperkalemia without the presence of marked renal dysfunction.[13] Decreased potassium excretion via the kidneys due to adrenocortical insufficiency is also a rare cause of hyperkalemia in the ICU. The clinical picture in these patients, however, is not dominated by hyperkalemia.

The important causes of hyperkalemia in an ICU setting are listed in Box 2.

Clinical Features

The clinical features of hyperkalemia are characterized by muscle weakness and conduction disturbances. Muscle weakness is associated with hypotonia, areflexia, and may proceed to flaccid quadriparesis.

Bradycardia, junctional rhythms, various degrees of heart block and hypotension are observed with increasing K^+ levels.

Fig. 1: ECG changes in hyperkalemia. Note the slow idionodal rhythm with tall peaked T-waves progressing to an idioventricular rhythm with marked widening of the QRS complex. Note also the absence of P-waves

Death usually occurs from cardiac arrest. Electromechanical dissociation may be observed.

Electrocardiography Features (Fig. 1)

- The earliest manifestation of hyperkalemia is a peaking of the T-waves—this is often seen when the serum K^+ exceeds 5.5 mEq/L. Absence of peaked T-waves may be due to the fact that earlier electrocardiography (ECG) tracings (when the patient was stable), might have flat or inverted T-waves.
- A rise in serum K^+ above 6 mEq/L often results in a widening of the QRS complex. Unlike a bundle branch block, all parts of the QRS complex are equally affected.
- A rise of serum K^+ above 7 mEq/L is usually associated with a widened P-wave and delayed atrioventricular (AV) conduction. Occasionally, this is accompanied by an elevation of the RS-T junction and a coving of the RS-T segment resembling changes seen in myocardial infarction. This is promptly corrected when the hyperkalemia is treated by dialysis.
- When the serum K^+ is between 7.5 mEq/L and 8 mEq/L, the P-wave disappears, pointing to cessation of atrial contraction. A junctional, and later an idioventricular rhythm is observed. The QRS complex terminally resembles wide sine waves. Death occurs from ventricular fibrillation or cardiac arrest.

Diagnosis

Diagnosis depends on clinical suspicion and the recognition of clinical and ECG features of hyperkalemia. It is confirmed by a rise in serum K^+. A false or pseudohyperkalemia may be observed if blood is hemolysed after collection. Excessive leukocytosis (above 750,000/mm^3) and thrombocytosis (above 1 million/mm^3) can also produce a hyperkalemia due to K^+ release from clotted blood. An unclotted blood sample will give the true serum K^+ value. As with all laboratory investigations, a rise in serum K^+ should be correlated with the clinical picture; when in doubt, it is best to repeat the test.

Management[12-14]

Hyperkalemia should be treated on an emergency footing; it is even more dangerous than hypokalemia. Therapy is always indicated when serum K^+ is above 6 mEq/L, even in the absence of ECG changes, as death can occur in these patients. The following methods are used to reduce the serum K^+ levels—

- *Intravenous calcium gluconate* is the emergency drug of choice when serum K^+ levels are above 7 mEq/L, or if there is evidence of wide QRS complexes, AV block or absent P-waves on an ECG. Between 10–20 mL of 10% calcium gluconate is given as a bolus over 3–5 minutes, and can be repeated after 5–10 minutes, if the ECG remains unchanged after the first injection. Calcium directly antagonizes the effect of K^+ by increasing the membrane threshold, improving conduction, and increasing the force of myocardial contraction. Its effect is temporary and lasts for about 30 minutes. Other measures, therefore, need to be taken after this emergency treatment has been given. Intravenous calcium can produce cardiotoxicity in patients on digitalis—if administered to fully digitalized patients, it is diluted in 100 mL N saline, and given over 30 minutes. Patients with severe hypotension, and those showing an idioventricular rhythm with very wide QRS complexes, may fail to respond to IV calcium. Emergency transvenous pacing should then be tried; this may help to buy time for drugs to act.

- *An insulin-dextrose infusion* will cause a quick shift of K^+ from the vascular and interstitial tissue compartments into the cells. 500 mL of 20% dextrose to which is added 20 units of actrapid insulin is given as an infusion over 1 hour. Hypoglycemia should be watched out for, and if present should be corrected by supplemental glucose. An insulin-glucose infusion can be expected to reduce serum K^+ by 1–2 mEq, and can be repeated after a few hours.
- *An IV infusion of sodium bicarbonate* (50–75 mL of a 7.5% solution), given over 10 minutes. Bicarbonate acts by *shifting K^+ from the extracellular to the cellular compartment*. It is a useful drug, though it may not always be very effective. Repeated use of IV bicarbonate can however aggravate intracellular acidosis and lactic acid production. Intracellular acidosis can result from increased CO_2 production following the use of IV bicarbonate. The CO_2 diffuses into the cells and combines with H_2O to form H_2CO_3. A significant increase in H_2CO_3 within the cells may be incompletely buffered, resulting in intracellular acidosis. Bicarbonate can also bind calcium, so if calcium gluconate has already been used, IV bicarbonate should be given at least 30–60 minutes later. Though some workers hesitate to use bicarbonate because of its possible side effects, we routinely use it to treat hyperkalemia, with satisfactory results.
- *Intravenous furosemide* in a dose of 40–100 mg should be used to promote excretion of K^+ via the urine. This method of course is of no use in patients with renal failure.
- *The use of sodium polystyrene sulfonate resin (Kayexalate)* can cause potassium to be excreted in large quantities via the gut. Polystyrene sulfonate is a cation exchange resin which binds K^+. However, for each mEq of K^+ removed, 2–3 mEq of Na^+ are retained. A sodium overload can therefore occur with frequent use, particularly in the presence of cardiac or renal insufficiency. It can be given orally or as a retention enema. The oral dose of kayexalate is 30 g in 50 mL of 20% sorbitol. The rectal dose is 50 g in 200 mL as a retention enema.
- *Dialysis* is the most effective method of reducing serum K^+ when other methods fail, particularly so in the presence of renal failure. Hemodialysis is preferred as it is quicker; however, peritoneal dialysis though slower, can also serve the same purpose.

HYPOKALEMIA[15]

The serum potassium is normally maintained between 4 mEq/L and 5 mEq/L. A fall in serum K^+ to below 3.5 mEq/L is termed hypokalemia. A serum K^+ level below 2.5 mEq/L is fraught with danger to life. It is being increasingly realized that severe hypokalemia is an important cause of death in critically ill individuals. This danger often goes unrecognized with disastrous consequences.

It has already been emphasized that the major quantity of K^+ within the body is in the intracellular compartment. The total quantity of K^+ in the body is roughly 50 mEq/kg body weight—i.e. 3,500 mEq in a 70 kg adult. Of this, less than 2% (i.e. <70 mEq) is within the extracellular compartment.[14] The large gradient of K^+ between the intracllular and extracellular compartments is due to the activity of the sodium-potassium membrane pump, which actively keeps the potassium within the cellular compartment. Transfer of K^+ from the intracellular to the extracellular compartment (including the vascular compartment) and vice versa, occurs frequently in various disease processes. The reasons or mechanisms underlying these shifts are not always clearly understood. It is obvious therefore, that the serum K^+ does not necessarily reflect changes in total body K^+. In fact, the latter may well be significantly depleted with a normal serum K^+. This is evident if the patient has lost water and K^+ in the same concentration as in plasma. Even if the loss of K^+ exceeds that of water, serum K^+ may be normal in spite of significant body deficit because of shift of K^+ from the cells to the extracellular compartment. Similarly, a raised serum K^+ may occasionally exist with normal or even depleted body stores of K^+. This is illustrated in diabetic ketoacidosis where the serum K^+ can be high even though the total body K^+ is depleted. When diabetic acidosis is corrected, potassium from the plasma and the extracellular compartment moves into the cells, and the body deficit of potassium is now correctly represented by a low serum K^+ concentration.

However, a low serum K^+ invariably indicates depletion of K^+ in the body—in fact, a decrease in serum K^+ is a late finding in K^+ depletion. Thus even a slight decrease in serum K^+ is of import and needs to be corrected.

The etiology of hypokalemia in an ICU setting is due to either loss of K^+ from the body, or a poor intake of K^+, so that a state of negative balance exists, or is due to shifts of K^+ from the extracellular and vascular compartments into the cells.

Loss of K^+

This is generally due to vomiting, diarrhea, nasogastric suction, pancreatic or intestinal fistulae, intestinal obstruction and burns.

Loss of K^+ can also occur through the urine—the most common cause being diuretic therapy in which adequate K^+ replacement has not been taken care of. The urinary K^+ loss in these patients is in excess of 30 mEq/L. Another important cause of increased urinary loss of K^+ with resulting hypokalemia, is the use of corticosteroids; the larger the dose used, the greater the K^+ loss.

Transcellular Shifts

The most important cause of hypokalemia due to shifts of K^+ from the extracellular compartment into the cells is metabolic alkalosis. In this condition, homeostasis induces shift of the H^+ ion from the cells to the plasma to restore pH to normalcy; in exchange, K^+ shifts from the vascular and interstitial tissue compartments into the cells. Beta-2 agonists when given systemically in severe asthma, particularly when combined

with theophylline, can induce a modest fall in serum K^+ through transcellular shifts of K^+.

Diagnosis

The clinical diagnosis rests on the following factors—

- A high index of suspicion of hypokalemia in any critically ill individual where the clinical background suggests a potassium deficit.
- Recognition of clinical features of hypokalemia. At times these are obvious and easily discernible, but unfortunately sometimes they are difficult to detect particularly in critically ill or in obtunded patients.
- Electrocardiographic features suggestive of hypokalemia. In the final analysis hypokalemia can be confirmed only by the estimation of serum K^+ by a flame photometer. It would be a truism to state that every critically ill individual under intensive care will need a serum K^+ estimation to determine the presence or otherwise of changes in this electrolyte.

Hypokalemia produces a disturbance in neuromuscular, muscular, and cardiac function. At times, only cardiac dysfunction is observed; at other times the clinical features are dominated by neuromuscular or muscular dysfunction. Occasionally, both neuromuscular and cardiac dysfunction may be observed. Long-standing K^+ deficits with hypokalemia can also produce a nephropathy characterized chiefly by inability to concentrate the urine. This feature, however, is hardly ever observed in patients under critical care.

Cardiac Dysfunction

This is the most dreaded feature of severe hypokalemia. The most important effect of hypokalemia on the heart is the propensity to cardiac arrhythmias. The most common and earliest abnormalities are ventricular ectopic beats. In ill individuals, the occurrence of such ectopics against a background of a possible potassium deficit should always lead one to suspect hypokalemia. The premature ventricular ectopics may lead to paroxysmal ventricular tachycardia, ventricular fibrillation and sudden death. Paroxysmal ventricular tachycardia may also occur without warning ectopics. In fact, sudden death due to ventricular fibrillation may be the sole catastrophic manifestation of a hypokalemic state.

Many arrhythmias observed during digitalis administration are triggered or worsened by hypokalemia resulting from the associated use of diuretics. Paroxysmal atrial tachycardia, with block and interference dissociation, are two important rhythm disturbances most frequently observed under the above circumstances. The occurrence of these arrhythmias in a patient on digitalis and diuretics should promptly point to underlying hypokalemia.

Marked hypokalemia can also induce hypotension, which is due to a lowered cardiac output and perhaps to poor sympathetic tone related to poor functioning of sympathetic nerve endings.

Neuromuscular and Muscular Dysfunction

Asthenia and apathy are often the earliest symptoms. Whenever the degree of asthenia is more than what is expected in a particular illness, the possibility of hypokalemia should be entertained. The tendon reflexes are sluggish and may be totally absent. Muscle weakness may progress to flaccid paralysis. In severe hypokalemia, the muscles of respiration are involved so that the patient hypoventilates; rarely, the muscles of deglutition may also be affected.

Abdominal distension due to mild ileus and urinary retention are at times the sole presenting features of hypokalemia. In severe cases, a complete paralytic ileus with fluid levels seen on an abdominal X-ray results, closely mimicking an acute abdomen. Following major surgery, hypokalemia is an important cause of delay in return of peristalsis.

Electrocardiography Features

ECG changes may be occasionally observed even with a normal serum K^+ when total body K^+ is markedly depleted. ECG changes frequently (but not necessarily always) appear when the serum K^+ is below 2.5 mEq/L. The following ECG changes may be observed: (1) flattening of T-waves with ST depression of more than 0.5 mm; (2) prominent U-waves, frequently best observed in the precordial leads; (3) occurrence of various arrhythmias as noted earlier.

It is important to realize that ECG changes are nonspecific and unreliable—their absence in no way negates the suspicion of hypokalemia aroused on clinical grounds.

Management[12]

This consists in replacement of K^+ to restore serum potassium levels within the normal range. Whenever possible, it is best to give KCl orally, 1 g thrice daily. Some patients vomit with oral medication, and an important, dangerous side effect following the use of oral potassium tablets, is the occurrence of acute duodenal ulceration with hemorrahge and perforation.

If the serum K^+ is below 3 mEq/L, and certainly if below 2.5 mEq/L, the IV route of administering potassium is to be preferred. Attempts have been made to formulate the K^+ deficit depending on the levels of serum K^+ in plasma. The estimated potassium deficit for a 70 kg adult vis-à-vis the serum K^+ levels is as follows: for aqueous solution. K^+ of 3.0 mEq/dL, the K^+ deficit is 350 mEq constituting about 10% of total K^+; for aqueous solution. K^+ of 2.5 mEq/dL, the K^+ deficit is 470 mEq or about 15% of the total K^+; for aqueous solution. K^+ of 2.0 mEq/dL, the K^+ deficit is 700 mEq or about 20% of the body K^+. These estimates are based on total body potassium of 50 mEq/kg lean body weight, but to my mind, can never even be reasonably accurate. The purpose of the exercise is to stress in general, the magnitude and importance of the problem, and to emphasize the urgency in restoring K^+ deficit.

Ordinarily with a K^+ level of 2.5 mEq/L or less, or if muscle weakness, arrhythmias, or cardiac dysfunction are present, 80–120 mEq of KCl in a dextrose infusion is given

over 24 hours. Replacement is of course adjusted by frequent monitoring of serum K^+ levels. We find this method to be safe and effective. Occasionally, large quantities need to be given at more rapid rates to restore low K^+ levels in the presence of ongoing potassium loss.

The recommended dose for a quicker restoration of serum K^+ levels is 0.7 mEq/kg lean body weight of KCl in a dextrose infusion given over 2 hours. This dose should not increase the K^+ by more than 1–1.5 mEq/L, unless there is metabolic acidosis or renal impairment.

When hypokalemia is below 2 mEq/L, or in the presence of multiple ventricular ectopics or ventricular tachycardia, 60–80 mEq of KCl in a dextrose infusion can be given over 2 hours under carefully monitored conditions.

Certain important features should be kept in mind regarding the IV administration of KCl—

- Intravenous potassium should not be administered, or administered very slowly and with great care, in patients with renal insufficiency or metabolic acidosis.
- Intravenous potassium should not be given through a central vein in high concentrations or at a rate exceeding 40 mEq in 2 hours, as it can result in dangerous, life-threatening cardiac toxicity. When infusing high doses, the use of two separate peripheral veins minimizes the risk of thrombophlebitis, and reduces the pain experienced due to chemical irritation of the venous wall.
- Magnesium depletion promotes potassium loss in the urine and impairs movement of K^+ from the cellular into the vascular compartment. The reason for this is not clear. From the practical point of view, if serum K^+ levels are difficult to raise, then the possibility of magnesium depletion should be entertained, and the magnesium deficit should be corrected. This generally allows for a quick restoration of serum K^+ levels to the normal range.

CALCIUM AND PHOSPHORUS[12,16-19]

The description of disturbances in calcium and phosphorus balance given below is chiefly with reference to critically ill patients under intensive care. Almost always, changes in serum calcium or phosphorus in an ICU setting, serve as markers of the severity of the illness, and do not in themselves pose major clinical problems nor do they present difficulties in management.

The normal total serum calcium is 8.5–10.2 mg/dL. About 50% of this calcium is bound to serum proteins, chiefly to albumin. An additional 5–10% is in combination with anions like bicarbonate, and the remaining is in the free or ionized form. The ionized form is the physiologically active component of calcium, and measures 4.8–7 mg/dL. It is to be noted that laboratory tests indicate the total serum calcium levels, and not the active ionized calcium level. The total serum calcium level does not always reflect the level of ionized calcium. Thus, a decrease in serum proteins, and in particular of serum albumin, leads to a decrease in the protein-bound fraction and in the total calcium, even though the ionized calcium remains unchanged. A hypocalcemia may be wrongly diagnosed under these circumstances. In hypoalbuminemic states, a correction factor that increases the total calcium by 0.75 mg/dL for each 1 g/dL decrease in serum albumin below 3.5 g/dL, gives a more correct picture of serum calcium levels. Ion-specific electrodes can however directly measure ionic calcium, allowing a very accurate quantification of the physiologically active calcium in the serum. Unfortunately, only few reference laboratories can measure ionic calcium levels in the blood.

In an ICU setting, the most common causes of lowered serum calcium levels are related to hypoalbuminemia. If these are excluded, then low serum calcium levels (i.e. low-ionized calcium levels) are invariably related to the causes listed below.

Alkalosis

An increase in the pH promotes binding of calcium to albumin (even though albumin levels are unchanged), and reduces ionic serum calcium; the total serum calcium however remains unchanged. Both metabolic and respiratory alkalosis can produce a fall in ionic serum calcium.

Sepsis

Hypocalcemia is observed at times in sepsis. This could be due to a respiratory alkalosis produced by increased ventilation commonly observed in these patients, as also due to efflux of calcium across a disrupted, damaged microcirculation.

Hypomagnesemia

Depletion of magnesium inhibits parathormone secretion and reduces the response of the end organ to parathormone, resulting in hypocalcemia. Hypocalcemia due to magnesium depletion is difficult to correct, as the infused calcium is excreted via the urine due to diminished action of the parathyroid hormone. Once the magnesium deficiency is corrected, serum calcium is quickly restored to normal. In the presence of normal renal function and in the absence of hypoalbuminemia, sepsis or alkalosis, a persistently low serum calcium in an ICU setting should always suggest the strong possibility of an associated magnesium deficiency. The combined presence of hypokalemia in the above situation strengthens the diagnosis of hypomagnesemia even if the serum Mg^{++} levels are normal.

Renal Failure

The serum calcium in renal failure may be normal, low or increased depending on the nature of metabolic abnormality induced in a given patient.

Pancreatitis

A low serum calcium is invariably present in severe pancreatitis, and it serves as a marker for the severity and prognosis of the disease.

Box 3: Common causes of hypocalcemia in an ICU setting

- Related to hypoalbuminemia (the most common cause)
- Metabolic or respiratory alkalosis
- Sepsis
- Hypomagnesemia
- Renal failure
- Pancreatitis
- *Other causes:* burns, massive blood transfusions, following cardiopulmonary bypass, and in fat embolism

Other causes of hypocalcemia in an ICU setting include burns, massive blood transfusions, following cardiopulmonary bypass and in fat embolism. In massive blood transfusions, the citrate preservative in banked blood binds calcium, whilst in fat embolism the circulating free fatty acids bind calcium causing hypocalcemia.

The common causes of hypocalcemia are given in Box 3.

Clinical Features

Hypocalcemia can cause tetany (carpopedal spasm), and neuromuscular excitability, which in severe cases can manifest with seizures.

Hypotension, vasodilatation, and a prolonged QT interval are also observed in severe hypocalcemia.

In an ICU setting, clinical features resulting from hypocalcemia are rarely observed. The hypocalcemia in critically ill patients as already mentioned, often draws attention to the nature and severity of the underlying illness, and at times is of prognostic value.

Management

Mild asymptomatic hypocalcemia requires no specific treatment. Well-marked hypocalcemia and symptomatic hypocalcemia are treated with IV calcium gluconate, 10 mL being given very slowly over 10 minutes and repeated if necessary. A maintenance drip of 10 mL calcium gluconate in 100–200 mL 5% dextrose saline given over 2–3 hours can then be administered.

HYPERCALCEMIA

Hypercalcemia is a dangerous metabolic disturbance; serum calcium levels above 14 mg percent can cause death if not promptly recognized and treated. There are many causes of hypercalcemia, the important ones are listed in Box 4.

Box 4: Important causes of hypercalcemia

- Primary hyperparathyroidism
- Metastatic carcinoma
- Sarcoidosis
- Myelomatosis
- Vitamin D intoxication
- Milk-alkali syndrome
- Ectopic parathyroid hormone producing tumors
- Hyperthyroidism
- Adrenal insufficiency
- Dysproteinemia
- Myxedema
- Osteoporosis following prolonged immobilization

The two most frequent causes in the ICU are hypercalcemia due to hyperparathyroidism, and that secondary to malignant disease.

The clinical features of hypercalcemia are varied, often misleading the physician with a wrong diagnosis. Drowsiness and mental apathy may simulate a stroke. Changes in mental state may lead to a wrong diagnosis of depression. Ileus, urinary retention, excessive muscular weakness and increasing renal failure are some of the other manifestations of an underlying hypercalcemia.

Management[17-19]

Hypercalcemia above 13 mg/dL or hypercalcemia associated with symptoms needs prompt treatment.

Volume Load Plus Furosemide

Hypercalcemia leads to increased excretion of calcium in the urine, with a resulting osmotic diuresis. Hypovolemia with marked hemoconcentration of the blood results. Multiple infusions of normal saline to increase the circulating volume produce a natriuresis, which in itself promotes excretion of calcium, and results in lowering of serum calcium levels.[17,18] It is preferable to combine a volume load (N saline infusion) with IV furosemide 40–60 mg given every 2–4 hours. The volume lost in the urine should be promptly replaced with N saline so that the "intake" matches the "output". The strategy is to aim at a larger output of urine, and yet replace it with an equivalent large "input" of N saline. Potassium replacements will also be necessary as diuresis progresses. Care must be taken to ensure that elderly patients or those with poor left ventricular function are not overhydrated and pushed into pulmonary edema.

Calcitonin

This drug can reduce serum calcium by inhibiting bone resorption. Salmon calcitonin is rapid acting, but expensive; it can effectively reduce the serum calcium within 2–3 hours.[19] It is administered subcutaneously or intramuscularly in a dose of 4 mg/kg every 12 hours for two doses. The dose can be doubled if the desired effect on serum calcium is not obtained within 2 days.

Mithramycin

This is an antimitotic drug, which reduces serum calcium by inhibiting bone resorption. It is slower acting (24–36 hours

Box 5: Common causes of hypophosphatemia

- Dextrose infusions
- Nutritional recovery syndrome
- Use of aluminum hydroxide as antacid
- Sepsis
- Diabetic ketoacidosis
- Respiratory alkalosis

to act) than calcitonin; the latter is therefore preferred for emergency use. It is given in a dose of 25 μg/kg preferably, in an infusion over 6 hours, and can be repeated after 2–3 days.[19] The risk of bone marrow depression is small as the dose used is less than that used in neoplastic diseases.

Calcitonin and mithramycin are often unavailable in developing countries.

Dialysis

Hemodialysis in particular, can effectively and quickly reduce serum calcium levels. It should be tried if other methods are ineffective. If saline diuresis is not possible as in patients with renal failure, hemodialysis is the only effective therapy for severe hypercalcemia.

PHOSPHORUS[20,21]

The normal serum phosphate level is between 3 mg/dL and 4.5 mg/dL. There is a slight diurnal variation in serum phosphate levels, the latter being lower in the mornings and higher at night. Phosphorus is chiefly an intracellular ion and less than 1% is located in the extracellular fluid compartment.

Hypophosphatemia is uncommonly met with in patients under critical care, or for that matter even in patients admitted to the general wards of a hospital.

The important causes of severe hypophosphatemia in a hospital population are given in Box 5.

Dextrose Infusions

This is probably the most important cause of hypophosphatemia. Phosphate levels were observed to fall within a few hours of IV dextrose infusions, particularly in alcoholics and debilitated patients. Increasingly low phosphate levels were also observed by the 10th day of starting total parenteral nutrition. Hypophosphatemia associated with dextrose infusions is related to transport of glucose and phosphorus into the liver and skeletal muscle through insulin action. The phosphorus within the cells is used as a co-factor for glycolysis. In adequately nourished patients infusions of IV dextrose do not affect phosphate levels, but in malnourished individuals, a sharp fall in the phosphate levels to less than 0.5 mg/dL may occur within a few days.

Nutritional Recovery Syndrome

Overzealous feeding, in particular, with a high carbohydrate intake in malnourished patients results in an illness characterized by lethargy, weakness, diarrhea and multiple electrolyte abnormalities which include a low phosphate level. Death can also result. This is the reason why feeds should be gradually increased in malnourished or very ill individuals.

Use of Aluminum Hydroxide as an Antacid

Aluminium hydroxide when used as an antacid binds phosphate in the bowel and produces phosphate depletion. Aludrox and digene are the two most common antacids used in India, and unfortunately most critically ill patients seem to be receiving these drugs.

Sepsis

Hypophosphatemia has been reported in sepsis, and can occur early in the natural history of sepsis. The mechanism leading to hypophosphatemia in sepsis is however unknown.

Diabetic Ketoacidosis

Glycosuria in diabetic ketoacidosis produces a loss of phosphate in the urine leading to depletion in the phosphorus content of the body. The serum phosphate level however may be normal because of the transfer of phosphates from the intracellular compartment to the extracellular one. During therapy with insulin the phosphate from the vascular and interstitial tissue compartment returns into the cells and a marked fall in plasma phosphate levels is observed. Nevertheless, specific replacement of phosphorus does not seem to improve the outcome of diabetic ketoacidosis.

Respiratory Alkalosis

This is an important cause of hypophosphatemia. The increase of pH within the cells promotes glycolysis and this induces the influx of phosphorus into the cellular compartment. Hypophosphatemia can thus occur in patients who are being overventilated whilst on ventilator support.

Clinical Features[20,21]

Even well-marked hypophosphatemia is often silent. Low phosphate levels are associated with depleted stores of 2,3-diphosphoglycerate within the red blood cells, causing a leftward shift of the oxyhemoglobin dissociation curve. As a consequence, oxygen bound to hemoglobin is less easily released to tissues.

Very low phosphate levels have been rarely reported to cause hemolysis.[20] Hypophosphatemia reduces cardiac contractility and when severe and chronic, has been reported to cause cardiomyopathy.[20]

The only convincing clinical feature of hypophosphatemia is the occurrence of proximal muscle weakness resembling a myopathy. We observed it in a patient who was taking excessive doses of aluminum hydroxide. The muscle weakness was associated with very low phosphate levels. Complete recovery ensued on stopping the antacid and on increasing the oral phosphate intake.

Management[12,21]

Phosphate levels below 1 mg/dL require IV replacement even when no obvious clinical disorder is evident. The recommended solution for use contains sodium phosphate (3 mM phosphorus/mL), potassium phosphate (3 mM phosphorus/mL), and neutral sodium phosphate (0.09 mM phosphorus/mL). When the serum phosphate level is below 0.5 mg/dL, the dose recommended is 0.5 mM/kg over 4 hours. When the serum phosphate level is between 0.5 mg/dL and 1 mg/dL, the dose recommended is 0.2 mM/kg over 4 hours.[21] Rapid infusion has been known to produce hypotension.[21] Hypophosphatemia is often associated with hypokalemia, hypocalcemia and hypomagnesemia. These electrolytes should be monitored, and if necessary, also replaced.

HYPERPHOSPHATEMIA[12]

Hyperphosphatemia is chiefly observed in renal failure when the glomerular filtration rate drops below 25 mL/minute. Widespread cellular necrosis as in patients with tumor lysis or rhabdomyolysis is also associated with hyperphosphatemia due to release of phosphate from damaged or destroyed cells. Diabetic ketoacidosis may be associated with a rise in serum phosphate even though body phosphates are depleted.

Management

Management of hyperphosphatemia is directed toward the underlying cause. Aluminum hydroxide orally is often used in chronic renal failure to bind phosphates within the gut and thereby reduce the degree of hyperphosphatemia.

MAGNESIUM ION

Increasing attention has been given to this ion in the last 10 years. Magnesium (Mg^{++}) has a significant presence (second only to K^+) as an intracellular cation. It is an essential co-factor in enzymatic reactions involving adenosine triphosphate, and as part of the membrane pump it helps to maintain electrical excitability in nerves and muscles. The recommended daily intake of magnesium is 6–10 mg/kg per day and the normal serum magnesium concentration is 1.5–2 mEq/L.

How important is the ion in critical care medicine? The difficulty in answering this query in critically ill patients stems from the fact that the magnesium ion is not uniformly distributed in body fluids. Only 0.3% of the body magnesium is in the serum and as much as 50% is within the bones. The magnesium distribution in adults is shown in Table 1. Hence, changes (in particular deficiencies) in body magnesium are unlikely to be reflected in the serum Mg^{++} levels, which can be normal in both Mg^{++} deficiency or excess. How then does one authenticate clinical features attributable to magnesium deficiency? And how does one gauge the true prevalence of Mg^{++} insufficiency in critically ill patients? There are a number of specialists in critical care medicine who feel that magnesium depletion is very frequent in an ICU population chiefly due to the lack of daily supplements, and the frequent use of diuretics in these patients.

Table 1: Magnesium distribution in adults[22]

Tissue	*Content (nmoles)*	*Total Body Mg (%)*
Serum	2.6	0.3
RBCs	5.0	0.5
Soft tissue	193	19.3
Muscle	270	27.0
Bone	530	53.0

Abbreviation: RBCs, red blood cells.

The important causes of Mg^{++} deficiency include[23]—

- Diuretics, in particular furosemide, which blocks reabsorption of Mg^{++} through the loop of Henle, causing an increased excretion of Mg^{++} in the urine.
- Alcoholism, which induces magnesium depletion chiefly through increased excretion of the ion in the urine. Magnesium deficiency may become manifest soon after ethanol withdrawal.
- Diarrhea, which causes loss of the ion, as secretions within the lower GI tract are rich in Mg^{++}.
- Aminoglycosides, which act by reducing reabsorption of Mg^{++} in the renal tubules.
- Reduced intake in critically ill individuals in the presence of abnormal losses of this ion.

Clinical Features[23]

The clinical diagnosis of Mg^{++} deficiency leaves much to be desired. Colleagues interested in this field diagnose Mg^{++} deficiency even with normal levels of serum Mg^{++}. The clinical situations suggestive of Mg^{++} deficiency include—

- Presence of other electrolyte abnormalities—in particular hypokalemia, hyponatremia, hypocalcemia and hypophosphatemia. Of all these, the association between hypokalemia and hypomagnesemia is now fairly well established. Refractory hypokalemia, at least in some patients, may be due to an associated hypomagnesemia. Repletion of Mg^{++} in such patients leads to a rapid correction of the K^+ deficit.
- Intractable arrhythmias have been dubiously ascribed to Mg^{++} deficiency. It is true that IV magnesium is occasionally an effective antiarrhythmic agent when other antiarrhythmic drugs have failed. But this could well be related to the specific antiarrhythmic effect of the ion, rather than to a true deficiency.
- Arrhythmias in myocardial infarction—magnesium infusions have been reported to reduce the incidence of arrhythmias in acute myocardial infarction and hypomagnesemia can enhance calcium entry into vascular smooth muscle of the coronaries, and initiate vascular spasm. The role of hypomagnesemia in relation to the clinical aspect described above.

- Muscle weakness has been occasionally reported with hypomagnesemia, but here again the evidence is unconvincing. Neuromuscular excitability with a positive Chvostek's or Trousseau's sign has also been reported. Seizures have also been noted to be a feature of severe hypomagnesemia.

In our opinion, the clinical features of import with reference to hypomagnesemia, are the presence of hypokalemia and cardiac arrhythmias in a setting where Mg^{++} loss through the urine or the gut, is likely to be increased.

Magnesium Replacement[24]

In patients with symptomatic Mg^{++} depletion and normal renal function, magnesium sulfate is given at the rate of 1 mEq/kg for the first 24 hours, and then at 0.5 mEq/kg for the next 3 days. Magnesium sulfate is available as a 10% or a 50% solution. 5 mL of the 10% or 1 mL of the 50% solution will provide 4 mEq of elemental magnesium. The 50% solution must be diluted before use.

In the presence of life-threatening hypomagnesemia causing cardiac arrhythmias or seizures, 4 mL of a 50% solution of magnesium sulfate is infused over 2 minutes. This is followed by 10 mL of 50% magnesium sulfate in 500 mL of N saline over the next 6 hours. 12 hourly infusions of 10 mL of 50% magnesium sulfate are then recommended for the next 5 days.

Magnesium administration should always be monitored by serum magnesium levels. Great care needs to be taken in administering magnesium intravenously in patients with renal insufficiency. The dose stated above is preferably halved, and given over double the time.

HYPERMAGNESEMIA[25]

Hypermagnesemia generally occurs in patients with chronic renal failure who are administered magnesium-containing antacids orally over prolonged periods of time. Diabetic ketoacidosis complicating renal failure induces magnesium transport from the intracellular to the extracellular compartment, and can raise serum Mg^{++} levels.

The most important clinical feature of hypermagnesemia is hypotension which is observed when Mg^{++} levels exceed 3–5 mEq/L. The hypotension does not respond to the usual measures. Complete heart block is observed with serum Mg^{++} levels of 7.5 mEq/L; respiratory depression and mental obtundation progressing to coma, occur with serum Mg^{++} levels of 10 mEq/L.

Treatment

Magnesium levels can be lowered and magnesium induced hypotension best countered by administering 20 mL of 10% calcium gluconate intravenously. Magnesium excretion in the urine can be induced by the use of IV furosemide. If renal function permits, a volume load should precede the use of furosemide. Hemodialysis can effectively lower elevated serum magnesium levels, and is the treatment of choice in patients with severe renal failure.

Acid-Base Disturbances in the Critically Ill

- Acid-Base Disturbances in the Critically Ill

CHAPTER 41

Acid-Base Disturbances in the Critically Ill

GENERAL CONSIDERATIONS

The maintenance of normal acid-base balance (pH 7.35–7.45) in the blood is of crucial importance and is a vital homeostatic function of the body. Any variation from the normal constitutes an emergency in that a significant change in the hydrogen ion (H^+) concentration of the plasma or the extracellular fluid is incompatible with life; a pH less than or equal to 7, or a pH more than or equal to 7.8 spells imminent danger and death.

Acid-base disturbances occur very frequently in patients who are critically ill. They may dominate the clinical picture as in severe diabetic ketoacidosis or in renal failure. The diagnosis and importance of acid base changes in these patients is obvious and is quickly appreciated. However, more often than not a change in the acid-base equilibrium occurs surreptitiously against the background of a critical illness. The manifestations of an altered acid-base homeostasis in such patients are often subtle, virtually impossible to clinically detect, and are often masked by the clinical features of the illness. There are no barriers to these disturbances; they are encountered in all fields and all specialties of medicine and surgery. Not uncommonly, the realization that sudden clinical deterioration or death in a particular patient may have been related to acid-base disturbances dawns on the physician a trifle too late. An early diagnosis of a change in acid-base equilibrium demands a sharp clinical acumen, a grasp of the physiopathology underlying these changes, and an intelligent interpretation of laboratory data.

No satisfactory assessment of the presence and degree of acid-base disturbances can be made without measuring the pH of the blood by the pH electrode. It is imperative that the importance of pH and acid-base measurements through a blood gas machine using the Astrup technique is universally recognized in all developing countries. Today, although many critical care units in the large metropolitan cities of India provide this very necessary facility, a number of critical care units in smaller cities still lack this basic amenity. Most students and doctors are taught to interpret arterial blood gases and acid-base disturbances by rule of the thumb or by reference to standard charts and graphs, which allow a prompt solution for the basic problem. This may be satisfactory—but only to a point. Correct interpretation of blood gases and acid-base disturbances necessitates a familiarity with basic physiology in this field. Then only can altered physiology in a critically ill individual be better understood. Intelligent and in-depth interpretation leads to a more rational management of the patient as a whole.

This chapter first outlines the elementary basics necessary for satisfactory clinical interpretation. It then deals with the clinical description, the laboratory interpretation and assessment, and the treatment of these disturbances.

BASIC CONCEPTS

Concept of an Acid

An acid is a potential H^+ or proton donor. Conversely a base is a potential proton acceptor.

The strength of an acid (HA) is measured by the extent to which it dissociates in an aqueous solution.

$$HA \rightleftharpoons [H^+] + [A^-]$$

When the above reaction is in equilibrium, for a strong acid $[H^+] + [A^-]$ will be in a greater concentration than HA in the undissociated form. Also, at equilibrium, the product of the

Table 1: Correlation between H^+ concentration and pH values

Hydrogen ion concentration (nmoL/L)	*pH*
10	8.00
20	7.70
30	7.52
40	7.40
50	7.30
60	7.22
70	7.15
80	7.10
90	7.05
100	7.00

concentration on one side of the equation will bear a constant relationship to the product of concentration on the other.

$$Ka\,[HA] = [H^+]\,[A^-]$$

$$Ka = \frac{[H^+]\,[A^-]}{[HA]}$$

where Ka is the acid dissociation constant. Strong acids have a high Ka. Similar equations would apply to the dissociation of a base.

Concept of pH

The acidity of an aqueous solution is measured by its H^+ concentration or activity. The H^+ activity is expressed as pH. This terminology was introduced to simplify expression of a wide range of H^+ found in various fluids within the body. A quantification of H^+ in various fluids in moles, would have been cumbersome and difficult. The notation pH is the negative logarithm of H^+ concentration. This allows a large range of H^+ concentrations to be simply expressed and measured. Thus,

$$pH = \log \frac{1}{[H^+]}$$

$$= -\log 10\,[H^+]$$

= negative exponent of an expression of $[H^+]$ to the power 10

Thus, a pH of 7.4 = $[H^+] \times 10^{-7.4}$

The normal H^+ concentration of blood is 40 nmoL/L or 40×10^{-9} moles/L. This is equivalent to a pH of 7.4. Changes in acid-base balance can be looked upon either as changes in the H^+ concentration or changes in pH. Table 1 given below shows the H^+ concentration in relation to the corresponding pH values.

Henderson-Hasselbalch Equation

In the earlier section on the Concept of an Acid, it has been noted that—

$$Ka = \frac{[H^+][A^-]}{[HA]}$$

If we wish to express H^+ concentration as pH (log 1/H), we may rewrite the above equation thus—

$$[H^+] = Ka\,\frac{[HA]}{[A^-]}$$

Taking reciprocals,

$$\frac{1}{[H^+]} = \frac{1}{Ka} \times \frac{[A^-]}{[HA]}$$

Taking logs,

$$\log \frac{1}{[H^+]} = \log \frac{1}{Ka} + \log \frac{[A^-]}{[HA]}$$

$$\text{i.e. } pH = pKa + \log \frac{[A^-]}{[HA]}$$

where pKa is the negative logarithm of the dissociation constant Ka. The above is the Henderson-Hasselbalch equation.

Buffers

Buffers are substances, which react with an acid or base and thereby minimize changes in pH. The metabolic processes within the body add a daily load of H^+ to the body. These H^+ if not properly dealt with within the body would produce a disastrous rise in H^+ concentration, and a catastrophic fall in the pH. The homeostasis of acid-base balance however remains unchanged because of the buffering systems within the body and due to the role of the kidneys.

The main buffer systems of the body are—

- Hemoglobin and to a much lesser extent organic phosphates within the red blood cells.
- Bicarbonates (HCO_3^-) and inorganic phosphates within the blood.
- Plasma proteins.
- Tissue proteins.
- Minerals (phosphates, carbonates) within the bones.

It is only possible in this book to deal with the HCO_3^- carbonic acid buffer systems. The reader is referred to a standard textbook on Physiology for a more thorough understanding of the subject.

The HCO_3^--carbonic acid reaction is important in regulating acid-base balance. It constitutes a weak buffer system, which can be used as a measure or reflection of all acid-base reactions within the body, because buffer systems are in dynamic equilibrium, and carbon dioxide (CO_2) diffuses freely across all tissues and membranes. Also, these chemical reactions occur very rapidly.

The CO_2 produced by tissue metabolism diffuses into plasma and the RBCs. The enzyme carbonic anhydrase within the RBCs catalyzes the formation of carbonic acid—

$$H_2O + CO_2 = H_2CO_3$$

The carbonic acid within the RBCs is dissociated thus—

$$H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

The HCO_3^- within the RBCs diffuses out into the plasma, while the H^+ is mopped up by the hemoglobin, which acts as a buffer base. The loss of one ion from the cell has to be compensated by the entry of an equivalent ion. Thus, chloride ions (Cl^-) from the plasma enter the RBCs in place of the HCO_3^- ions, which have diffused out into the plasma.

When the blood reaches the lungs, the chloride (Cl^-) shift is reversed and HCO_3^- enters the RBCs. The HCO_3^- within the RBCs breaks down into H_2O and CO_2. The CO_2 diffuses out through the capillaries into the alveoli, and is washed out into the outside air.

The HCO_3^--carbonic reaction can be looked at from another angle as regards the role it plays in controlling acid base balance. Thus, when H^+ enters tissue fluids—

$$H^+ + HCO_3^- \rightleftharpoons H_2CO_3 \rightleftharpoons CO_2 + H_2O$$

The CO_2 is rapidly washed out via the lungs leading to a rapid control of H^+ production, but of course at the expense of a fall in HCO_3^-.

The Henderson-Hasselbalch equation for the HCO_3^--carbonic acid reaction aptly illustrates the role played by this reaction in regulating acid-base balance.

$$pH = pK + \log \frac{HCO_3^-}{H_2CO_3}$$

$$pH = 6.1 + \log \frac{HCO_3^-}{H_2CO_3}$$

$$pH = 6.1 + \log \frac{HCO_3^-}{0.03 \times PCO_2}$$

where 0.03 is the solubility of CO_2 in plasma, and PCO_2 the partial pressure of CO_2 in plasma.

If instead of pH one considers the H^+ concentration, then the following modification of the Henderson-Hasselbalch equation can be used.

$$[H^+] = 24 \times \frac{PCO_2}{HCO_3^-} \text{nmoL/L}$$

Normally, $[H^+] = 24 \times 40/24 = 40$ nmoL/L (pH 7.4).

The Henderson-Hasselbalch equation expresses the relationship between three reactants: H^+, HCO_3^- and PCO_2, and can be used as an expression of acid-base balance within the body.

ROLE OF THE KIDNEYS IN ACID-BASE BALANCE

The kidneys play an important and crucial role in H^+ regulation. They do so in the following ways—

- *Regulating excretion and reabsorption of bicarbonate* Bicarbonate is filtered by the glomerulus, the quantity of HCO_3^- in the filtrate being dependent on the plasma bicarbonate, and the glomerular filtration rate. The HCO_3^- is then dealt with as follows—
  - Reabsorption of HCO_3^- in the proximal renal tubules at a rate, which is dependent on the PCO_2. The higher the PCO_2, the greater the degree of HCO_3^- reabsorption; the lower the PCO_2, the lesser the degree of reabsorption of HCO_3^-, and the greater its excretion. This enables respiratory acidosis (due to a high $PaCO_2$) to be compensated through retention of HCO_3^-, and respiratory alkalosis (due to a low $PaCO_2$) to be compensated by an increased excretion of HCO_3^- (see subsections on Respiratory Acidosis and Respiratory Alkalosis).
  - In metabolic acidosis, H^+ is excreted into the urine. The enzyme carbonic anhydrase catalyzes the reaction

    $$H^+ + HCO_3^- \rightleftharpoons H_2CO_3 \rightleftharpoons H_2O + CO_2$$

    The CO_2 is reabsorbed and is excreted into the lungs. This is an important means by which the pH is controlled.
- *Use of buffering systems* Hydrogen ions can be mopped up by phosphate buffers, thus tending to increase the pH, while at the same time conserving HCO_3^-.

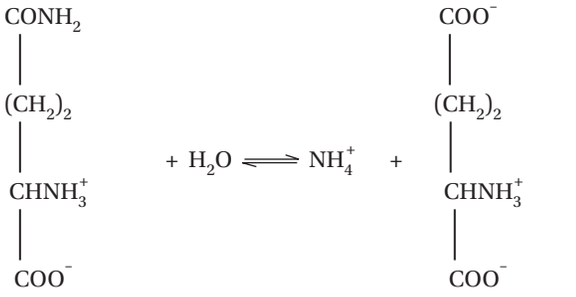
  Thus, under the influence of carbonic anhydrase—

  $$H^+ + HCO_3^- \rightleftharpoons H_2CO_3 \text{ (in the tubular cells)}$$
  $$H_2CO_3 \rightleftharpoons HCO_3^- + H^+$$

  The HCO_3^- ion is reabsorbed. The H^+ is mopped up by $NaHPO_4$ thus—

  $$H + NaHPO_4 \rightleftharpoons NaH_2PO_4$$

  this is excreted via the urine.
- Formation of ammonia. NH_4^+ is formed in the tubular cells by conversion of glutamine to glutamate. Thus,



GLUTAMINE GLUTAMATE

  NH_4^+ combines with chloride (Cl^-) and is excreted via the urine, the reaction being controlled by the enzyme glutaminase. NH_4^+ excretion to be fully operative takes time. It is however an extremely important mechanism for pH control, as excretion of ammonia allows the excretion of a significantly large quantity of H^+ via the kidney.
- *Reabsorption of sodium* The active reabsorption of sodium (Na) from the filtrate into tubule cells causes a potential gradient across the cell membrane. The positively charged

H^+ within the tubule cell thus passes across the membrane into the filtrate, and is buffered within the filtrate by a phosphate buffer.

$$H + NaHPO_4 \rightleftharpoons NaH_2PO_4$$

- In summary, the kidneys help to maintain acid-base balance in the following ways—
  - Retention of HCO_3^- when the PCO_2 increases.
  - Excretion of HCO_3^- when the PCO_2 falls.
  - Reabsorption of HCO_3^- when there is accumulation of H^+ in the blood.
  - Excretion of titratable acid and NH_4^+ to counter an increase of H^+ in the blood.
  - Excretion of H^+ when there is a primary loss of HCO_3^-.
  - Increased HCO_3^- excretion in the urine, together with a loss of K^+ in the urine, when there is a primary increase in plasma HCO_3^-.

11

DISTURBANCES IN ACID-BASE BALANCE: TERMINOLOGY

Terms used: acidemia, alkalemia, acidosis, alkalosis.

- The normal pH of arterial blood is maintained within the range of 7.35–7.45.
- Acidemia exists when the pH of arterial blood is below the normal range, i.e. less than 7.35.
- Alkalemia is the state in which pH of arterial blood is above the normal range, i.e. greater than 7.45.
- Acidosis is an abnormal state leading to an increase in the acid in the body.
- Alkalosis is an abnormal state leading to a fall in acid or an increase in the alkali in the body.
- When acidosis induces compensatory changes in the body so that pH remains within the normal range, it is termed compensatory acidosis. When acidosis produces a fall in pH below 7.35, it is termed uncompensated acidosis. Uncompensated acidosis and acidemia are thus synonymous.
- Similarly, alkalosis can be compensated or uncompensated, and alkalemia is synonymous with the latter.
- Acidosis and alkalosis (as also acidemia and alkalemia) may result from primary respiratory or metabolic disturbances so that we have respiratory acidosis and metabolic acidosis, as also respiratory alkalosis and metabolic alkalosis.
- Respiratory acidosis and respiratory acidemia (uncompensated respiratory acidosis) result from alveolar hypoventilation, which leads to hypercapnia.
- Respiratory alkalosis and respiratory alkalemia (uncompensated respiratory alkalosis) result from alveolar hyperventilation, which causes hypocapnia.
- Metabolic acidosis and metabolic acidemia are caused by either accumulation of acid or loss of base from the body.
- Metabolic alkalosis and metabolic alkalemia are due to accumulation of base or loss of acid from the body.
- Mixed acid-base disturbances are caused by a combination of respiratory and metabolic factors.

LABORATORY DIAGNOSIS OF ACID-BASE DISTURBANCES

A suspicion of possible acid-base disturbances should always be entertained in each and every patient with a critical illness. Disturbances in acid-base equilibrium can also occur under some reasonably well-defined clinical conditions. Thus in an unconscious hyperpneic patient, the possible diagnosis of diabetes or uremia should be established by relevant blood and urine tests, and in suspected aspirin poisoning, the acetyl salicylic acid levels in the blood confirm the diagnosis. Such investigations help in two ways: (1) they point to the possible nature of the acid-base disturbance and (2) they direct attention to the root cause of such a disturbance, which proves invaluable in the management of the patient.

ESTIMATION OF SERUM ELECTROLYTES

This is mandatory in every patient with acid-base disturbances, as electrolyte abnormalities are frequently seen and are often inseparable from changes in acid-base balance. Thus, hyperkalemia is frequently seen in metabolic acidosis, and hypokalemia and hypochloremia are commonly observed in metabolic alkalosis.

INTERPRETATION OF pH AND ACID-BASE MEASUREMENTS BY THE ASTRUP TECHNIQUE

In this technique, the pH and PCO_2 of the blood are measured by a sensitive instrument (radiometer). The values of standard HCO_3^-, actual HCO_3^-, CO_2 content, and base excess or deficit are then read from a standard nomogram. These concepts are briefly explained below.

The standard HCO_3^- is the HCO_3^- content in the plasma of blood, which has been equilibrated at a PCO_2 of 40 mm Hg, as also with oxygen so as to saturate it with oxygen. The standard HCO_3^- is a measure of the nonrespiratory HCO_3^-. It is the most active, mobile, rapidly reacting fraction of the total buffer potential, and its rate of excretion and retention is governed by the kidneys. A fall in the standard HCO_3^- therefore indicates a metabolic acidosis; conversely a rise in the standard HCO_3^- indicates a metabolic alkalosis. A normal standard HCO_3^- indicates metabolic equilibrium.

The actual HCO_3^- content is the HCO_3^- concentration in mEq or mmoL/L in the plasma. It is not directly estimated; its value is derived from a nomogram in the Astrup technique, or from the CO_2 content of blood, which can be estimated by the van Slyke Apparatus.

The CO_2 content of plasma is the actual HCO_3^- content + dissolved CO_2. As stated above, it can be estimated by gasometry (Van Slyke Apparatus), or is derived from a nomogram if the pH and $PaCO_2$ are known.

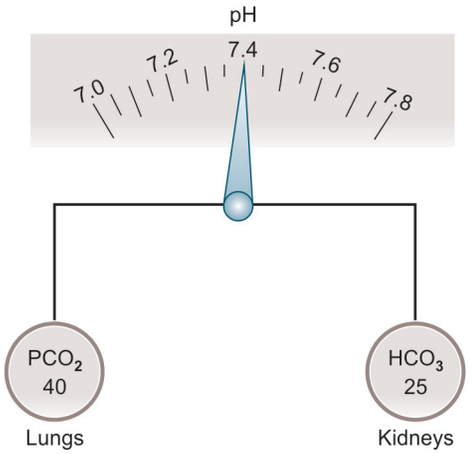


Fig. 1: Normal acid-base balance

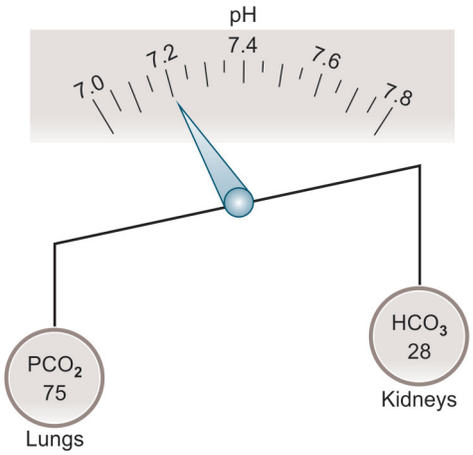

Fig. 2: Uncompensated respiratory acidosis and acidemia

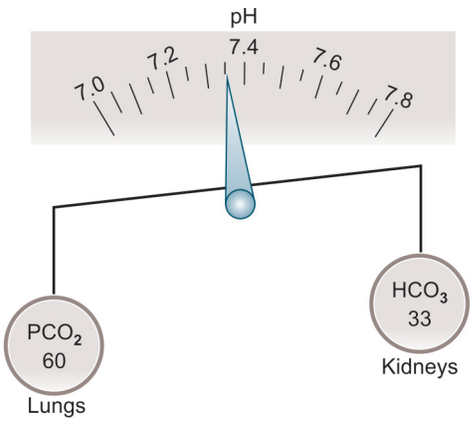

Fig. 3: Compensated respiratory acidosis

Base excess defines the presence in blood of excess or deficit of base, the physiological range being ±2.3 mEq/L. It denotes the amount of strong acid or base per liter of blood, which has been added as a consequence of a metabolic disturbance. It is an in vitro concept, and is again derived from a nomogram if the pH and $PaCO_2$ are known.

Some of the terms described above are apt to prove confusing to the resident working in critical care medicine. For purposes of simplification, acid-base changes are best interpreted by a consideration of the Henderson-Hasselbalch equation—

$$pH = pK + \log \frac{HCO_3^-}{PCO_2 \times 0.03}$$

In other words, pH is the "balance" between the respiratory parameter represented by $PaCO_2$, and the metabolic parameter represented by HCO_3^-. This is most simply illustrated in Figure 1.

A primary change in the respiratory parameter ($PaCO_2$) disturbs the "balance" illustrated in Figure 1 to produce respiratory acid-base disturbances; a primary change in the metabolic parameter (HCO_3^-) disturbs the balance and produces metabolic acid-base disturbances.

A rise in $PaCO_2$ primarily due to alveolar hypoventilation causes respiratory acidosis, and when this acidosis lowers the pH to less than 7.35, respiratory acidemia results. A fall in $PaCO_2$ produced by hyperventilation induces respiratory alkalosis and if the pH rises to more than 7.45, respiratory alkalemia results.

Homeostasis demands that primary changes in $PaCO_2$ lead to secondary changes in the plasma HCO_3^-, so that the pH is kept within the normal range as far as possible. An acute rise in $PaCO_2$ (due to sudden hypoventilation following poisoning or a near respiratory arrest), will lead to a very small rise in the plasma HCO_3^- (described in subsection on HCO_3^--carbonic acid reaction). The degree of retention of plasma HCO_3^- is just 0.1 mmoL or 0.1 mEq per 1 mm Hg rise in $PaCO_2$. The standard HCO_3^- will remain unchanged. This can produce a gross imbalance between the respiratory and metabolic parameters, and can lead to a sharp and dangerous fall in pH (Fig. 2).

On the other hand, a slow or chronic rise in $PaCO_2$ (so frequently observed in patients with chronic airways obstruction) allows renal compensation to come into play. The kidneys retain HCO_3^- 3–4 mEq or mmoL/L being retained for every 10 mm Hg rise in $PaCO_2$. Significant HCO_3^- retention thus compensates for the chronic rise in $PaCO_2$, and helps to preserve the "balance". Retention of bicarbonate by the kidneys takes time; it probably starts 4–6 hours after the rise in $PaCO_2$, and is complete after 2–3 days. Compensation however can only occur up to a point—a rise in $PaCO_2$ more than 65 mm Hg is generally associated with a fall in pH below normal in spite of HCO_3^- retention. The degree of rise in HCO_3^- enables one to determine whether in a given patient the respiratory acidosis is acute or chronic. Uncompensated respiratory acidosis (respiratory acidemia) and compensated respiratory acidosis are illustrated in Figures 2 and 3, respectively.

Comparison of degrees of rise in HCO_3^- in vivo due to acute and chronic rise in $PaCO_2$ is illustrated in Figure 4.

A fall in $PaCO_2$ primarily due to alveolar hyperventilation leads to a compensatory fall in plasma HCO_3^-, the degree of

11

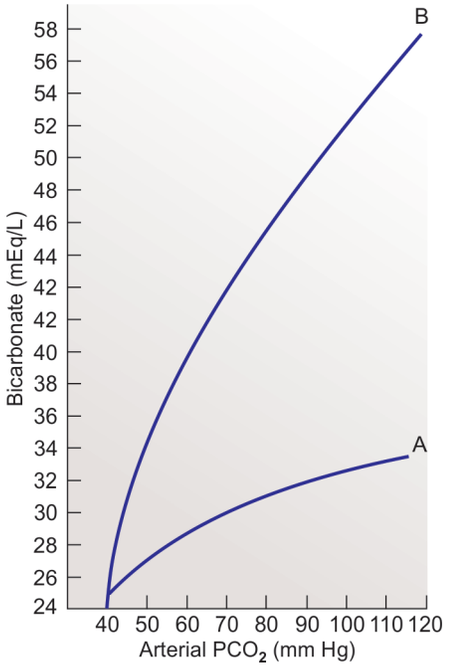

Fig. 4: Comparison curves showing rise in HCO_3^- levels in vivo with chronic and acute hypercapnia. A = rise in acute hypercapnia. B = rise in chronic hypercapnia, the curve in this case is higher and steeper than that in acute hypercapnia, because of retention of HCO_3^- by the kidney

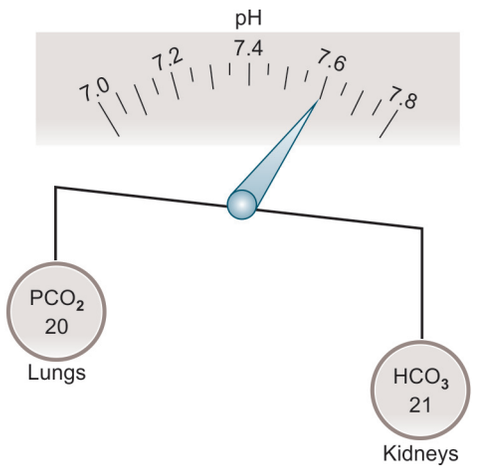

Fig. 5: Acute uncompensated respiratory alkalosis

fall approximating 0.1–0.3 mmoL/L for 1 mm Hg fall in $PaCO_2$. Acid-base balance in acute, uncompensated respiratory alkalosis is illustrated in Figure 5.

When primary metabolic problems produce a fall in HCO_3^-, metabolic acidosis results. When the pH falls to less than 7.35, metabolic acidemia results.

Metabolic alkalosis results following retention of HCO_3^- due to metabolic causes; metabolic alkalemia ensues when the pH rises to more than 7.45.

Primary metabolic changes in HCO_3^- result in secondary changes in $PaCO_2$, thus minimizing changes in the pH. Thus, metabolic acidosis stimulates the respiratory center,

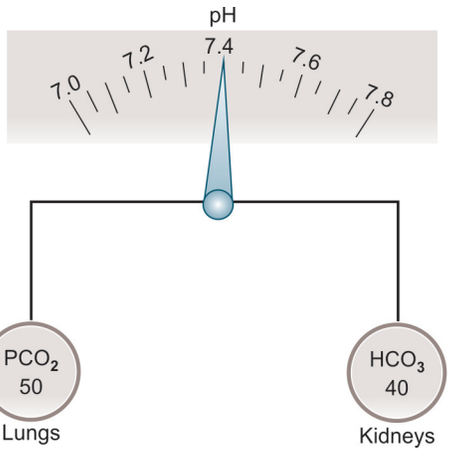

Fig. 6: Compensated metabolic alkalosis

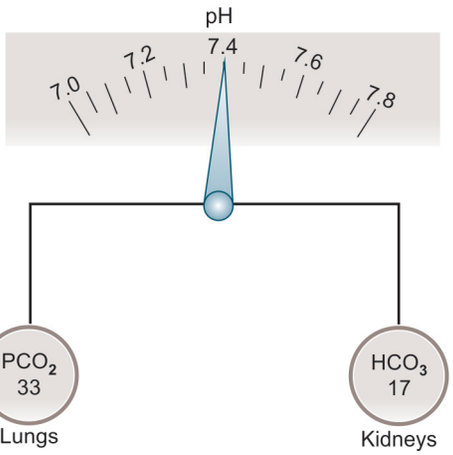

Fig. 7: Compensated metabolic acidosis

and the resulting hyperventilation reduces the $PaCO_2$. The degree of compensatory fall in $PaCO_2$ roughly equals 1.2 mm Hg for every 1 mmoL or mEq/L fall in HCO_3^- (or roughly equals 1.5 HCO_3^- content + 8). On the other hand, metabolic alkalosis depresses the respiratory center and produces a compensatory rise in $PaCO_2$, the degree of rise being 0.6–1 mm Hg for 1 mmoL or mEq/L rise in HCO_3^-. The expected $PaCO_2$ can also be considered as = 0.7 × HCO_3^- + 20 (±1.5). Figures 6 and 7 illustrate compensated metabolic acid-base disturbances.

MIXED ACID-BASE DISTURBANCES

Acid-base disturbances in critically ill patients are often due to both respiratory and metabolic problems occurring independently. A consideration of the clinical picture, the pH, $PaCO_2$ and HCO_3^-, invariably clarifies the diagnosis. The degree of compensation present in relation to HCO_3^- in primary respiratory disturbances, and the degree of compensation present in relation to $PaCO_2$ in primary metabolic problems, enables one to judge whether acid-base disturbances are due to mixed causes. The examples briefly quoted below help to give a more practical understanding of the problems involved.

A patient with chronic bronchitis emphysema deteriorated over a period of weeks, and was admitted to hospital in a critically ill condition with acute respiratory failure. The $PaCO_2$ was 82 mm Hg, PaO_2 34 mm Hg, pH 7.15, HCO_3^- 26 mEq/L. This patient obviously had respiratory acidosis ($PaCO_2$ 82 mm Hg). However, in a slowly deteriorating respiratory problem, the rise in $PaCO_2$ should have been offset by a rise in plasma HCO_3^- at a rate of 4 mEq/L for every 10 mm Hg rise in $PaCO_2$, i.e. approximately 40 mEq/L. Even in severe acute respiratory failure, the HCO_3^- should increase at a rate of 1 mEq/L for every 10 mm Hg rise in $PaCO_2$. The low HCO_3^- associated with the high $PaCO_2$ seen in this patient, is therefore due to an associated metabolic acidosis, possibly due to severe hypoxemia inducing a lactic acid acidosis.

Another patient with a history of diabetes and chronic bronchitis was admitted to hospital in a drowsy state. His pH was 7.21, $PaCO_2$ 42 mm Hg, PaO_2 50 mm Hg, HCO_3^- 14 mEq/L. He had ketosis in the urine with ketonemia. The above values pointed to the presence of metabolic acidosis; however, the comparatively high $PaCO_2$ (it should ordinarily have been 28 mm Hg), indicates an associated respiratory acidosis.

A frequently observed mixed acid-base disturbance in critical care units is a combination of respiratory acidosis and metabolic alkalosis in patients with chronic airways obstruction, who are hypokalemic due to the use of diuretics. The following example in a patient with the above problem is illustrative: pH 7.44; $PaCO_2$ 60 mm Hg; HCO_3^- 38 mEq/L; serum K^+ 3 mEq/L. The rise in the HCO_3^- significantly exceeds the maximum of 0.4 mEq/mm Hg rise in the $PaCO_2$. This is due to a hypokalemic metabolic acidosis.

A combination of respiratory acidosis and metabolic acidosis is often observed when respiratory failure due to alveolar hypoventilation, is combined with increasing hypoxia and poor tissue perfusion due to poor pump function. The following example is illustrative of this profile: pH 7.1; $PaCO_2$ 55 mm Hg; HCO_3^- 15 mEq/L. Instead of the expected rise in HCO_3^- due to a high $PaCO_2$, there is a fall in the HCO_3^- because of metabolic lactic acid acidosis induced by hypotension and poor tissue perfusion due to associated cardiac failure.

A combination of respiratory alkalosis and metabolic alkalosis is at times observed in hepatic failure. The latter causes tachypnea with respiratory alkalosis. If there is associated vomiting, or there is aspiration of gastric contents through a nasogastric tube, the loss of H^+, K^+ and Cl^- leads to an associated metabolic alkalosis. The following example is illustrative: pH 7.61; $PaCO_2$ 25 mm Hg; HCO_3^- 34 mEq/L.

A combination of respiratory alkalosis and metabolic acidosis may occur in septic shock and also in terminal acute liver cell failure. Both these conditions can cause tachypnea with respiratory alkalosis. The metabolic (lactic acid) acidosis is related to shock and poor tissue perfusion. The same combination is often observed in patients who are hyperventilated on mechanical ventilation (with resulting respiratory alkalosis), and who are hypotensive from shock or poor pump function (which causes lactic acid acidosis).

Box 1: Common causes of metabolic acidosis

1. Normal anion gap—
   - Diarrhea
   - Intestinal or pancreatic fistulae
   - Renal tubular acidosis
   - As compensation for respiratory alkalosis
   - Ureterosigmoidostomy
   - Infusion with fluids having high chloride content
2. High anion gap—
   - Lactic acidosis
   - Ketoacidosis (alcoholics, diabetics)
   - Renal failure
   - Poisonings (salicylates, acids, methyl alcohol, ethylene glycol)

Renal failure with excessive vomiting, or with a loss of gastric secretions from nasogastric aspiration, can result in a combination of metabolic acidosis and metabolic alkalosis, with the pH well within the normal range.

Arterial pH of blood gases and HCO_3^- levels should always be interpreted with reference to the history, clinical findings, and other investigations in every individual problem. Occasionally, the complexity of an acid-base disturbance is only apparent on a follow-up of the patient.

CLINICAL FEATURES AND MANAGEMENT OF ACID-BASE DISTURBANCES

Metabolic Acidosis

The diagnosis of metabolic acidosis rests on a clinical awareness of its presence in situations where it is a recognized complication. It should always be suspected in severe uncontrolled diabetes, in acute or chronic renal failure, in poisoning with acids, aspirin, or methyl alcohol, and in patients who have a continuing loss of HCO_3^- (as in diarrhea, or intestinal or pancreatic fistulae). Severe hypoxia, particularly when associated with poor tissue perfusion, is an important cause of metabolic acidosis due to accumulation of lactic acid. Poor tissue perfusion may be localized as in peripheral vascular disease, or generalized due to poor pump function, or to shock from any cause. Metabolic acidosis can also occur after cardiac arrest—the longer the period required for resuscitation, the greater the chances of increasing metabolic acidosis.

Metabolic acidosis is often divided into two groups: (1) normal anion gap and (2) high anion gap. The group with a normal anion gap is characterized by loss of HCO_3^-. This results in a replacement of Cl^- for the lost HCO_3^- to preserve electrical neutrality, and the increase in serum chloride causes a hyperchloremic metabolic acidosis. The group with the high anion gap is characterized by the addition of a fixed acid, e.g. lactic acid. The common causes of metabolic acidosis are

Box 2: Effects of acidemia

- Cardiovascular—
  - Decreased cardiac contractile function
  - Centralization of blood volume (venoconstriction and arteriolar dilatation)
- Hypotension
  - Decreased fibrillation threshold
  - Decreased cardiac sensitivity to catecholamines in severe acidemia
  - Less likelihood of conversion to sinus rhythm once fibrillation is established
  - Tachycardia
- Neurologic—
  - Obtundation and coma
  - Increased cerebral blood flow
  - Increased sympathetic discharge
  - Decreased responsiveness to circulating catecholamines (severe acidemia)
- Respiratory—
  - Increased minute ventilation
  - Dyspnea
  - Respiratory muscle fatigue
- Metabolic—
  - Inhibition of anaerobic metabolism
  - Hyperkalemia (inorganic acidemias)
  - Hyperphosphatemia

summarized in Box 1 and the effects of academia are listed in Box 2.

Anion Gap

It is assumed that the negatively charged anions and the positively charged cations are equal for purposes of electrical neutrality. If so, then the unmeasured anions and unmeasured cations can be determined using the serum Cl^-, HCO_3^- and Na^+. The difference between the unmeasured anions and cations in the serum is termed the anion gap, and is equal to $(Na^+) - (Cl^- + HCO_3^-)$. The normal anion gap is 10 ± 4 mEq/L.[1] An increase of over 15 mEq/L in the anion gap is generally considered to be abnormal.

The serum anion gap is illustrated below in detail in Table 2.

Unmeasured anions + $(Cl^- + HCO_3^-) = Na^+$ + unmeasured cations

Thus, unmeasured anions-unmeasured cations (which constitute the anion gap) = $Na^+ - (Cl^- + HCO_3^-)$

The fall in HCO_3^- which characterizes metabolic acidosis is ordinarily considered to be due to: (1) titration with an endogenously produced organic acid, in which case the fall in HCO_3^- is not matched by a rise in Cl^- and the anion gap widens or (2) a loss of HCO_3^- [either from the gastrointestinal tract or the kidneys via the urine] in which case the fall in HCO_3^- is matched by rise in the Cl^- and the anion gap remains normal. Hence, the division of metabolic acidosis is into anion gap acidosis versus non-anion gap acidosis. The exception to be noted is that administration of hydrochloric acid results in normal anion gap.

Table 4: Serum anion gap

Unmeasured anions in serum (mEq/L)		*Unmeasured cations in serum (mEq/L)*	
Proteins	15	K^+	4.5
Organic acids	5	Ca^{++}	5.0
PO_4^-	2	Mg^{++}	1.5
SO_4^-	1		
Total	23	Total	11.0
The anion gap = 12 mEq/L			

Strict adherence to the above division, particularly in critical care medicine can lead to inaccuracies. The normal serum anion gap is chiefly composed of proteins, in the main albumin. Hypoalbuminemia is extremely common in critically ill patients and spuriously lowers the anion gap, thereby masking an underlying anion gap acidosis. Serum albumin should therefore always be measured in assessing acid-base disturbances. For every 1 g decrease in serum albumin below 4 g the serum anion gap should be corrected by 2.5–3 mEq/L. Hence, a serum albumin of 2 g would amount to an increase in the anion gap by 6 mEq/L.

Another important point of clinical relevance is to remember that in some cases of lactic acidosis, the anion gap may remain well in the normal range. In fact, the serum lactate may be quite elevated in the presence of a normal anion gap.[3] It is also important to note that the kidney can excrete many organic anions especially ketoacids, replacing them with Cl^-, thereby effectively reducing the anion gap. This chiefly is dependent on kidney function, in particular the glomerular filtration rate. The hypovolemic hyperglycemic, ketotic diabetic will present therefore with a high anion gap; on the other hand, the occasional diabetic ketonic patient who is euvolemic or who is being treated with intravenous fluid will present with a nonanion gap acidosis.

Other causes of reduced anion gap include paraproteinemias, an increase in unmeasured cations (Ca^+, K^+, Mg^+), and hyponatremia. The reason for a reduced anion gap in hyponatremia is unclear. In dilutional hyponatremia, the extra water (H_2O) in serum should decrease serum Cl^- as much as serum Na^+, leaving the anion gap unchanged. However, this is not necessarily the case; the Cl^- does not show an equivalent reduction as the Na in many cases of hyponatremia. Perhaps unmeasured cations like Ca^+ and Mg^+ may increase in the serum during hyponatremia, and the Cl^- remains comparatively elevated to provide electrical neutrality.

It should be noted that the concept of the anion gap rests on the assumption that unmeasured cations are rarely present in significant amounts. In fact, in critically ill patients it has been shown that unmeasured, unidentified cations are indeed present.[4] In these patients, the calculated anion gap would be much lower than the actual concentration of unmeasured anions, thus allowing an anion gap acidosis to masquerade as nonanion gap acidosis.

The concept of the anion gap though useful may in some instances be an imperfect measurement in the diagnosis of metabolic acidosis. The clinician should therefore never rule out the possible etiology of metabolic acidosis particularly in critically ill patients on the basis of the anion gap alone.

Stewart Method or Factor[5-8]

The classical approach to acid base disturbance has been challenged by Stewart because it ignores a principle of chemistry. which states that the H^+ concentration of an aqueous solution is determined by the dissociation of H_2O. These changes in H^+ occur not so much because of addition of H^+, but more from a shift in the equilibrium of the equation $H_2O \rightleftharpoons H^+ + OH^-$. Stewart showed that ($H^+$) is determined by only three independent variables—the strong ion difference (SID), the concentration of weak acids (mainly proteins) and PCO_2. According to the above concept, metabolic acidosis results either from alteration in the SID or total weak acid concentration. The SID is the net charge balance of all strong ions present in the system. By strong ions is meant ions that for all purposes are completely dissociated. Thus, SID = [Na + K + Ca + Mg + PO_4 – Cl – (lactate)].

The equation is often referred to as "apparent" SID or SIDa in order to emphasize that other unmeasured strong anions or cations may be present.[9] The normal value for SID is 40–42 mEq/L.

Again, according to the above concept neither hydrogen nor hydroxy ions are strong ions because H_2O is a weak electrolyte. HCO_3^- also is not a strong electrolyte because it can combine with other chemicals such as CO_2 or hydrogen. The principles of physical chemistry dictate that strong ions are inert, so that weak electrolytes like H_2O must alter their dissociation so as to maintain electrical neutrality. If therefore we give a patient sodium bicarbonate ($NaHCO_3^-$) serum HCO_3^- rises not because we have given HCO_3^-, but because of the addition of the strong cation Na^+, which causes the dissociation of H_2O to "shift" to the left resulting in fewer H^+ and hence to higher pH. Similarly in lactic acidosis, the cause of the acidosis is the strong organic ion, i.e. lactate and not the accompanying H^+.

In conclusion, though the traditional Henderson-Hasselbalch approach is generally sufficient to explain acid base disturbances in critical care medicine, the "Stewart approach", though complex, may help us to understand cryptic acidosis occasionally found in the intensive care unit (ICU). Unmeasured ions as identified by the Stewart method have been shown to predict mortality in a pediatric ICU better than either base excess, anion gap or lactate levels.

Clinical Features[5]

The clinical features of metabolic acidosis include—

- Hyperventilation due to stimulation of the respiratory center. This is first characterized by an increase in the depth of breathing, followed by an increase in the rate.
- An obtunded mental state—drowsiness progressing to deep coma.
- The smell of ketones in the breath points to diabetic ketoacidosis, while an ammoniacal smell in the breath is observed in uremic ketoacidosis.
- *The only manifestation of metabolic acidosis may be a progressive deterioration in the clinical state of a critically ill individual.* Metabolic acidosis impairs the function of most organs of the body, particularly the heart. This can be slow, insidious and unsuspected; if the acidosis remains uncorrected, it can lead to irreversible organ dysfunction and ultimately to death. Hence, the importance of measuring the arterial pH and blood gases in every critically ill patient.

Lactic Acid Acidosis[5]

This deserves special consideration as it is fairly frequent yet an often missed entity in critically ill patients in the ICU.

Lactic acid is a product of glucose metabolism. It is produced at an average rate of 1 mEq/kg per hour, the serum lactate levels being less than or equal to 2 mEq/L. Exercise can raise the serum lactate levels to 4 mEq/L. The lactate is metabolized by the liver and is used for gluconeogenesis or for energy production.

Etiology

The most common cause of lactic acid acidosis in ICU patients is shock, in particular cardiogenic shock, and septic shock. Sepsis can produce lactic acid acidosis in the absence of hypotension or the other clinical features of shock. This is due to the fact that oxygen supply is not commensurate with the increased demand for oxygen by the tissues (see Section Sepsis and Septic Shock). Multiple organ failure is also frequently associated with lactic acid acidosis—this is chiefly related to poor pump function, and to liver cell dysfunction. The rise of serum lactate in these conditions is due to the increased production of lactic acid, and decreased clearance of lactate by the liver. The latter may well be related to poor liver function consequent to hypoperfusion of the liver observed in shock.
Other important causes of lactic acid acidosis in the ICU are—

- Hypoxia. A low PaO_2 by itself may not induce a significant rise in serum lactate. In most patients with a low PaO_2, it is the associated presence of a low cardiac output that is responsible for a rise in lactic acid.
- Severe anemia. (Hb <5 g/dL) if not adequately compensated for by a hyperdynamic circulatory state can also lead to an increase in lactic acid levels in the blood.
- Severe liver cell dysfunction, particularly when associated with hypotension or shock can lead to lactic acid acidosis.

Rare causes of lactic acid acidosis in the ICU include—

- *Thiamine deficiency* This causes lactic acidosis by reducing the mitochondrial oxidation of pyruvate. The conversion of pyruvate to acetyl-coenzyme A is blocked by the lack of thiamine, and the pyruvate is converted to lactate. In critically ill patients, particularly in those with prolonged illnesses and with poor nutrition, thiamine deficiency must be suspected when the other more common causes

Box 3: Important causes of lactic acid acidosis in an intensive care unit (ICU) setting

- Shock of any etiology, particularly cardiogenic or septic shock
- Hypoxia, especially when associated with a low cardiac output
- Severe uncorrected anemia (Hb <5g/dL)
- Marked liver cell dysfunction, particularly when associated with shock or hypotension
- Thiamine deficiency
- Severe respiratory or metabolic alkalosis
- D-lactic acid acidosis often seen following small bowel resection or jejunoileostomy done for severe obesity
- Drugs, e.g. epinephrine or nitroprusside

of lactic acid acidosis do not seem to be responsible. A quick reversal of acidosis following thiamine injections points to the diagnosis of lactic acidosis due to thiamine deficiency.

- *Alkalosis* Increased serum lactate levels have been reported with severe metabolic alkalosis and respiratory alkalosis. This is probably due to extra production of lactate due to increased activity of pH dependent enzymes involving the glycolytic pathway. Severe alkalosis with a pH more than 7.6 is generally necessary for a rise in lactate levels, as a modest increase in lactate production is ordinarily metabolized by the liver, unless liver cell function is deranged, or there is associated hypoperfusion of the liver due to a poor circulatory state.
- *D-lactic acid acidosis*[5] The usual lactate produced in the body is a levo-isomer. The dextro-isomer is produced by bacterial fermentation of glucose in the colon. *Bacteroides fragilis*, other anaerobes, and Gram-negative organisms within the gut are also capable of inducing the formation of D-lactic acid. D-lactic acid acidosis is most frequently reported following small bowel resection and following jejunoileostomy for the treatment of severe obesity. The condition should therefore be suspected in a patient with an ill-explained metabolic acidosis with a high anion gap, particularly if there is a history of small bowel surgery or persistent diarrhea. A standard assay of lactate would not detect lactic acid, as it only measures the levo form of lactate. Special assays for D-lactic acid can only be done in highly specialized reference laboratories.
- *Drugs* Rarely the use of epinephrine and nitroprusside in the ICU may induce a lactic acid acidosis. The important causes of lactic acid acidosis in an ICU setting are listed in Box 3.

Diagnosis[11]

Lactic acid acidosis should be suspected whenever metabolic acidosis is associated with an increased anion gap.

The anion gap The anion gap in lactic acidosis is often more than 30 mEq/L. Even in patients with renal failure an anion gap more than 30 mEq/L should prompt one to suspect an additional lactic acidosis.

Estimation of lactate levels may vary in samples of arterial and venous blood. The venous blood lactate is higher because it represents lactate production, while arterial blood lactate is lower as it probably represents effect of both production and hepatic clearance. In patients with a Swan-Ganz catheter in situ, samples from the pulmonary artery are probably more representative of blood lactate levels. There is a good correlation in lactate levels in blood drawn from the pulmonary artery, and that drawn from arterial blood.

Treatment[5,12]

In the final analysis, treatment should be directed toward the cause. In emergency situations, it is vital to temporarily correct a severe acidosis and then deal with its root cause, otherwise death may result. It is wrong to await results of laboratory investigations in desperate situations where the clinical picture obviously points to severe metabolic acidosis. In such situations, acidosis is corrected by administering 75–100 mL of 7.5% $NaHCO_3$ as a bolus dose. Further, administration is guided by laboratory reports.

Ordinarily a pH of 7.25 or less deserves prompt correction. The amount of HCO_3^- in mEq required to correct metabolic acidosis is given by either of the two formulae given below—

1. Sodium HCO_3^- to be given = Body weight (kg) × 0.3 × base deficit.
2. Sodium HCO_3^- deficit = 0.5 × weight (kg) × (desired HCO_3^- -serum HCO_3^-).

The usual recommendation is to give one half of the HCO_3 deficit as an IV bolus, and to replace the remaining deficit over the next 4–6 hours. It is best not to be over-reliant on formulae but to administer ($NaHCO_3$) at a frequency and dose, which keep the arterial pH above 7.3.

In the presence of an associated respiratory acidosis it is important to first correct the respiratory acidosis, and then tackle the metabolic acidosis. ($NaHCO_3$) given intravenously to a patient with respiratory acidosis induces further CO_2 production and this could further increase the degree of respiratory acidosis. When the pH is very low in combined respiratory and metabolic acidosis, measures to correct both can be undertaken simultaneously.

Risks of sodium bicarbonate therapy[12] There is some degree of risk and therefore some degree of controversy on when to use $NaHCO_3$ for the correction of metabolic acidosis. This is because $NaHCO_3$ can produce undesirable effects which include hyperosmolarity, fluid overload due to large quantities of Na^+ in the $NaHCO_3$, hypokalemia, hypocalcaemia, and increased serum lactate levels. At times hypotension and a reduced cardiac output have been observed, probably due to calcium binding by the HCO_3^-. It is also obvious that an ongoing metabolic acidosis will remain uncorrected as soon as the administration of $NaHCO_3$ is stopped or reduced, because the cause of acidosis remains uncorrected. Alkali ($NaHCO_3$) stimulates

6-phosphofructokinase activity and organic acid production. This is not helpful in the management of lactic acid acidosis and ketoacidosis.[13] These effects limit the alkalizing effects of HCO_3^-. However, the alkali effect on 6-phosphofructokinase may help in partial regeneration of depleted adenosine triphosphate (ATP) stores in vital organs thereby improving organ function.

Theoretically, the CO_2 produced by the administration of HCO_3^- may partly diffuse into the RBCs and combine with the H_2O to form carbonic acid, thus adding to the H^+ load. In practice, however, we have rarely encountered problems with the administration of $NaHCO_3$. The most frequent side-effects to be looked out for are hyperosmolarity, hypokalemia, hypocalcemia and fluid overload. These can all be corrected by timely measures. We feel that this controversy in the use of $NaHCO_3$ is unnecessary, and that its advantages far outweigh the possible drawbacks. Its use is particularly gratifying when poor pump function is associated with metabolic acidosis. A restoration of pH toward normal leads to improved pump function, increase in systemic blood pressure and improved perfusion to the tissues.

Alternative alkalizing agents[12] Concern over the production of CO_2 following the use of $NaHCO_3$ led to the development of carbicarb, which consists of equimolar concentration of $NaHCO_3$ and sodium carbonate. Carbicarb limits, but does not eliminate the generation of CO_2. The risk of hyperosmolarity and hypervolemia remain.

Another CO_2 consuming alkalinizing agents is tris-hydroxymethyl aminomethane (THAM), a commercially available solution of 0.3 N tromethamine. It is not more clinically efficacious than $NaHCO_3$ has a number of serious side effects and is not in use.

Metabolic Alkalosis

The suspicion of this acid-base disturbance rests on an awareness of its likely occurrence in certain pathological conditions. Metabolic alkalosis is very frequently encountered in patients under critical care, as the four most important causes are vomiting (or nasogastric aspiration), the use of diuretics, the use of corticosteroids, and hypokalemia—all these factors being very frequently encountered in critical care medicine.[14,15] Galla and Luke[16] report an associated mortality of 40% when the arterial pH rises above 7.55. It is probably the gravity of the underlying illness, which contributes to this mortality. The danger with metabolic alkalosis is related to its ability to sustain itself in spite of correcting the underlying etiological factor. This is attributed to Cl^- depletion, which limits HCO_3^- excretion in the urine by promoting its reabsorption, and reducing its secretion into the renal tubules.

Etiology

- Vomiting or nasogastric suction is an important cause of metabolic alkalosis. Gastric juice contains 50–100 mEq/L of H^+ so that loss of gastric contents leads to significant H^+ loss. There is also an associated loss of Cl^-, Na^+, and potassium, as well as volume depletion due to H_2O loss.
- Diuretics, in particular furosemide, produce alkalosis chiefly through the loss of Cl^- and potassium via the urine. Cl^- follows Na^+ and H_2O during diuresis; the Cl^- that is not reabsorbed is replaced by HCO_3^-. The increased HCO_3^- reabsorption maintains or enhances the alkalosis. Increased K^+ loss in the urine leads to an increase in the H^+ secretion into the distal tubules, probably in an attempt to reabsorb K^+, and replace it with H^+ in the tubular fluid.[16] Magnesium is also lost in the urine during diuresis and this promotes K^+ loss through mechanisms not clearly understood. A decrease in extracellular volume probably contributes to alkalosis by increasing the concentration of HCO_3^- in the serum. A decrease in circulating volume also stimulates aldosterone release, and promotes the loss of K^+ and H^+ in the distal tubule. Thus, the importance of correcting the Na^+, K^+ and Cl^- loss as well as replenishing volume in management is self-evident.
- Administration of excess alkali either orally or through IV use promotes metabolic alkalosis. This is particularly observed when renal dysfunction prevents excretion of HCO_3^-, or when there are associated electrolyte (e.g. Cl^- depletion), which interfere with HCO_3^- excretion by the kidneys. Over-enthusiastic use of IV $NaHCO_3$ for the correction of metabolic acidosis can produce a dangerous swing to metabolic alkalosis. Massive blood transfusions (due to citrate in the blood), are also reported to cause a significant metabolic alkalosis.[17]
- Metabolic alkalosis occurs during corticosteroid therapy, in patients with adrenocortical hyperfunction, in aldosteronism, and it almost always complicates a well-marked hypokalemia.

Box 4: Common causes of metabolic alkalosis

- Vomiting or nasogastric aspiration
- Use of diuretics, particularly furosemide
- Excessive administration of alkali [orally or intravenous (IV)], particularly in the presence of associated renal dysfunction or electrolyte abnormality
- During corticosteroid therapy in patients with adrenocortical hyperfunction, aldosteronism, especially in the presence of well-marked hypokalemia

The common causes of metabolic alkalosis are given in Box 4.

Clinical Features

It is remarkable, how silent metabolic alkalosis can be. Severe alkalosis (serum HCO_3^- >40 mEq/L and pH >7.6) can cause mental obtundation, seizures, cardiac dysfunction and cardiac arrhythmias. Ventilation may be depressed (so that the $PaCO_2$ is secondarily raised), but this is not always the case. Marino[18] believes that the infrequency or lack of hypoventilation in metabolic alkalosis is related to the baseline activity of the

peripheral chemoreceptors, through which metabolic acid-base disorders chiefly exert their effect on ventilation. Under normal conditions the peripheral chemoreceptors have a low activity with a low "input" from the chemoreceptors to the brainstem respiratory centers. There is thus very little scope for alkalosis to further inhibit activity. On the other hand, acidosis stimulates these receptors, resulting in an increased "input" from the receptors to the respiratory centers, and thus causing hyperventilation.

It is also worth noting that a metabolic alkalosis shifts the oxygen dissociation curve to the left, thus reducing delivery of oxygen to the tissues. In a critically ill patient who already has a low PaO_2, a sudden shift of the oxygen dissociation curve can precipitate a further sharp fall in the PaO_2 and PvO_2. If pump function is poor and the patient already has a low PvO_2 (due to a low cardiac output), then the further fall in PaO_2 can have disastrous consequences.

Management

This is directed to the underlying etiology. Almost always (particularly in ICU patients), metabolic alkalosis is chloride responsive, and the Cl^- should be replaced in the form of normal saline. This also permits adequate replenishment of fluid loss. Hypokalemia also needs to be corrected by an infusion of KCl (20–40 mEq or more) in a dextrose infusion. It is important to note that uncorrected hypokalemia can perpetuate metabolic alkalosis. In patients with mineralocorticoid excess, aldactone helps to correct the hypokalemia and restore acid-base balance. When magnesium levels are depleted, magnesium should be replaced, thus allowing for easier correction of hypokalemia.

The volume of 0.9% saline necessary for correction of metabolic alkalosis can generally be gauged by clinical assessment of the degree of fluid loss, and the degree of electrolyte disturbances. The formula given below[18] is often used for estimating the Cl^- deficit—

Chloride deficit = 0.27 × weight (kg) × (100-present Cl^- in mEq/L)

Volume of saline to be administered (L) = Cl^- deficit/154*

(*The Cl^- present in 1 L N saline = 154 mEq).

Clinical judgment should never be replaced by didactic formulae and it is best to rely on the former rather than on the latter.

Use of Hydrochloric Acid

We have never found it necessary to use hydrochloric acid to correct metabolic alkalosis. It may however be used in rare instances where saline and potassium replacement are ineffective in correcting a severe metabolic alkalosis. The amount of HCl required is determined by the H^+ deficit.[19]

Hydrogen ion deficit (mEq) = 0.5 × weight (kg) × (present HCO_3^- - desired HCO_3^-)

Volume (L) of 0.1N HCl = H^+ deficit/100*

Volume (L) of 0.25N HCl = H^+ deficit/250*

Infusion rate = 0.2 mEq/kg/hour

*mEq of H^+ per liter of solution.

It is perhaps best to use a 0.1N HCl solution. However, when volume needs to be restricted, 0.25N HCl may be preferred. The infusion is best given through a central line, as if given peripherally it can cause a thrombophlebitis. Though we have never used an IV HCl solution for metabolic alkalosis, it has been proven to be safe and effective.[19] Other Cl-containing acids such as ammonium chloride (NH_4Cl) solutions and arginine hydrochloride have been used to correct metabolic alkalosis, but are best avoided. Arginine hydrochloride can cause severe hypokalemia in patients with renal dysfunction. NH_4Cl can result in high ammonia levels with possible toxic effects particularly in patients with liver cell dysfunction.

Hemofiltration

Continuous arteriovenous hemofiltration is valuable in the management of severe metabolic alkalosis with markedly increased extracellular volume. A reduction of H_2O content through continuous hemofiltration should be combined with judicious administration of normal saline and potassium in dextrose. The H_2O loss through ultrafiltration should be greater than the fluids infused, so as to correct the increase in extracellular volume.

Respiratory Acidosis

This is due to a rise in the $PaCO_2$ of arterial blood; it complicates acute and chronic respiratory failure. The clinical features, diagnosis and management have been dealt with in an earlier chapter (see Chapter Acute Respiratory Failure in Adults).

Respiratory Alkalosis

This results from alveolar hyperventilation with a fall in the arterial $PaCO_2$, and in the carbonic acid content of plasma. It is common in hysterical or functional states, and in patients who are over-ventilated while on ventilator support. It can also occur because of hyperventilation produced by brainstem lesions. The recognition and diagnosis of respiratory alkalosis in patients on mechanical ventilation has been dealt with separately (see Chapter Mechanical Ventilation in the Critically Ill).

Nutritional Support in the Critically Ill Adult

- Nutritional Support in the Critically Ill Adult

CHAPTER 42

Nutritional Support in the Critically Ill Adult

GENERAL CONSIDERATIONS

Good nutrition is often vital for survival in a critical illness. In poor developing countries, many illnesses unfold against the background of malnutrition. The chances of a patient succumbing to a critical illness increase with the degree of malnourishment present prior to the illness. A critically ill patient is often hypercatabolic from infection, injury and sepsis, and is very prone to develop malnutrition even if reasonably well nourished to start with. Specific or multiple organ failure compounds the issue. These patients have an increase in energy requirements, and because of metabolic abnormalities have problems in the handling of energy substrates provided to them. Clinically, they rapidly lose body weight, and in particular show a marked loss in the lean body mass. Nutritional support is therefore vital in the management of any critical illness. The more prolonged and more catabolic (or hypermetabolic) the illness, the greater the need and importance of nutritional support for survival.

In the large public and municipal hospitals of our country, in my opinion, over 50% patients suffer from protein or calorie malnutrition. The cause of malnutrition in affluent groups is related to background disease, and occasionally to fads and fancies in eating habits. During the course of a critical illness, a loss of lean muscle mass of 10% is significant, a loss of 20% is critical, and a loss of 30% or more is generally lethal.[1] In a critical illness, absence of adequate nutritional support leads to a form of starvation. Skeletal muscle is therefore soon catabolized for gluconeogenesis and energy. Additional endogenous nutritional support is provided by important proteins synthesized by metabolically active tissue. These proteins have a rapid turnover and include liver enzyme proteins, renal tubular enzymes and proteins formed in the gastrointestinal mucosa.[1] Endogenously derived nutritional support enables a critically ill individual to adapt to the stress of a critical illness, and provides the patient with an additional source of energy. The adaptation however is of benefit only in mild to moderate, short-lasting illnesses. In a severely catabolic long-lasting critical illness, the above response becomes maladaptive, and may well contribute to failure of individual or multiple organ systems, and thus be responsible for both increased morbidity and mortality.

PRINCIPLES OF NUTRITIONAL MANAGEMENT IN THE CRITICALLY ILL

The principles of nutritional support and management have evolved significantly over the last 20 years. These include changes in nutritional assessment, guidelines in total energy provided; in nutritional requirement related to specific diseases and in immune-enhancing enteral nutrition. Malnutrition, which often evolves during the course of a critical illness is known to be associated with serious complications, such as sepsis and pneumonia leading to a worsening outcome and often death.[2] The importance of good nutritional support in management needs repeated emphasis.

The society of Critical Care Medicine and the American Society of Parenteral and Enteral Nutrition convened an expert panel to establish guidelines for providing and assessing nutritional support therapy in adult critically ill patients.[3] In the past, nutritional support in critically ill patients was regarded as adjunctive care designed to preserve lean body mass, maintain immune function and prevent metabolic complications. The current recommendation of these societies published in 2007 is that nutritional support should be considered as nutritional therapy directed toward

attenuating the metabolic response to stress, preventing oxidative injury and improving the immune response.[3]

The basic principles of nutritional therapy in the critically ill patients are briefly enumerated below—

- Enteral nutrition (use of the gut for nutrition) has more advantages compared to parenteral nutrition (nutrients administered intravenously). The latter should therefore be offered only if the gut does not work, and hence cannot be used. When it is possible to provide even part of nutritional support via the gut, one should do so; parenteral nutrition is then used as a supplement to feeding via the gut. As a corollary to this principle, the importance of maintaining the structural and functional integrity of the gut cannot be overstressed.
- Conventional parenteral or enteral nutritional support has not been shown to always produce an anabolic effect in malnourished critically ill patients. For example, patients with fulminant Grade IV tetanus (one of the most catabolic of all diseases), even if they survive, lose a great deal of body weight and lean muscle mass in spite of excellent nutritional support (3,000 calories, with over 100 g proteins). The objective of parenteral nutrition in a critical illness is therefore to blunt or reduce the effects of hypercatabolism.

  Till the early nineties, it used to be felt that the nutritional requirements of highly catabolic critical illnesses should be met by an increasing and excessive supply of calories. Patients in critical care units thus often received over 3,500–4,500 calories/day. Today, this concept has been revised, and nutritional support is devised to provide a caloric intake of only 1,500–2,100 calories/day to most critically ill patients in the intensive care unit (ICU). Only exceptional problems require a larger caloric intake. This revision is related to two observations: (1) Excessive caloric intake as already mentioned, does not prevent weight loss or loss of lean muscle mass; (2) Overzealous calorie administration contributes to a number of deleterious side effects. These include hyperglycemia, excessive carbon dioxide production, overhydration with peripheral and pulmonary edema, hepatic dysfunction with steatosis and an increased incidence of noncatheter-related infections.
- Most critical care units would prefer to initiate nutritional support early rather than late in the natural history of a critical illness. This is based on the logic that it is perhaps easier to prevent or reduce the complications of starvation, than to treat them after they have occurred. Early nutritional, and in particular early parenteral nutritional support, may however be overdone. Cost in our country is an important factor, and parenteral nutrition is extremely costly. The use of preoperative parenteral nutrition in patients with mild malnutrition is of doubtful efficacy and may not result in any overall benefit. On the other hand, nutritional supplementation prior to surgery in severely malnourished patients clearly reduces the incidence of postoperative complications.[4]
- Nutritional support should always be individualized both with regard to the appropriate mode of administration, and the nutritional requirements of each patient. This will depend on the nature of the disease and the nutritional state of the patient.

  A little of "this" added to a little of "that" does not constitute good nutritional support; it only constitutes bad medicine.
- Nutritional support to a patient should be monitored with regard to the adequacy of the nutritional regime, response to treatment and possible side effects.

CLINICAL EFFECTS OF NUTRITIONAL DEPRIVATION

The deleterious clinical effects of poor or absent nutrition include wound dehiscence, poor healing, breakdown of surgical anastomosis, and poor immune response to infection. Poor host resistance has been related to a deficiency in proteins and in essential amino acids. Complicating sepsis or infection is thus an important feature in patients who have received poor nutritional support.

Non-specific effects are also observed in the central nervous system. These include apathy, drowsiness, and inability to clear secretions in the upper respiratory tract. The cause of these effects is unclear. They may be related to diminished energy supply to the brain, resulting in impaired function, or to toxic effects produced by the accumulation of products from the breakdown of muscle protein. Starvation produces an alteration in the amino acid profile, and this may in turn affect the neurotransmitter profile within the brain, and thereby alter central nervous function.
